and other spasmophilic conditions, this result is by no means universal, and in certain cases the amount of calcium at least may be actually increased. The comparative fruitlessness of such lines of research is explicable on several grounds. In the first place, it does not follow that because the blood has a normal calcium content the whole of it, or any considerable part of it, is available either for bone building purposes or for the neutralization of acid bodies, which, according to Hamilton and Tobler, are the important functions of calcium in the metabolic processes of the body. Varying proportions of such calcium may be, so to speak, "dead," having served their purpose in the economy; little of this base may be in an ionic state and serviceable for either purpose, especially for the purpose of neutralization. In accordance with this view, whether a large or a small amount of calcium is present in the blood will depend largely on the efficiency of the excretory processes in eliminating "dead" calcium either in the urine or in the faeces, and the amount present is no index of the available supply. Further than this, there are several automatic mechanisms for maintaining the calcium content of the blood at a constant and normal level. Hence estimations of the amount of calcium present in the blood do not afford a reliable index of the amount of calcium available in the whole body, either for the purposes of bone formation or for the neutralization of acid bodies—the question of dépôts comes into consideration.

Dr. Bengt Hamilton<sup>1</sup> has calculated that the total amount of calcium required for the purposes of internal metabolism in the infant—that is to say, for the neutralization of acid radicals—is about 0.200 gram in the twenty-four hours, and that unless this amount is afforded as income in the food or can be spared from the blood reserves the deficit must be made good by borrowing from the calcium dépôts of the body—that is, mainly from the bones themselves. Hamilton points to the interesting fact that at birth there are wide fluctuations in the amount of these reserves, and that the latter are generally stored up during the final two months of intrauterine life—an explanation which helps us to understand why premature infants are liable to develop symptoms of rickets at a very much earlier date than is usual in the case of full-term infants.

We know that in rickets, and indeed in conditions antecedent to the development of its manifest symptoms, there is always an increased output of calcium, mainly in the faeces, and to a lesser extent in the urine, and that this, in conjunction with the general depletion of the total calcium content of the body, is the most striking and constant factor in the pathology of the disease. No theory of the pathogenesis of rickets can be satisfactory which does not offer an explanation of these phenomena.

If, as Hamilton and Tobler maintain, the chief function of calcium in internal metabolism is to neutralize acid bodies, and that new bone will not receive the required quantity of this base until such vital needs have been satisfied, it seems probable that the solution to the problem will be found in discovering some common cause in all cases of rickets for an existing shortage of this base. An income of calcium which may be adequate for the neutralization of a normal production of acid bodies may be quite insufficient if the latter are produced in excess. If, therefore, among all the etiological factors of rickets we could find some common explanation of excessive acid production, or some common reason for default of calcium, we should have at least a logical basis of the pathogenesis, and we could then understand why on the same dietary one child will become rachitic and another remain in health, and also why, under similar conditions of environment, one child may develop symptoms of rickets while another may show none. I feel convinced that we can find in all cases of rickets, from whatsoever cause arising, definite reasons for explaining either an excessive acid production or a relative shortage of calcium—in other words, some definite disturbance of their normal relationships.

If the whole of the food consumed is used for physiological purposes and all its potential energy represented in the form of growth, heat production, work, or secretions, it is clear, on theoretical grounds at least, that no part of it can leave the body except in the form of completely

\* Delivered before the Oxford Division of the British Medical Association, March 28th, 1923.

oxidized and energy-free end-products—in other words, in the form of carbonic acid gas, urea, and water. In practice, however, there will always be some waste—that is, some products of incomplete combustion which will be represented in part at least by acid bodies of larger molecular size than  $\text{CO}_2$ . Such acid bodies, unlike  $\text{CO}_2$ , cannot be removed from the body without loss of the mineral bases which are required for their neutralization. This inevitable loss, in the case of babies, as far as calcium itself is concerned, is represented by 0.200 gram in the twenty-four hours—that is to say, if Hamilton's figures can be relied upon as accurately representing the irreducible minimum. In addition to this there will, of course, be a corresponding depletion of other mineral bases such as sodium, potassium, ammonium, iron, and magnesium. When, however, large amounts of acid are produced, correspondingly large quantities of calcium, as well as of other elements, will be requisitioned, and if they are not forthcoming in the food they must be withdrawn from the reserve dépôts.

If excess of food—that is to say, any amount over and above the existing physiological requirements—is consumed, there will be a corresponding increase in the production of acid bodies, and I propose now to explain how it is that all the known etiological factors in the production of rickets may lead to some disturbance of balance between the intake and output of energy.

The degree to which food consumed can be utilized in the body will naturally depend either on the amount of

depressed by deprivation of the essential stimuli, and the appetite still remains. The only possible alternatives to carbon dioxide production are: (1) storage, (2) non-combustion, or (3) semi-combustion of the food consumed. The limits of storage are restricted, non-combustion means albuminuria and glycosuria, while semi-combustion means the production of the intermediate products of metabolism, most of which are acid bodies which require neutralization.

It will be noted that most of the etiological factors of rickets are also depressants of metabolism, as is set out in Fig. 1.

Contrariwise most of the prophylactic and remedial measures which are employed in the treatment of rickets are also stimulants of metabolism, as shown in Fig. 2. Consequently I repeat that the obvious cause of rickets is a defective oxidation of the food consumed, with a consequent increased production of acid bodies which must be neutralized at the expense of basic elements, including calcium. It may be argued that there is not sufficient direct evidence to justify the acceptance of this very obvious theoretical line of reasoning; to this I can only reply that the most practical proof of an excessive production of acid bodies is the presence of an excess of ammonium-nitrogen in the urine; ammonium of all bases is the cheapest and most available, and one of the most characteristic features of rickets is an excess of ammonium salts in the urine, as has been shown by Dr. Amy Hodgson.<sup>2</sup> Further proof would, I am quite sure, be forthcoming if

food itself or on the physiological demand for its utilization—in other words, on the relationship of the intake and the output. Whether, therefore, any particular diet is excessive or not cannot be decided by arbitrary codes or diet tables. If the body is an efficient working machine, and the output of energy in the form of heat or work is correspondingly high, a liberal diet may not be physiologically excessive, whereas with a defective machine and a small output even a very exiguous diet may be relatively excessive. The efficiency of the machine itself will depend on a great variety of antecedent conditions—its innate qualities, and the uses to which it has already been subjected; hence we can well understand why hereditary, ante-natal, and previous environmental conditions play a part in the existing output of energy, in the fate of the child, and in the etiology of rickets. Without any change in the machine itself the actual output of energy will in large measure depend on the circumstances under which it is working—that is to say, on the environment and on the stimuli for activity which the latter affords. In the case of the child such stimuli are not exclusively physical; many of them are of a psychological character, and hence we can understand how it is that such influences as joy, pleasure, play, sunshine, opportunities for exercise, and exposure to fresh air can be etiological factors in rickets. In this connexion I would especially direct attention to the influence of cool air in stimulating metabolism. Dr. Leonard Hill has proved that the output of carbon dioxide, which is an index of metabolism, may be doubled by exposing the child to the open air.

Although under such conditions appetite is increased and more food consumed, it may well be asked what happens to the food when the metabolic processes are

the degree of depletion of the alkaline reserves of the blood were to be consistently estimated in cases of active rickets. Clinically there is abundant evidence of such depletion, especially in the crises which complicate severe cases of the disease. Theoretically the alkaline treatment of rickets, by affording substitutes for calcium as neutralizing bases for acid products, ought to be most efficacious; and so in my experience it is, but to be effective it must be continuously employed as long as acid bodies are formed in excess. Such treatment by calcium spacers if spasmodic or intermittent will fail.

Since calcium is not readily excreted by the kidneys but mainly by the bowel, we must search the faeces for evidence of this base in combination with acid bodies, and here again we find the expected result, for calcium soaps present in excess are a striking feature of the rickety and pre-rickety condition. Such soaps may be, and probably are, excretions from the blood, and represent the defective oxidation of fats rather than the surplus of fat which has never been absorbed and passed through the processes of internal metabolism.

It is not always easy to understand why all the known factors of rickets impair the efficiency of the body as a working machine and thus limit the output of work. Some of the dietetic causes may owe their results to the withholding of certain elements necessary for the performance of certain special functions. For instance, iodine starvation may depress the metabolic processes by depriving the thyroid gland of the particular element which is necessary for the elaboration of its specific secretion. On these grounds we can understand how it is that certain authorities have regarded rickets as the result of thyroid defects; and even in the light of more recent knowledge there

seems to be no reason for excluding in exceptional cases the thyroid from all participation in the disease. For the thyroid secretion is the great stimulator of the metabolic processes.

If these views on the pathogenesis of rickets are well founded, it seems illogical to expect that there can be one cure for the condition; each case, in accordance with its own particular etiology, must be treated on specific lines. It would be unreasonable, for instance, to expect good results from treating a case of rickets due to carbohydrate excess on the same basis as one due to a chronic infection or vitamin starvation. The specific treatment of rickets lies in the specific treatment of the contributory factors, although the symptomatic treatment of the resulting mineral depletion certainly lies in the adequate supply of available calcium salts, and in alkali therapy.

I have drawn up a schematic diagram (Fig. 3) to show the common etiological factors of rickets in such a way that their contributions to the common end-result may be easily visualized. These various factors are arranged in

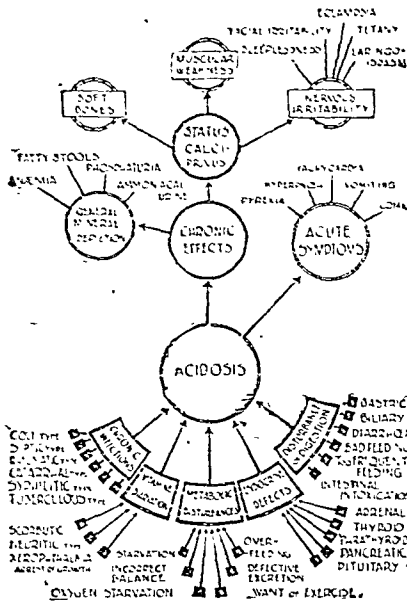

FIG. 3.

groups. Like a vast watershed they afford their respective contributions of acid products to the common reservoir—the blood—which is indicated in the centre of the figure.

The clinical picture of any given case of rickets must be just as composite as the etiological factors which are responsible for its production. The symptoms and the general clinical picture of a case which is due to vitamin starvation, or calcium inanition, will be quite different from a case due to carbohydrate excess or a chronic infection, although they may have certain symptoms in common—namely, those which are due to the resulting acidosis.

Since almost every variety of malnutrition, either acting alone or in combination with others, can lead to one and the same end-result, we can easily understand why there has been so much confusion between the symptoms proper to the rickets condition and those due to the contributory causes—a confusion which is really one between cause and effect.

In conclusion, I would once again repeat that the essential basis, or the *causa vera*, of rickets is most probably a relative excess of acid bodies produced in the system by a disproportion between the intake and the output of energy—a condition which results either from an innate inefficiency of the body machine itself, or from defects in the environment, the latter being regarded as including the quantity and the quality of the food as well as the character of the stimuli afforded by the hygienic surroundings.

## NEPHROPTOSIS: ITS CAUSATION, SYMPTOMS, AND RADICAL CURE.

BY

JOHN J. BELL, F.R.C.S.I., F.R.C.S. EDIN.,

SURGEON TO THE WADDILOVE SAMARITAN HOSPITAL FOR WOMEN.

ABOUT thirty years ago Dr. Suckling of Birmingham was led to the conclusion that, as many cases complaining of nervous dyspepsia, neurasthenia, and depression had also movable kidney, there might be in these associations more than a casual relationship. His further investigations convinced him that the renal displacement and the nervous disturbances stood in the relation of cause and effect. When my attention was first drawn to Dr. Suckling's work, published in 1907, I had already seen and treated many cases in the usual way. In consequence of the striking results disclosed in his work, I decided to operate on all suitable cases.

## CAUSATION.

Movable kidney may be classed under two heads: (1) accidental; (2) constitutional or congenital. Cases of the first class are usually due to accident or injury of a crushing nature, and are easily diagnosed by the history and acute symptoms. The second class comprises the vast majority of all cases, varying from the least increase of the normal mobility to the complete dislocation of the organ from its anatomical site.

To account for the fact that many more women than men suffer from nephroptosis various explanations have been advanced—such as frequent pregnancy, loss of flesh, loss of intra-abdominal pressure, chronic constipation, chronic cough, etc.; but these causes do not account for more than a small percentage of the cases I have seen. I am convinced that there is something in the anatomical formation of women which is the primary physical origin of the condition. I suggest that there is a congenital or family defect of shape of the renal pouch, which predisposes to an easy descent of the organ, and that there is some inherent weakness in the suspensory tissues which disposes them to stretch easily. Can we deny the hereditary influence, in tone of tissue, while admitting it in type of outline of body, in temperament, and in nervous responses? I am strongly disposed to consider the larger proportion of cases as directly due to some transmitted congenital defect. In support of this I would cite the instance of a father with double nephroptosis and two daughters with a similar condition; another of a mother and two daughters; and at least twenty cases of sisters. Suckling states that he has often found movable kidney in children, and that he is inclined to the view that it is hereditary and congenital. Billington and Pardy confirm this observation.

Volkow and Dilitzin state that the paravertebral niches in which the kidneys rest are shallower and more open below in women than in men. This observation is supported by Morris, who examined one hundred men and found movable kidney in two only, and in a series of operations by him for this condition ninety-six were upon women and only two upon men.

In addition to the congenital tendency and anatomical defect in the formation of the renal pouch, there are contributory causes, of which the most important are nutrition and occupation. A large proportion of my cases in the Samaritan Hospital have been operatives from half-time age. Inquiries from doctors in large practices in other manufacturing towns confirm my view that the too early employment of girls in occupations causing long standing and weight carrying is an important causative factor. Another contributory cause which has been suggested is repeated pregnancy, but I believe it to be a negligible factor, for over 50 per cent. of my cases were unmarried or non-paious, and I have examined many mothers of large families and found no displacement. Loss of intra-abdominal pressure may, in some cases, aggravate the condition, but is never its cause. Other alleged causes are tumours of the kidney and calculi, but I do not attach much importance to them. Were nephroptosis the result of accident, physical strain, etc., we

should expect the larger proportion of cases to be found in them, whereas I have only seen it in ten men as against three hundred women.

#### *Examination of the Patient for Nephroptosis.*

Many cases of nephroptosis have been missed by examining the patient in the recumbent position. It is a common experience to find that the movable organ goes back on lying down, and deep breathing or coughing may not cause it to descend.

There are three ways of examining for a movable kidney. The first and most important one is with the patient standing, with back toward the examiner. The body being uncovered from breast to above symphysis, the patient is instructed to breathe deeply, slightly leaning towards the side examined. The thumb of the right or left hand, according to the side examined, is pressed deeply into the back below the last rib, the fingers grasping the front of the body and compressing the structures, alternately pressing and releasing until all rigidity passes off. The kidney, if movable, can then be felt; usually it slips up suddenly from the grasp, and renal tenderness is generally shown by the patient wincing.

In the second method the patient is placed upon a couch, in the sitting position, knees drawn up and body slightly bending forward, and then examined as in the standing position. In fat patients it is often necessary to try a third position. Place the patient on right or left side, as the case may be, with the knees drawn high up; this causes the abdominal contents to fall away from the flank, and the freely movable kidney can be palpated. A point of importance in each method is to begin the compression of the anterior wall over the iliac fossa, gradually ascending. If this is not done one can easily miss a kidney low down.

#### DIFFERENTIAL DIAGNOSIS.

In my experience only one condition has given any real difficulty—an elongated right lobe of the liver. When this is thin and freely movable it may easily be mistaken for movable kidney. It is, however, more anterior and does not slip from the compressing fingers in the same way as the kidney does. Nevertheless pressure upon this lobe may push it backwards, and give the impression that it is a kidney slipping back into its fossa. The two conditions are often present in the same subject. I need only mention tumours of gall bladder and ascending colon, and tumours of kidney, as possible sources of error.

A patient may present a typical history and symptoms of movable kidney, but on careful examination no kidney can be felt; on this account mistakes are sometimes made and patients are told that there is no displacement. I have often had to examine several times before finding displacement.

Another difficulty arises where the kidneys move downwards and inwards under the rectus, or when from their thinness we compress over them. Another point to note is the excitability of the muscles of the body wall. This is especially likely to arise if pressure be made too rapidly or too deeply. A further difficulty met with is rotation of the lower pole inwards: in such cases we do not find displacement, nor can we palpate any portion of the kidney, but still the symptoms definitely point to mobility. This is frequent in the early stages of descent.

#### SYMPTOMS.

Symptoms may be classified as direct or reflex. The former comprise intermittent pain in the small of the back of a dull aching kind, radiating from loin to thigh, described by some as dragging and tiring in character, increased by walking, long standing, or train journeys, inducing a feeling of over-fatigue. Reflex symptoms may arise in any organ supplied by the autonomic nerves.

Complaint may be made of violent headaches associated with giddiness and disturbance of vision, and sometimes ending in violent sickness and prostration. Or the patient describes palpitation, shortness of breath, increased upon exertion, and sometimes induced by the effort of undressing, but commencing after lying down. There is a small rapid pulse, with low blood pressure, and a mildly cyanotic appearance in face and lips, as if there were vasomotor disturbance. Again, the history may be one of chronic indigestion, sick-

ness, vomiting, in some cases haematemesis, discomfort after meals, giddy attacks, with sallow skin and tired appearance. Rarely is there any local tenderness in the region of the stomach. Or there is a feeling of sickness and giddiness on getting into the erect position after a night's rest. This symptom is very significant when it occurs in a young subject. It appears to be due to the sudden descent from the pouch of one or both organs. Similar attacks are common after any form of energetic physical exertion.

In another case the story may be one of intermittent diarrhoea with colicky pains, and evident tenderness in the caecal region, distension in the lower abdomen, a feeling of weight and heaviness, and great discomfort. Later on colitis may ensue. Or, again, the patient may complain of frequent micturition, day or night, often both, and sometimes haematuria, but there is no pus in the urine, no albumin, no sign of gravel, only an increase in mucus. The normal quantity of urine may not be increased in twenty-four hours, and generally the specific gravity is low. Many of these cases end with contracted bladder. In some cases the amount of urine secreted during the daytime is diminished, though there is no irritation, but, after retiring, there is frequent necessity to empty the bladder. This, I believe, is due to recession of the kidney, which, in the recumbent position, functions more actively when relieved from the inhibitory effect caused by descent.

We come next to that class of cases where the symptoms are referable to the female generative organs. The late Goelet of New York was one of the first to call attention to the reflex effect of nephroptosis upon the uterus and ovaries. The conditions he enumerated as provoked by movable kidney were: ovarian congestion due to interference with the ovarian vein; dysmenorrhoea, due to congestion of ovaries; profuse leucorrhoea; and endometritis. Menorrhagia and metrorrhagia are undoubtedly increased by this condition, and premenstrual headache is often intense. Amenorrhoea is sometimes present, and uterine displacement is a frequent concomitant. I am satisfied that in all cases of chronic pelvic symptoms, where there is no evidence of a local pathological condition, we should examine the renal region for mobility repeatedly if necessary.

Then we come to those cases with acute abdominal pain and vomiting, profuse sweating, pain in abdomen, and all the signs of shock—"Dietl's crisis"—sometimes diagnosed as due to acute appendix, acute gall stones, renal colic, or calculus. Lastly, I would draw attention to the fact that many of these cases of nephroptosis have chronic irritation of the appendix, and that it is not uncommon for the appendix to be removed, but without benefit. Conversely, the kidney may be fixed and a diseased appendix left. This coexisting condition is a sequel to the dropped right kidney producing irritation by its descent behind the caecum.

Many cases of nephroptosis are treated for neurasthenia, dyspepsia, and vague neuralgias, with little or no success. Closer investigation would reveal that the symptoms are secondary to and dependent upon renal displacement.

#### *The Nervous System.*

The autonomic nervous system comprises the sympathetic and parasympathetic; speaking generally of their functions, it may be said that when the sympathetic and parasympathetic are distributed to the same structure their actions are antagonistic. As Cannon graphically puts it, the parasympathetic serves for bodily conservation, as seen in its action on the pupil, which it contracts to save the retina from the excessive effects of light. By slowing the heart rate it gives the heart muscle longer periods of rest; by providing the flow of saliva and gastric juice, and by supplying the muscle tone necessary for contraction of the alimentary canal, it is essential to digestion. The sympathetic activates the body for struggle. It dilates the pupil to receive more light and stimulates the heart to beat more quickly to supply blood to the muscles. It contracts the blood vessels in the visceral area and inhibits the functions of the digestive organs.

Should the sympathetic be stimulated to overaction in any of its branches we should naturally expect disturbance of the ordered function of the gland or organ it governs. If this stimulation be more or less continuous there will be engendered in those nerve tracts a special susceptibility to such

stimulation, and consequently an increased liability to overaction. If we remember the distribution of the sympathetic chain with its numerous ganglia or exchanges acting as distributing centres, we can comprehend that stimulation received at one point may be passed along from the first receiving station to some other exchange centre, and produce disturbance of the function of another gland or organ remote from the point of stimulation. This action may be seen in reflex vomiting of early gestation, in unilateral renal calculus producing a pain in the other kidney, or in spasm of the pylorus in appendix disease. Sir James Mackenzie's investigations show that the majority of symptoms of disease are disturbances of normal reflexes, and give support to my view that abnormal stimulation of the renal nerves is transmitted to the proximal ganglia, and, passing through the synapses therein, sends out radiation impulses which affect other structures and organs. I believe that in this way a movable kidney, by tugging upon its pedicle, sets up irritation in the nerve, which is transmitted to the proximal ganglion, and that through the synapses therein the irritation is passed either upwards or downwards or both, through other ganglia, thus calling into action, or overaction, the nerve supply to the stomach, bladder, heart, or any structure controlled by the autonomic nerves, producing in one case dilatation, in another irritation, and in a third palpitation. It is this mechanism of transmission and radiation of stimuli which makes possible the comprehension of the numerous and varied symptoms arising from dropped kidney. It has been shown, moreover, that stimulation can be carried to the extent of causing pathological changes in nerve tissue. Langdon Brown says:

"The sympathetic response may be so dissociated, perverted, or prolonged as to produce through the thyroid, Graves's disease, through the pituitary, diabetes insipidus, and through the pancreas and other endocrine organs, excessive mobilization of sugar, which is the first stage of diabetes. It may disorganize digestion by exciting spasm, by producing atony in stomach and bowel, and inhibiting the secretion of gastric juices, etc."

We need only continue the irritation for sufficient time and there must ultimately follow a complete breakdown in the normal responses. As Jelliffe puts it, "after years of maladjustment permanent changes result, and a vicious circle is established in which cause and effect are inextricably interwoven in their general result." Timme, by a series of experiments on the nerves of the stomach, has demonstrated the possibility of unbalanced action in them, and has also shown that such unbalanced actions are constantly brought into operation by mechanical factors, toxins, hormones, and by mental stimuli.

We thus realize the importance of the perfect balance of these two divisions of the autonomic nerves to the health of the individual. We are cognizant of many factors which disturb their normal harmony, and, though not yet generally recognized, I believe movable kidney is one of the most important of these factors, even in the early stages of descent. Chronic recurrent overstimulation of the nervous mechanism, whether from constant tugging as in movable kidney, or chemical as in retained products of excretion, produces permanent changes in the nerves and ganglia.

These factors have an important bearing upon treatment, for it will be obvious that the sooner disturbing causes are corrected the better for the patient, and, conversely, that in long-standing cases changes may have taken place which cannot be cured, either by palliative or operative treatment.

#### *Suprarenal Glands.*

In nephroptosis, as can be demonstrated at operation, the suprarenal glands are pulled down along with the kidney, and there must be some interference with the circulation, consequent upon stretching of their vessels. I wish to emphasize the importance of this point, for it has been shown that the blood supplied to these organs is proportionately greater than to any other organ in the body, and that they consume proportionately more oxygen. This consumption is increased threefold during a rise in blood pressure produced by the action of adrenaline. The chromaffin cells forming the medulla of the gland secrete adrenaline, and the action of adrenaline is to activate the sympathetic. It is also known that adrenaline has an effect upon the glycolytic functions of the liver, increasing the blood sugar content

which is necessary to supply the muscles of the body with energy. Excessive stimulation through temporary congestion caused by increased movement in the early stages of nephroptosis may produce an increased output of adrenaline, and as this is the hormone for activation of the sympathetic, this may be an explanation of the severe headache, rapid action of the heart, and increased blood pressure, which are common symptoms in renal ptosis.

On the other hand, any reduction of the amount of blood passing through the glands, as may arise in stretching of the vessels, thereby contracting the lumen, would reduce the output of adrenaline, or the same result may follow exhaustion after a period of overaction. This would diminish the production of blood sugar, which would affect the muscles by reducing their pabulum, and consequently engender a state of fatigue and exhaustion, which is a well known symptom of hypo-adrenalism—a very common sequel in chronic cases of nephroptosis. As the amount of adrenaline present in the blood under normal conditions is equal to a dilution of one in twenty millions, a slight increase or diminution in secretion will very seriously affect the action of the sympathetic and the musculature. The whole range of the chemical action of adrenaline has not yet been physiologically determined, but enough is known to justify our conclusion that variation in adrenaline output is an important factor in the symptomatology of nephroptosis.

#### *Toxaemia.*

Toxaemia, I believe, only becomes operative when the kidney has become so displaced as to interfere with the normal circulation and proper drainage through the ureter. The later effects of displacement are, first, obstruction to return of blood through the veins, increased size of gland, and hyperaemic congestion caused by descent and inward rotation of the lower pole. Secondly, obstruction of the ureter, with intermittent back pressure, resulting in dilatation of the pelvis of the kidney, widened calyces, and flattened pyramids. There is consequently a reduced excretion of urine, particularly during the daytime, with lowered specific gravity, causing retention of poisons. Continued mild auto-intoxication will in time reduce the vital powers of the strongest, and this is particularly the case if the primary cause lies in an organ of elimination such as the kidney. This is well shown in chronic Bright's disease, or in lethargic colon, or in chronic infection, as in antrum, nose, or throat. Suckling thought that most of the nervous symptoms of movable kidney (neurasthenia, melancholia, and insanity) were due to toxic products retained in the blood. In my opinion, however, the cardinal symptoms in the early stages of nephroptosis are due to nerve irritation and suprarenal instability. We need not, however, be surprised to find a moderate diminution of renal excretion producing many complex symptoms, among which not the least are changes in the functional integrity of the higher levels of cerebration, including, according to Suckling and Billington, acute mania and melancholy.

#### *TREATMENT.*

The opinions of physicians and surgeons have been variously expressed, some holding the view that a two months' rest in bed will do all that is required; others that a well made corset fitted with pads will effect a cure; and yet others that in most cases no treatment is necessary. This divergence of view may have arisen as a consequence of unsatisfactory methods of treatment. One cause of unsatisfactory results in surgical treatment has been imperfect method and technique. This has led conscientious surgeons to declare that the results of operation do not justify its general use. Failure to obtain good results is frequently due to a second movable kidney, which has been overlooked, being apparently less mobile, or considered unlikely to affect the symptoms. The left kidney often gives the impression that it is not freely movable, whereas I have been astonished at the extent of mobility disclosed when the left loin was opened. I would therefore lay great stress upon the omission to fix the left kidney as the explanation of operative failure in many cases. When surgeons recognize the frequency of double nephroptosis, and operate on both sides, I am confident that the value of nephropexy will be as well established as that of appendicectomy. If I find any mobility on the left

side, however slight, I now invariably fix both sides at the same time.

Another cause of incomplete cure is fixation too low in the loin, so that the kidney is at an abnormal angle in relation to the ureter. This interferes with proper drainage, and places the kidney in the angle of flexion of the body which is often the cause of continued symptoms.

After fifteen years of careful study of over three hundred cases, and fitting and adapting various kinds of belts upon some two hundred, I am compelled to state that I have never once seen a cure arising from their use. There has never been invented a belt capable of keeping a dropped kidney in its place, which could be tolerated by the patient. Its pressure would ulcerate the skin in less than a week.

Operation, properly performed, is the only means whereby those who suffer from the effects of nephroptosis can be effectually cured. In 1910 Mr. Billington published his book giving the results of his work on the surgical side. His cases number hundreds, and the results leave no room for doubt as to the best method of treatment. Since that time he has operated upon many more, and has placed the surgical treatment of dropped kidney outside the realm of question or doubt. I fail to comprehend the teaching which, while recommending operation on hernia, displaced uteri, varicocele, and various abdominal conditions causing reflex dyspepsia, such as ileal kinks, intestinal bands, and chronic appendix, yet hesitates to deal with dislocated organs of such importance as the kidneys on similar lines.

#### *Method of Operation.*

It was not until Mr. Fullerton of Belfast published his method that nephropexy was placed upon a sound mechanical basis. Since its publication I have practised his method with slight modification. Formerly I used the oblique incision parallel with the last rib and about a fingerbreadth below, carrying it forward through the external and internal oblique muscles, exposing the lumbar fascia. This method damaged the important muscles of the back and side, and I now use the almost vertical incision recommended by Edebohl and divide the lumbar fascia transversely; the opening, which can be pulled apart, allows the bulging of perirenal capsule and fat. The capsule should be thoroughly separated from the muscles behind, and then clipped through deep in, and stripped off the kidney with the contained fat and pushed deep into the wound and left there. The kidney can then be lifted out quite easily and all adhesions in whatever part divided, paying particular attention to a strong band of tissue passing down from the lower pole of the kidney—the so-called reno-colic ligament. The ureter and the pelvis of the kidney should be cleared of all fat and bands, if any. Care should be taken to avoid any aberrant artery or vein; these I leave alone, unless they definitely hold the kidney down, but this is not usual.

The operation as designed by Mr. Fullerton consists of raising a tongue-shaped flap of capsule from the back of the kidney, passing this through the external arcuate ligament, and drawing the kidney up into position and stitching the suspension flap to the capsule below. Billington and Pardhy bring the flap over the last rib. The merit of this plan is that the kidney can be got higher up, according to the length of flap. In addition to this I follow the plan of Mr. Billington in using Brodel's silk-gut suspension stitches, two of which I pass through the lower portion of the capsule in the form of a letter U, bringing the free ends through the muscle and the skin, tying them over a pad of gauze, when the operation is finished. They should be left for three weeks. Care should be taken that none of the fat or loose tissue finds its way between the upper pole and the stripped psoas muscle, as this prevents strong union. Immediate risks are confusion of the gland, rupture of artery, vein, or ureter, and opening of the pleura. Later risks are shock, embolism, and sepsis.

The mortality in my whole series is two—one due to post-operative shock, with acute paresis of the bowels; the second was due to embolism caused by laceration of a large abnormal vein in the lower pole of the left kidney, which I ligatured.

#### *Results of Treatment.*

Mr. Billington, in his recent work, gives the percentage of cures as 90; Mr. Pardhy informs me that he has a

like result. In a first series of 100 cases operated upon by me, my percentage of complete cures is 73. This low percentage has arisen from the reason already mentioned—namely, that in a number of my early cases I fixed up only one kidney, and also that a number of long-standing cases were constitutionally in a condition in which, I believe, permanent changes had taken place in the autonomic nerves which no operation could completely cure. Nevertheless, in the remaining 27 cases there was great improvement, and the operation was fully justified, particularly so where there was only one kidney down. In the second series of 50 cases, the percentage of cures rose to 94, owing to the facts that most of the patients were younger subjects, and that in 45 of them I fixed both kidneys.

## THE RADIAL PULSE IN INTRATHORACIC ANEURYSMS.

BY

C. O. HAWTHORNE, M.D. GLASC., F.R.C.P.,  
F.R.F.P.S.G.

DIFFERENCES between the arterial pulses as these are studied at corresponding points on opposite sides of the body have an established position in the list of physical evidences suggestive of intrathoracic aneurysm. Since the introduction of the sphygmograph and the sphygmometer it has been possible more confidently to detect these differences and more precisely to define them. Indeed, it may not be unfair to say that unless the contrast between the compared pulsations is a very decided one its value as a trustworthy observation, until confirmed by instrumental evidence, would hardly be admitted. Certainly the advantage of such graphic and numerical displays is beyond dispute, though, as will here be shown, they include opportunities for error peculiar to themselves. Where their worth resides, apart from their merits as summarized and permanent records, is in the confirmation or contradiction they afford to the judgement dictated through the unaided finger. In this respect at any rate, whatever may be true in other directions, the facts of the pulse may miss an adequate recognition in the absence of registration by an apparatus which eliminates the personal factor of the individual observer. In other words, a graphic or numerical record has this merit: it speaks in terms not of a personal impression but of a physical fact.

The usual statement made on the point here under consideration is that the radial pulses in a case of intrathoracic aneurysm may differ the one from the other in force and in volume; and to this statement there is universal assent. But an alleged further difference—namely, a delay in the arrival of one pulse in relation to the arrival of its fellow—is a sharply contested issue. Everyone allows a possible sense or impression of delay as judged by the finger, and writers in pre-instrumental days—rightly or wrongly—assumed this impression to represent an actual occurrence. Graphic records, however, have shown that in some instances where delay seems to be beyond challenge it does not really exist, and that the suggestion to the finger of a unilateral pulse delay must be attributed to a more gradual rise of pressure within the artery between which and the left ventricle there is interposed the elastic sac of an aneurysm. Not unnaturally this observation has thrown doubt on the accuracy of the assertion that in intrathoracic aneurysm the radial pulse on the side corresponding to the aneurysm may in point of time fall behind its fellow. As appearances have certainly been misleading in some instances a facile conclusion is that they are misleading in all, and in the circumstances it may be admitted that the *onus probandi* now falls on those who affirm real delay—as distinct from the mere appearance of delay—to be among the possibilities. Manifestly, to secure this position graphic records are essential, for without such records there can be no effective answer to those who are able to show that the test of the finger has in particular instances undoubtedly proved deceptive; and who, further, have a ready and reasonable explanation of the source of the mistake. It is on registered tracings,

therefore, that the case for actual pulse delay must stand if it is to stand at all.

The record now submitted (Fig. 1) is claimed to be a demonstration of actual pulse delay in the left radial artery as compared with the time incidence of the right radial, and the tracings were obtained from a case of intrathoracic

explained, delay as interpreted through the finger may be apparent only, it is necessary to add that delay as registered in a graphic record falls outside this comment and must be accepted as the announcement of an actual occurrence.

While a time difference of the radial pulses, when it exists, needs careful demonstration, there are in not a few cases of aneurysm other differences that may be openly displayed in the contrasted sphygmograms. One of these is a difference in the height of the right and left waves; another is difference in form; and the full message is provided when both are present. Of the two, difference in form is much the more significant. Indeed, mere difference in the height of the contrasted waves is by itself of little moment, for this may exist with a perfectly normal cardio-vascular apparatus. Thus, Fig. 2 is taken from a healthy adult, and although the excursion of the wave in the left radial tracing is decidedly more extensive than that of the right radial, the other features of the tracings are substantially identical, and no experienced eye would read into the picture a suggestion of aneurysm. On the other hand, in Fig. 3 the waves in the two tracings are of one and the same height, but they are strikingly different in form, the right showing the sharply defined lines and angles of a normal sphygmogram, while the left suggests a swinging or pendulum-like movement—the ascent is gradual and the secondary waves proper to the descending line are absent. In Fig. 4 the contrast is a glaring one, and is exhibited both in the height and in the form of the waves of the sphygmograms. As a matter of fact, Figs. 3 and 4 were obtained each from a case of

FIG. 1.—Sphygmometer: Right, maximum 135, minimum 55; Left, maximum 75.

aneurysm. This diagnosis is beyond question, for a *post-mortem* examination revealed a considerable fusiform aneurysm of the aortic arch extending beyond the origin of the left subclavian artery. The wall of the aneurysm showed but little fibrinous deposit, and doubtless, therefore, during life the sac responded freely to the alternate rise and fall of blood pressure determined respectively by the systole and diastole of the left ventricle. In a word, the aneurysm was an elastic bag placed in the course of the circulation between the left ventricle and the left radial artery. Such an

FIG. 2.—Sphygmometer: Maximum, Right and Left, 135.

FIG. 3.—Sphygmometer: Right, 120; Left, 80.

FIG. 4.—Sphygmometer: Right, 160; Left, 50.

arrangement might on the face of it suggest a delay in the arrival of the pulse wave at the left wrist as compared with the time occupied by the passage of the wave along the arterial trunks of the opposite limb. That it did, as a matter of fact, effect this delay is apparent from the contrasted tracings. These were taken simultaneously on a polygraph, a wrist splint being fixed on each forearm; and it is obvious that the commencement of the rise in pressure in the left radial falls behind the corresponding movement in the right radial by an appreciable interval of time—approximately one-fifth of a second. Thus even if, as is alleged, there is normally a difference of one to two one-hundredths of a second in favour of the right radial pulse, the present record is an announcement of pathological delay in the radial artery on the side corresponding to the situation of the aneurysm. It is a proof that in the individual case here reported the delay was a real happening and not merely an apparent one. Other cases must, of course, be tested by a similar order of inquiry, but if the above record is accepted it is necessary to admit that among the possible evidences of intrathoracic aneurysm a place must be found for a true asynchronism of the radial pulses.

This evidence does not stand alone. Dr. Leonard Findlay<sup>1</sup> has published tracings which tell the same story, and has demonstrated by an ingenious apparatus the delaying effect of the introduction of a distensible sac on pulsations produced in a system of elastic tubes. His paper includes a very full discussion of the whole subject, and he rests the case for real delay in one or other radial pulse both on clinical and on experimental evidence. Hence even when the admission is freely made that, for reasons already

aneurysm, and, as can well be understood, gave definite aid to the diagnosis. Yet such sphygmograms cannot be quoted as compelling confidently a diagnosis of aneurysm; they necessarily mean some unilateral interference with the course of the arterial pulse, but it does not follow that this interference is provided by an aneurysm. Fig. 5, for example, shows facts essentially identical with those of Fig. 4; yet the case was not one of aneurysm. It was, indeed, a quite manifest case of chronic interstitial nephritis, and as no evidences of aneurysm could be discovered the differences between the radial pulses provided an opportunity for clinical speculation. The riddle was read at the *post-mortem* examination, for this revealed in the right subclavian artery a firm clot adherent to the arterial wall for a matter of two inches and largely obstructing the lumen of the vessel.

One other possible difference between the circulatory conditions existing in the right and left upper limbs in intrathoracic aneurysm may be noted—namely, a difference in the sphygmometer measurements. In the cases from which Figs. 1, 3, and 4 were taken the difference was a considerable one, the records being: in the first, right 135, left 75; in the second, right 120, left 80; and in the third, right 160, left 50. In each case it was observed that the auditory method applied to the left brachial artery detected no sound, so that the maximum reading had to be fixed solely by the finger, and no minimum reading was possible. Some degree of difference between the readings in the right and left limbs is not uncommon, but nothing like the contrast exhibited here can be passed as normal. On the basis of numerous measurements, Dr. O. K. Williamson<sup>2</sup> came

to the conclusion that a difference of 30 mm. or upwards in the sphygmometer readings obtained from the two upper limbs speaks strongly in favour of aneurysm; that a difference of 20 mm. may mean either aneurysm or dilatation of the aorta; and that with a still slighter difference may be found either of the conditions just mentioned, or arteriosclerosis, or mediastinal tumour. Broadly, the position is that to be of diagnostic value the inequality between the measurements must be a pronounced one, and even then, as

FIG. 5.—Sphygmometer: Right, 40; Left, 160.

shown by the case from which Fig. 5 was taken, the possibility of a unilateral interference with the arterial circulation other than aneurysm must be remembered. Further, such differences as are illustrated by the readings recorded in Figs. 1, 3, and 4 are unusual even in cases of aneurysm, and frequently—probably in the majority of cases—the readings are identical or approximately identical. A parallel remark applies to the other pulse differences noted in this paper. Neither unilateral delay in the pulse wave, nor modification in the height or in the form of the wave, is to be observed as a frequent clinical experience in thoracic aneurysm. The absence of such conditions from an individual case is therefore of little diagnostic moment, and while their positive values, when present, may be considerable, even these are subject to such qualifications as are here described and illustrated.

### A NOTE ON THE NATURE OF THE BLOOD SUGAR.

BY

L. B. WINTER AND W. SMITH.

(From the Biochemical Laboratory, Cambridge.)

IN a recent paper<sup>1</sup> we gave the results of an investigation into the nature of the blood sugar by a new method. Hewitt<sup>2</sup> has lately criticized both the method employed and also the interpretation placed thereon. He states that we "reached the conclusion that the normal blood sugar is  $\gamma$  glucose." In discussing the experimental evidence which we brought forward in our original paper we stated: "The nature of the normal blood sugar we leave for the present undecided." Later, in view of the fact that Hewitt and Pryde<sup>3</sup> had shown "with some certainty"<sup>2</sup> that  $\gamma$  glucose is formed from  $\alpha$ ,  $\beta$  glucose in equilibrium of the intestine, we suggested that the unstable sugar which was found to be present might be  $\gamma$  glucose. We stated further that "The enzyme responsible for the conversion being apparently absent from the blood, and the reaction of the blood being alkaline, suggests that it is impossible for so reactive a sugar to exist free in the blood."

It is obvious therefore that our only reasons for ever suggesting the presence of  $\gamma$  glucose were based on the work of Hewitt and his collaborators. They state<sup>4</sup>:

"It may be presumed on *a priori* grounds that a structural change of the nature referred to has some fundamental reason." The reason was not clear, but a possible explanation was afforded by the differences we showed to exist between the normal and diabetic blood sugars, and more recently by the fact that the nature of the diabetic blood sugar becomes similar to that of normal persons after injections of insulin.<sup>5</sup>

Hewitt<sup>2</sup> objects: "Polarimetric evidence alone, therefore, must exclude rigorously the presence of  $\beta$  glucose in amount greater than that found normally in aqueous solution of glucose in equilibrium." Control experiments showed that the equilibrium of  $\alpha$ ,  $\beta$  glucose was hardly affected by the experimental technique; further, after the alcoholic extraction no trace of copper-reducing substance was found to be left behind. Preferential extraction by alcohol or alteration in equilibrium of  $\alpha$ ,  $\beta$  glucose is therefore definitely excluded. In some experiments the initial rotation was below that which would be given by  $\beta$  glucose alone, and in the case of diabetics above that of  $\alpha$  glucose alone. The suggestion that the normal blood sugar contains  $\beta$  glucose, and diabetic blood  $\alpha$  glucose, is therefore not valid. Further, in one experiment a laevo-rotation was observed, but as this has not been repeated no stress has been laid on it; in this connexion it is of interest to note that Hewitt and Pryde attach considerable importance to the one laevo-rotation observed in their own experiments.

The fact that we obtained a glucosazone from normal blood may be due to the fact that some of the normal blood sugar is the stable  $\alpha$ ,  $\beta$  form. It seems probable that normal blood sugar is an equilibrium mixture of  $\alpha$ ,  $\beta$  glucose, and a reactive sugar.<sup>5</sup>

The question of sterility is disposed of by the following facts: (a) the polarimeter tubes were sterilized; (b) the copper-reducing value was unaltered at the end of three or four days; (c) the fluid was perfectly clear throughout, and no sign of any growth was observed.

With regard to the criticisms on the general technique adopted, though admittedly it is not perfect, we maintain that by it we have been able to obtain a clear and concentrated protein-free filtrate from blood by which we are able to show with ease the very wide differences in the nature of the blood sugar under different conditions. We may merely mention here that the nature of the diabetic blood sugar differs from normal, and that after administration of insulin the blood sugar of the diabetic approaches normal; and further, that after administration of adrenaline the blood sugar differs again from normal. A most striking difference is observed in the blood sugar of normal animals after insulin (unpublished experiments); the blood sugar in this condition, though dextro-rotatory, has no copper-reducing value, as determined by the Wood-Ost method.

The downward change in optical values of the diabetic blood sugar is not always observed, and it would appear that in this pathological condition the blood sugar may be very complex.<sup>6</sup>

Hewitt criticizes the experiments in which we endeavoured to test whether there is present in the blood an enzyme capable of converting added  $\alpha$ ,  $\beta$  glucose or *d*-fructose into a reactive sugar. The experiments of Cooper and Walker,<sup>7</sup> directed to the same end, are also not allowed to pass unchallenged. The first point he makes is that the blood was extravascular; criticism on this line is purely destructive and would invalidate a vast amount of work which has been done with blood. A more legitimate objection which he makes against the experiments of Cooper and Walker is that an enzyme, if present, was probably unable to pass through the membrane of the dialyser owing to its physical properties. Our own experiments he dismisses on the ground that the method employed was in every way suitable to destroy  $\gamma$  glucose; he omits to notice that if differences in the blood sugar could be demonstrated by this method, the same method would probably be capable of showing a difference had any change taken place in the nature of the sugar which had been added to the blood. He agrees, however, "that no such enzyme can be demonstrated in the blood,"<sup>2</sup> and

refers to a paper by De Souza and himself.<sup>1</sup> They injected sugars into the blood stream, and collected the urine passed immediately afterwards. The one merit of the method employed is that the blood is not extravascular, but is a means of demonstrating the presence of such an enzyme in the blood the method does not lend itself to any conclusions. It is unlikely that more than a proportion of the injected sugar would be changed into a reactive form in the time allowed (five minutes); further, the sugar excreted would presumably be that which was unchanged, and therefore useless to the body during that period; further, if any change was observed it could not be a proof that an enzyme was present in the blood.

After a careful study of the figures given by Hewitt and Pryde in their paper,<sup>2</sup> it is reasonable to conclude that the rotations observed with isotonic and hypertonic solutions were of the same degree as those observed with hypotonic. It is stated that in the case of hypertonic and isotonic solutions a specific rotation below  $+40^\circ$  was not recorded. No figures are given, but this statement implies that changes of that order were observed. In the absence of fuller details, it would appear from the figures 1 and 2 that only about a quarter of the sugar originally introduced into the intestine was present when the fluid was removed for polarimetric examination. Supposing that a quarter of the sugar remains in the intestine when an isotonic or hypertonic solution is introduced, then the observed alteration in rotation required to change the specific rotation from  $+52.5^\circ$  to  $+40^\circ$  would be  $0.34^\circ$  for the isotonic solution, and  $0.50^\circ$  for the hypertonic solution of glucose employed, or alteration of rotation (not specific rotation) very similar to, or even larger than was observed, according to the figures, which are stated to "show the optical changes most markedly." It is a curious fact that marked changes should have been observed in hypotonic, and not in isotonic solutions. The authors state: "Contact with the mucous membrane of the living intestine probably effects the production of  $\gamma$  glucose in excess of any amount normally present in glucose solutions which have attained a permanent specific rotation." Were it a genuine effect due to an enzyme in the intestinal cells, it would be likely that the most marked change would be observed in the isotonic solution in the short time allowed (five minutes), since, presumably, changes in the body preferably occur in fluids isotonic with the tissues—for example, perfusion experiments are always performed with approximately isotonic solutions. On the above reasoning precisely similar alterations in observed rotation (not specific) must have taken place in hypo-, iso-, and hyper-tonic solutions of sugars, but only in the case of hypotonic solutions do these differences lend themselves to the elaborate treatment which they have received in this paper, owing to the fact that a small difference in observed rotation of a hypotonic solution makes a large difference in specific rotation. A conclusion derived from neglecting inconvenient facts with the acceptance of others is of questionable use. The conclusions drawn from these facts were only given in the following paper,<sup>3</sup> in which they state: "It may be presumed on *a priori* grounds that a structural change of the nature referred to has some fundamental reason."

Further doubt is thrown on the work by the admitted difficulty in seeing through the fluid for polarimetric observation, a difficulty which becomes obvious when the wide variations in the successive readings are noted; incidentally, the readings are given to three places of decimals. Small reliance therefore can be placed on the one laevo-rotation observed. No copper-reducing value of the sugar is given; the statement is merely made that it agreed remarkably well with the final rotation.

The one experiment recorded in which fructose was used may be adequately explained by temperature variations, to which this sugar is notoriously sensitive. There is evidence that fructose is more rapidly utilized in the body than glucose, presumably because it is more rapidly converted into normal blood sugar. It is remarkable therefore that Hewitt and Pryde attained such little success with the use of fructose.

Hewitt rightly observes: "The dangers attending the

use of permanganate with biological material are obvious." The technique adopted by these authors when using permanganate has been briefly referred to by us as being not above suspicion.<sup>4</sup> They omitted to perform the only conclusive test—namely, a comparison between the rates of decolorization at the beginning of the experiment, and at the end when the sugar had attained equilibrium. The italics used in discussing their experimental method hence have not the importance the authors attach to them.

We may conclude that the experimental evidence put forward by Hewitt and Pryde does not support Hewitt's recent contention<sup>2</sup> that " $\gamma$  glucose and  $\gamma$  fructose are formed and can be detected when the stable  $\alpha$  and  $\beta$  isomerides are in contact with living intact intestine." We are glad to note that the possible significance of their experiments performed three years ago has not escaped Hewitt, and that experiments are now in progress on the diabetic organism. We feel that it is necessary to point out the above facts in order to correct any doubt on our work which Hewitt's criticism may have caused.

#### Summary.

1. There is definite evidence that a reactive sugar is present in the blood.
2. There is no chemical evidence that  $\gamma$  glucose is formed in the body.
3. There is definite evidence that some of the blood sugar of diabetics is fundamentally different from that of normal persons.
4. No evidence at present exists that the intestine plays an essential part in the causation of this difference.

## THE TREATMENT OF GENERAL PARALYSIS BY MALARIA.

BY

W. L. TEMPLETON, M.B., Ch.B.,

ASSISTANT MEDICAL OFFICER, CITY OF LONDON MENTAL HOSPITAL, DARTFORD.

A SHORT account of the treatment of general paralysis of the insane by infection with malaria was given by Dr. E. W. Scripture at a meeting of the Medico-Psychological Association on November 23rd, as reported in the *BRITISH MEDICAL JOURNAL* of December 8th, 1922 (p. 1121). The principle depends on the fact that remissions in chronic disease may occur after an attack of an acute specific fever. Many methods of producing fever artificially have been tried, with varying results, but Wagner-Jauregg, quoted by Pilcz,<sup>1</sup> has drawn up a scale of efficiency of the various methods used as follows: (1) chemical substances—for example, sodium nucleinate; (2) toxalbumins—for example, tuberculin, staphylococci; (3) acute disease; the last is the most efficient. With tuberculin treatment Pilcz<sup>2</sup> obtained a remission in 26 per cent. of his cases, and eight remained well three years after treatment. The treatment by malaria gives a much higher percentage of remissions. During a recent residence in Vienna as a post-graduate I had an opportunity of seeing some of the clinical results, which are very encouraging.

The method consists in the withdrawal of from 2 to 4 c.cm. of blood from the vein of a patient suffering from benign tertian malaria (whether the patient be in the febrile stage or not), and in its subcutaneous injection into the subject of general paralysis, who will develop within about a week typical attacks of malaria. He is allowed to have ten to twelve such attacks, when the malaria is cured by the administration of quinine in doses of 1 gram for three days in succession; then in doses of 0.5 gram for fourteen days. In no case did the malaria persist; it invariably cleared up after the first few doses of quinine. During the febrile attacks and occasionally after, there is very often an exacerbation of mental

symptoms, consisting chiefly of auditory hallucinations and delusions of persecutions. In the majority of cases these symptoms promptly disappear when the febrile attacks have terminated. Following upon the febrile attacks and going parallel with the quinine treatment, weekly doses of neo-salvarsan are administered intravenously; commencing with 0.3 gram; six doses in all are given, in the scale of 0.3, 0.4, and four of 0.6 gram.

Of the 350 cases treated down to February, 1923,<sup>2</sup> complete observations were made in 296 only. Of these, no fewer than 202 showed remissions of varying degree, and 112 showed complete remission with the disappearance of former mental disturbances and a return of former business capacity; 68 per cent. showed remissions, and 38 per cent. complete remissions, and this in spite of the fact that many advanced cases were included.\*

Of especial practical importance is the time during which remissions persisted. Of the patients who had complete remissions, 3 treated in 1917 are still actively employed at business and show no evidence of relapsing. These remissions are therefore of five years' duration. In 17 the remissions have already lasted two to three years, and in a further 34 treated correspondingly later the remission has persisted for one to two years. Of the total for whom complete remission has at any time been claimed 3 only have relapsed or have shown any tendency to relapse. Of those for whom incomplete remission has been claimed the majority were far advanced forms of the disease, and yet even here much benefit was seen, particularly in the cessation of acute symptoms and in the non-progression or even regression of the dementia. Of those showing all the signs of an already present dementia many again became sociable and inoffensive, and regained a certain degree of occupational ability.

Several of the German clinics have already made a trial of the method, with good results. Weigandt<sup>4</sup> reports that of 50 cases treated by this method remissions were obtained in 88 per cent., and good remissions in 48 per cent. The remissions do not follow immediately upon the febrile attacks, but very often show a gradual progressive course over a period of weeks and even months, so that cases which at first seemed incomplete, when re-examined months later showed complete absence of symptoms. One very remarkable fact is that there is no parallelism between the clinical and serological findings. Many who show a complete remission of symptoms still give a positive reaction in blood serum and cerebro-spinal fluid, and yet the same cases, when examined months later, have shown a negative Wassermann result in both. In connexion with this Gerstmann<sup>2</sup> quotes a case treated by the tuberculin-mercury method in 1909 in whom a complete remission still persists. When examined recently the report was: Wassermann reaction positive in the blood and cerebro-spinal fluid; globulin test positive; lymphocytes 186.3.

In this country and in some others the difficulty consists in obtaining suitable cases of benign malaria for purposes of inoculation. Once a single case has been inoculated there is then no difficulty in transferring the infection to other paralytics, and though this involves the transference of syphilitic blood, yet, in cases which have been thoroughly examined and found positive for syphilis, this is of little consequence. The method of continuous transference has been practised in Vienna, where two strains of plasmodia are being used—one after having been passed through 58 hosts, and the other through 38, in both cases without any reduction in the virulence of the infection. Attempts are being made to keep the parasite alive outside the body; so far it has not survived for more than eight hours. The latest report<sup>2</sup> from the Wagner-Jauregg clinic contains an interesting account of the histological findings in the case of a patient treated by malaria who died of intercurrent disease. The authors seek to draw conclusions from the greater infiltration of the temporal lobes as to some extent explaining the occurrence and persistence of the auditory hallucinations mentioned. In general the histological changes in cases which had shown remission under malarial treatment were those of the so-called stationary paralysis of Alzheimer, with an almost complete absence of the changes usually found in progressive general paralysis.

\* These figures are given in a personal letter from Dr. Gerstmann, and differ slightly from those in the *Zeit. f. d. ges. Neur. und Psy.*

The proportion of complete remissions (38 per cent.) is high for general paralysis, but it is certain that with cases treated at an earlier stage than many of those included in the Vienna figures this percentage would be much higher. Professor Wagner-Jauregg<sup>5</sup> goes so far as to say that in cases of short duration entire success can be predicted with almost absolute certainty. Whether this be justified or not can only be determined by a widespread trial of the method.

## Memoranda:

## MEDICAL, SURGICAL, OBSTETRICAL.

## A SMALL EPIDEMIC OF PLAGUE.

THE epidemic here reported occurred on an India-going vessel. It began on March 7th, 1922, nine days after the ship left Karachi, the last port of call. There were six cases, all among the lascar crew of the ship; no Europeans were affected.

*Case 1.*—A Goanese steward, aged 32, was taken ill on March 5th, 1922; he was first seen on the morning of March 7th. He complained of intense pain in the small of his back, with severe frontal headache, and had vomited twice during the night. His temperature was 103°, his pulse rate 120. His temperature rose the same night to 104.2°, and he became slightly delirious. There were no physical signs in the chest or abdomen. Towards evening vomiting became incessant. Next day the patient's general condition somewhat improved, but vomiting was still incessant. On examination an exquisitely tender small bubo was found in the left groin. The diagnosis of plague was made on discovery of this bubo. Towards evening the patient became markedly worse, and was delirious at intervals. He continued so until death occurred on the afternoon of the following day.

*Case 2.*—A native sailor, aged 32, first seen on March 15th, had a large bubo, which was hard and somewhat tender, in the left groin. The constitutional disturbances were very slight; fever was absent, the pulse rate 90. Next day his temperature rose to 106°, and the patient showed some degree of lethargy. Without his condition apparently altering he died suddenly soon after midnight.

*Case 3.*—A native sailor, aged 35, was seen first on March 15th, but had apparently been ill for two days before. He was obviously very ill when first seen, with a temperature of 103°. There was some enlargement of the inguinal lymphatic glands on both sides, but no tenderness. He died suddenly the same evening.

*Case 4.*—A Goanese steward, aged 37, reported sick on March 19th, just as we were going into port at Port Said. His temperature was 100.8°, his pulse rate 100. There was a small tender bubo in the left axilla. He was sent ashore as a case of suspected bubonic plague and died three days later.

*Case 5.*—A native sailor, aged 35, was taken ill on March 24th, and was first seen on the morning of March 26th. He had a temperature of 104°, pulse rate 124. In his left groin was a large, exquisitely tender bubo. He was seen on the following morning by Dr. Duval, assistant M.O.H. for Dunkirk, who confirmed the diagnosis and supplied serum, which was given daily in doses of 50 c.cm. This was the first supply of serum which we had had. On March 27th the patient was very weak, and in the evening he sank into a low delirium. Next day he was in a typhoidal condition, having a weak irregular pulse, muttering constantly, and taking food and stimulants only with much persuasion. On March 29th he was still in a very collapsed state, and on March 30th the Dunkirk authorities consented to take him into hospital, where he died the following day.

*Case 6.*—This case may have been a virulent pneumonia, but I have added it under the impression that it was really a case of pneumonic plague. The patient, the galley cook, aged 41, was taken ill during the night of March 29th; he was first seen on the morning of March 30th, when his temperature was 104°, his pulse rate 132. He had a slight, often repeated cough, with expectoration of blood-stained sputum; there was marked cyanosis and embarrassment of breathing (respiration rate 42). In the chest there was nothing to be detected, save a few râles at the bases of both lungs. The temperature continued to rise to 106°; by evening the patient became worse, and died at two o'clock the following morning.

The origin of the outbreak was not traced; very few rats, dead or alive, were seen on the ship, and even after fumigation with sulphur dioxide at Dunkirk only about half a dozen rats were discovered. If the infection were from man to man, which is said by the Royal Commission on Plague to occur only in 3 per cent. of cases, the first patient had a much longer incubation period than usual; as he had not been ashore for thirteen days previously (in Karachi), whereas the usual incubation period is said to be from two to five days.

No serum nor vaccine could be obtained until Dunkirk was reached. The well known iodine treatment (2 minims of tincture of iodine every two hours) was tried in the first five cases without any success, but obviously the numbers are too small to justify any conclusions being drawn. Apart from this treatment, and the injection of half a drachm of tincture of iodine into the buboes in two cases, the treatment was symptomatic. In Case 5, which occurred at Dunkirk, serum was used in doses of 50 c.cm. per diem. The result was difficult to judge, for although the temperature and pulse fell, the bubo did not diminish in size, the patient's general condition was little better, and he ultimately died.

At Dunkirk each member of the crew was given 10 c.cm. of serum, which is said to act as a prophylactic for twelve days, and at a later date (when the vessel arrived in England) a further dose of 1 c.cm. of vaccin anti-pestueux was given. After the complete inoculation of the crew, no further cases of plague occurred.

Liverpool.

E. NOBLE CHAMBERLAIN, M.B., Ch.B.

### THE TREATMENT OF PNEUMONIA.

The treatment of pneumonia by Dr. Wynn of Birmingham with pneumococcal vaccines, as related by Dr. Newell in the issue of the *BRITISH MEDICAL JOURNAL* for April 21st (p. 676), gives such splendid results that it will be obviously the duty of general practitioners to test the validity of the conclusions, since the ordinary treatment of this disease by drugs, etc., is very disappointing. It is not an over-estimate to state that, in the case of adults, there is one death in every four or five patients attacked by the disease. As the last four cases of pneumonia that I had occasion to treat all recovered, I am tempted to state the treatment adopted.

The youngest was a woman aged 38 with double pneumonia: the oldest was a man of 70; the other two were about 60. Alcohol was used freely in all cases, and the patients were allowed to take whisky and soda-water whenever they desired it. It was left to the patients to take it or leave it according to their own inclination. Digitalis was given in sufficient quantity to reduce the pulse rate from 120 to 100; 1 grain of quinine was administered every two hours with the suitable dose of digitalis, preferably in pill form. If the temperature was 104° F. 1 or 2 grains of antifebrin were added to the pill, for a high temperature, in my opinion, has an exhausting effect on the heart. Opium gr. 1/4 was given to soothe the cough and the patient. The prescription was therefore as follows:

R Quinine	...	...	...	...	...	gr. 1
P. digitalis	...	...	...	...	...	gr. 1/2 or 1
Antifebrin	...	...	...	...	...	gr. 1 or 2
P. opio	...	...	...	...	...	gr. 1/4

Fi. pil. 1 or pulv. 1. Sig.: One to be taken every two, three, or four hours, according to circumstances.

The quantity of digitalis and antifebrin is determined by the pulse rate or the rise of the temperature. On these lines we protect the heart, and the results are excellent.

Rothsay.

JOHN T. MACLACHLAN, M.D.

### UPPER CANINE TOOTH IN ANTRUM OF HIGHMORE.

About eleven months ago a lady aged 59 began to have discomfort in the region of the right upper canine tooth. She had lost all her other upper teeth, but said that this one had never come through.

In February last, as the pain increased, an x-ray photograph was taken by Dr. Anstey Chave, and showed the tooth lying very obliquely and pointing rather more towards the mid-line than downwards. The gum was lanced on several occasions by Mr. Bidlake of Reigate, and on May 1st an attempt was made to extract the tooth under gas. The wedge-shaped crown was very difficult to hold with the forceps, and at the third attempt the tooth shot completely out of sight and no sign of it could be felt anywhere. As we thought it had probably entered the right antrum of Highmore, the patient was again x-rayed, and the plate showed the tooth lying loose in the antrum with the crown pointing backwards.

I took her into the Reigate and Redhill Hospital, and under a general anaesthetic, administered by Dr. Whittington, I incised and reflected the mucous membrane in front of the right upper jaw, and found a hole about half an inch in diameter in the anterior wall of the antrum, through which I easily extracted the tooth with a pair of long sinus forceps.

Reigate.

## Reports of Societies.

### DIATHERMY AND MEDICAL PRACTICE.

A MEETING of the Brighton and Sussex Medico-Chirurgical Society was held on May 3rd, with Mr. A. J. HUTCHISON, President, in the chair, when Dr. H. T. CUBBON read a paper on diathermy in medical practice.

Dr. Cubbon described medical diathermy as the heating through of diseased tissue to a temperature insufficient to destroy the tissue or impair its vitality. The main physiological effects of diathermy were due, he said, to its thermo-penetration. The dilatation of the peripheral vessels, increased perspiration, and elimination of solids in the urine aided in the elimination of toxins. The local effects of heat generated in the tissues were to reduce spasm and increase tension, with consequent relief of pain. The relief of pain was the most valuable property of diathermy. Diathermy was an effective method of supplying a supplementary ration of heat in marasmic diseases of children, in malnutrition associated with stricture of the oesophagus or cancer of the stomach, and in hypothermia following profuse haemorrhage. Owing to its penetrating power diathermy was very useful in the treatment of neuritis, and it was often of service in relieving the symptoms due to high blood pressure, although the effect appeared to be only temporary. Diathermy was effective in the treatment of pain and spasm caused by haemorrhoids which were not due to affections of the liver, heart, or compression of the rectum. It had also been found an effective method in dealing with gonococcal infections of the cervix, and in gonococcal arthritis before structural changes had taken place. Diathermy was an excellent method of relieving the pain and muscular spasm in cases of lumbago and torticollis of recent origin; chronic cases responded better to the constant current. Diathermy was useful in controlling and relieving cases of painful menstruation. Treatment should be given daily for three days before the expected period and in some cases during the period also. Cases of amenorrhoea for which no obvious cause could be found could often be remedied by diathermy applications of low intensity. The treatment should be given for six days before the period was calculated to be due. M. August of Paris had had success in treating cases of abdominal pain in which no other lesions beyond adhesions and inflammation of the omentum were present. Out of 23 cases which he had operated upon, 15 could be considered cured, 4 were more or less well, and 4 had gained no benefit. In coccygodynia, great relief and usually complete cure could be obtained by diathermy. One electrode must be placed in the rectum and the other electrode applied externally over the coccyx. Diathermy would quickly relieve the acute pain of gout, but it had to be administered with caution and combined with treatment for the elimination and neutralization of uric acid, as the patient might suddenly develop severe constitutional symptoms—possibly the result of absorption into the system of the dissolved uric acid in the joint—as the result of the heat applied. Diathermy would be found a useful adjunct to the treatment of infantile paralysis. The temperature of the paralysed limb could be maintained at a normal level by this method and so aid in the restoration of the nutrition of the limb. Until the normal temperature was attained electrical treatment was of little use. Diathermy had likewise been found useful in treating the pain associated with herpetic neuralgia in aged patients. The following maladies were not suitable for this method of treatment, although it might be thought that diathermy would be suitable: chilblains, chilblain circulation and Raynaud's disease—these cases responded better to the constant current; cases of trigeminal neuralgia did not respond well to diathermy, and the treatment of rheumatoid and osteo-arthritis was disappointing.

After remarks by the President, Drs. BROADBENT, BOYLE, NEVILLE COX, LYON SMITH, and STORMONT spoke, and Dr. CUBBON replied.

*Acute Suppurative Infections of the Fingers and Hands.*

Mr. J. R. GRIFFITH then read a paper on the treatment of acute suppurative infections of the fingers and hands. After expressing his indebtedness to Dr. Ranavil, Mr. Griffith said that these infections were dangerous in that they might spread through the lymphatics into the general circulation, and also because they might cause local destruction of tissue both by pressure and by cutting off the blood supply. Treatment was, therefore, directed towards evacuating inflammatory products and relieving tension by means of incisions which did as little damage as possible and did not involve uninfected spaces. The advantage of treating infections of the finger pulp by means of lateral incisions was discussed, and the method was described of treating infections of the nail bed by exposing and excising the root, a flap having been formed by making two lateral incisions continuous with the lateral margin of the nail. Mr. Griffith recommended the treatment of infections of the fascial spaces of the palm and thenar eminence by an incision through the web of the finger in the first case and by an incision through the dorsal aspect of the first interosseous space in the second case. Collections of pus in the forearm spreading from the hand were usually situated between the flexor aspect of the interosseous membrane and the pronatus quadratus deeply and the flexor tendons superficially. This space might be drained by means of an incision along the anterior margin of either the radius or the ulnar; this incision avoided important structures. The treatment of infections of the tendon sheaths was then discussed, and in the case of the middle finger the importance of providing adequate drainage by means of long lateral incisions was stressed. In the case of infections of the thumb and little finger tendon sheaths, the possibility was emphasized of extension of the infection from one sheath to the other and from a sheath to the neighbouring tissue spaces in the hand and forearm, and methods of dealing with these infections and complications were detailed. The after-treatment consisted of prolonged arm baths in 2 per cent. saline; early mobilization was to be encouraged—it did not spread the infection when incisions were adequate.

The PRESIDENT, Drs. WALKER and FITZMAURICE-KELLY spoke, and Mr. GRIFFITH replied.

### TREATMENT OF CONCEALED ACCIDENTAL HAEMORRHAGE.

At a meeting of the Edinburgh Obstetrical Society on May 10th, with the President, Dr. J. LAMOND LACKIE, in the chair, Dr. R. A. LENNIE (Glasgow) read a paper on the treatment of concealed accidental haemorrhage by conservative Caesarean section.

Dr. Lennie said that it seemed to be the prevalent opinion that in cases of concealed haemorrhage, on account of the damage to the uterine wall, if Caesarean section was performed the uterus must at the same time be removed. This had not been his experience in the Glasgow Maternity Hospital, and he described three cases in which hysterectomy was purposely omitted owing to the collapsed condition of the patient.

*Case 1.*—1904. A primipara, aged 27, was admitted to hospital with a history of vaginal haemorrhage of several hours' duration. The os was the size of a shilling; the conjugata vera measured 2½ inches; the uterus was much distended and tender, and the abdominal wall was oedematous. After admission the patient's pulse became thready and rapid. Caesarean section was performed by Dr. Jardine, the child being delivered alive. The uterine cavity was full of blood clot and the placenta was partially detached. After delivery of the child the uterus retracted well, and the puerperium ran a normal course.

*Case 2.*—1920. A 10-gravida, aged 41, was admitted to hospital with *ante-partum* haemorrhage. She was 7½ months pregnant, blanched and exhausted; her pulse was thready and rapid; the urine was loaded with albumin. She had severe and continuous abdominal pain; the uterus was tense and tender; no foetal heart was heard nor were foetal parts felt; the os was closed and the patient was not in labour. After admission the uterus gradually increased in size and rigidity and tenderness became more marked. Intravenous salines were given with pituitrin, and Caesarean section was performed by Dr. McLennan four hours after admission. The anterior and posterior walls of the uterus showed a purplish mottled discoloration, and on incising the uterus small interstitial haemorrhages were found throughout the uterine muscle. The placenta was completely detached, there was a large amount of blood clot

in the uterine cavity, and the foetus was dead. The uterus retracted readily after being emptied. Hysterectomy was considered inadvisable as the patient was in *extremis*. The puerperium was uneventful.

*Case 3.*—1922. A primipara, aged 24, 7 months pregnant, was admitted to hospital with evidence of concealed haemorrhage. The os barely admitted one finger, and there was a constant trickle of blood. Oedema had been present for several weeks, and the urine contained a fair amount of albumin. Caesarean section was performed by Dr. Lennie. The uterus showed a black mottled appearance and the incision revealed numerous intramural haemorrhages, while its cavity was full of blood clot. The placenta was almost completely detached by a large retroplacental haematoma, and the membranes were also separated from the uterine wall by blood. When the contents were evacuated the uterus retracted even more readily than in ordinary sections, and there was practically no bleeding during the operation. Progress was good for the first two weeks, when the patient contracted phlegmasia alba dolens, followed by myocarditis and death forty-seven days after operation. Dr. Lennie considered that if hysterectomy had been performed the patient would have died on the table.

Dr. Lennie held that when Caesarean section was performed in a case of concealed haemorrhage the uterus should be left *in situ* as the musculature was still capable of contraction and retraction.

The paper was discussed by Dr. FORDYCE, Professor WATSON, Dr. DAVIDSON, and Dr. YOUNG.

### CASES AND SPECIMENS.

Dr. W. F. THEODORE HAULTAIN and Dr. J. S. HALL read a short paper on a case of fits occurring in the fourth month of pregnancy with no other signs of toxæmia.

The patient was a 2-para, 4½ months pregnant, admitted in a semi-conscious state. Her blood pressure was 135, and the urine was normal. The nervous system was normal except for slightly exaggerated deep reflexes; a positive Kernig sign and head retraction were present, with a tendency to opisthotonos. Lumbar puncture showed a normal fluid under slight pressure. After lumbar puncture the patient gave a cry and went into a short clonic followed by a tonic spasm, the whole lasting about two minutes and being repeated five times in two hours. She afterwards went downhill rapidly, her temperature rose to 103°, and her respirations to 38, and she died fourteen hours after admission.

At the *post-mortem* examination the liver showed small points of haemorrhage through its substance and under its capsule. The kidney showed toxic appearances, but no definite pathological change. The uterus and contents appeared to be normal. The brain showed no lesion either macroscopically or microscopically, the pathologist who carried out the examination giving it as his opinion that "the changes present were consistent with the effects produced by a toxæmia of pregnancy." Dr. Haultain, however, was disinclined to admit that the case was one of eclampsia.

Dr. F. J. BROWNE described a specimen of an acardiac foetus.

The foetus was an extremely macerated (papyraceous) twin, the other twin being alive and healthy. There were two lower limbs, a trunk, and one upper extremity attached to the centre of the upper border of the trunk. There was no diaphragm, and the chest cavity was represented by a mass of gelatinous tissue containing no trace of heart or lungs. The abdomen contained no organs except one kidney, a ureter and bladder with two hypogastric arteries; the specimen was received in a very macerated condition and in consequence these vessels could not be traced further than the pelvis. There was a common placenta and the umbilical cord was inserted at its centre but bifurcated about one inch from its insertion, the main cord going to the normal foetus, and the other, very slender, but containing two arteries and a vein, going to the acardiac foetus. About one inch from the foetal insertion of the cord there was a true knot very tightly drawn which might have been the cause of foetal death. Between this knot and the umbilical end there was a sac containing intestine, although the abdomen was completely closed. Dr. Browne described the probable course of the common circulation; he thought that there was an anastomosis in the last common part of the cord between the umbilical veins of the two foetuses. The specimen was classified as *Holoacardiacus accephalus bipus monobrachius*.

Dr. H. S. DAVIDSON showed a specimen of lipoma about the size of a Tangerine orange, removed from the right external abdominal ring of a woman aged 41. The only symptoms had been some discomfort and slight tenderness.

### HYPERPLASIA OF THE HYPOPHYSIS CEREBRI.

A MEETING of the Section of Medicine of the Royal Academy of Medicine in Ireland was held on May 11th, with the President, Dr. T. G. MOORHEAD, in the chair, when Dr. J. D. CUMMINS reported a case of hyperplasia of the hypophysis cerebri in an unmarried woman aged 33, who had amenorrhoea, progressive stoutness and lethargy, bitemporal hemianopia, and unequal impairment of central vision; there was no enlargement of the sella turcica. Disharmony between the hormone-producing organs was held to be the

cause; and complete cure was effected within five months by the administration of one grain of thyroid extract daily. The PRESIDENT said that two years ago he had shown a somewhat similar case at the Academy, a woman, aged 55, who was suffering from all the symptoms of a pituitary tumour, and was shown by x rays to have a definite enlargement of the sella turcica; there was almost complete blindness of the right eye, and blindness of the nasal half of the left eye. He treated the patient first with pituitary extract, and later, for a period of six months, with thyroid extract, and, although he did not attribute the improvement to these remedies, it was a remarkable fact that this patient was now practically well. Dr. J. H. POLLOCK read a note on some clinical aspects of the Wassermann reaction, which was discussed by Dr. KIRKPATRICK, Dr. BIGGER, Dr. ROWLETTE, Dr. SPEARES, Dr. NESBITT, Dr. PARSONS, Dr. MICKS, and the PRESIDENT. Dr. H. C. DUNN read notes on cases of scleroderma in a child, Ritter's disease, and von Jaksch's disease. The first case was a female child, aged 4 years, with a sclerotic condition of the right side of the face and neck. The case had been seen by Dr. Walter Smith and Dr. Wallace Beatty, who confirmed the diagnosis of scleroderma. The case was remarkable on account of the age of the patient. The second case was a child 14 days old. Blisters were noticed on the body on the day before admission to hospital. These increased rapidly to large bullae which ruptured, leaving a raw red surface. The greater part of the body and limbs were involved, and the process resembled severe scalding. The case was diagnosed as dermatitis gangrenosa infantum (Ritter's disease). It ran a very rapid course and ended fatally forty-eight hours after the eruption appeared. The third was a female child aged 1 year and 3 months, who was admitted to hospital in an emaciated anaemic condition, suffering from severe diarrhoea. Blood films were diagnostic of von Jaksch's disease. The child died six days later.

#### TREATMENT AFTER ABDOMINAL OPERATIONS.

At the West London Hospital on May 4th Mr. McADAM ECCLES read a paper on treatment after abdominal operations to the West London Medico-Chirurgical Society. Dr. WELLS, the President, occupied the chair. Mr. McAdam Eccles said that it had been contended that it was only the surgeon or practitioner who had experienced an abdominal operation on himself who could adequately treat a fellow sufferer; he would speak from personal experience of appendicectomy. Post-operative vomiting was partly due to the general anaesthesia, but not entirely, for Mr. Eccles had seen it occur after spinal anaesthesia. The treatment he recommended for post-operative emesis was: (1) to allow the patient a pint of hot water to drink with half a drachm of sodium bicarbonate dissolved in it; (2) a saline enema of half a pint was slowly given to relieve thirst, and this, if retained, was repeated in a few hours; (3) to prop the patient up with pillows, as this position stopped vomiting. Flatulence after laparotomy might be due to at least four causes: (1) purge and enema previous to operation; (2) a preliminary dose of morphine and atropine; (3) excessive manipulation of bowel, causing paresis; (4) too rigid confinement of abdominal patients to the dorsal position. Early flatulence was best relieved by a pituitrin enema. Of great service was a hot fomentation placed over the whole abdomen; it was superior to a layer of cotton-wool. Solid food should be given as soon as possible. For late flatulence there was nothing superior to a good dose of castor oil. Pain after abdominal operations was best relieved by a rectal injection of aspirin gr. x and sodium bromide gr. xx. As for diet, except where the intestine had been actually interfered with, the sooner the patient had semi-solid and solid food the better. When a drainage tube had been inserted it should be removed as soon as possible. A tube pressing against the intestine might cause a fistula within forty-eight hours of its insertion. For retention of urine after operation a catheter should never be passed if it could be possibly avoided. Finally, it should be remembered that under the strain of coughing or vomiting abdominal sutures might give way; the actual line of sutures should therefore be inspected every day. An interesting discussion followed.

## Rebiefus.

### CUNNINGHAM'S TEXTBOOK OF ANATOMY.

*Cunningham's Textbook of Anatomy* must be well known to readers of the BRITISH MEDICAL JOURNAL, and we therefore venture to assume that a description of the last edition may fairly be given in terms of comparison with earlier editions.

Perhaps the most noteworthy feature of the fifth edition<sup>1</sup> is that, despite the introduction of much new matter, the volume is slightly smaller. This result has been reached by substitution rather than by addition, and by a systematic and critical revision of the whole text. The appearance of new collaborators—Dr. E. B. Jamieson replacing Professor Arthur Thomson, Professors T. B. Johnston and S. E. Whitnall the late Professor Paterson, and Professor J. T. Wilson Sir Auckland Geddes—has naturally been associated with considerable changes in the sections for which they are severally responsible.

Dr. Jamieson, in the osteological section, has paid special attention to epiphyseal lines, and has supplied illustrations showing many of the long bones as seen from the side as well as from the front and back—an innovation of distinct value, and one which we should like to see adopted in other sections, particularly in those concerned with muscles and joints. The progress made in myology has scarcely permitted of any notable change, but certain new illustrations of the pelvic floor help to elucidate the anatomy of this somewhat complicated region. In the sections on the vascular and digestive systems respectively admirable and original illustrations are provided of the middle cranial fossa and orbit, and of the mouth after removal of the tongue—this last should be of particular interest and assistance to the surgeon. In the section dealing with the peripheral nerves the tables in which the segmental origin of the nerves supplying the various muscles was given have been removed, mainly no doubt because of their doubtful accuracy and value; in this section certain schematic drawings are still retained, and one representing the distribution of the ophthalmic division of the fifth cranial nerve has been added; so excellent and clear, however, are the illustrations throughout the book that these departures from realism are, we think, neither necessary nor desirable. We remark with satisfaction that in the embryological section certain diagrammatic schemata to be found in earlier editions have been replaced by drawings of actual mammalian oöcytes.

It was in the section concerned with the ductless glands that we expected to find the greatest change, in view of the extension of knowledge regarding these structures; nor have we been disappointed. From a section of fourteen pages it has extended to one of twenty-five pages, and the three groups into which the glands were classified in the fourth edition have been expanded into five by the formation of distinct pharyngeal and cerebro-glandular groups. Like all composite works, the book suffers from occasional inconsistencies—on page 183, for example, we are told that the stapes is developed from the hyoid arch, while on page 835 it is described as arising from the mesoderm in the region of the fenestra vestibuli; on page 711, again, we are told that the cerebral portion of the spinal accessory nerve takes its origin from the dorsal motor nucleus of the vagus, while on page 594 we are informed that it arises from the nucleus ambiguus. Nor can these inconsistencies be excused on the plea that our knowledge regarding these subjects is still uncertain and imperfect, for we are—or perhaps we should now say we were—under the impression that a consensus of opinion had been reached upon both these matters. Further, we value osteology so highly as an easy, interesting, and accurate means of acquiring precise anatomical information that we regret to see it not used to the utmost; whatever abridgement of the subject of anatomy may be considered, in the interest of other subjects, advisable, the markings upon the various bones should be regarded as sacrosanct. We should have liked

<sup>1</sup>*Cunningham's Textbook of Anatomy*. Edited by Professor Arthur Robinson, M.D., F.R.C.S. Ed. Fifth edition. Oxford Medical Publications. London: Henry Frowde, and Hodder and Stoughton. 1922. (Roy. 8vo, pp. xxvii + 1577; 1109 figures, 2 plates. 42s. net.)

to have seen, for example, the coloured area of insertion of the extensor carpi radialis brevis bear a closer relation to the sunken area so sharply circumscribed by nature on the adjacent parts of the dorsal surfaces of the second and third metacarpal bones; we regret, too, that in a work running to some 1,450 pages only one and a half lines can be spared for that minuscule, the pisiform bone, and that no mention should be made of the constant deep and narrow groove on its inner surface into which a part of the posterior annular ligament creeps to its attachment.

True, these are small matters—mere spots on the sun—but the standard reached by *Cunningham's Textbook* is so high, its position among medical books so honourable, that we would fain see it above all criticism. It is in this spirit that we have made these later observations, but let us hasten to add that they in no way prevent us from offering our warmest congratulations to the editor and his collaborators on the successful completion of an arduous and highly commendable piece of work.

### EXERCISE.

A THIRD edition of Professor TAIT MACKENZIE'S book on *Exercise in Education and Medicine*<sup>2</sup> has just been published. The first edition appeared in 1909, and was followed in 1915 by a considerably enlarged edition. Since then the author has had the experience of the war at his disposal. He accepted a contract commission in the R.A.M.C. in 1915, and after a short time on duty in one of the hospitals was appointed to advise on physical training at Aldershot. In 1916 he was transferred to the Heaton Park Command Dépôt, where he remained as medical officer in charge until his contract expired. It is in connexion with the experience thus gained that fresh matter has been added to the new edition of his book.

The chief addition is in the chapter on mechanical means for massage and exercise, where nineteen pages have been introduced descriptive of the apparatus standardized during the war to replace the costly and cumbersome Zander machines. These new appliances were used in the military, naval, and re-education institutions of France, Canada, India, and Japan as well as in England, and in America more especially in the Brooklyn Naval Hospital and the Reconstruction Hospital of New York. They had the fourfold object of isolating the muscle groups most frequently in need of development, of giving resistance by a graduated load, of measuring the range of movement and work done, and of arousing and holding the patient's interest. The additional pages also include a short note on the re-education after amputation of the leg, and on corrective gymnastics for re-education of lost or impaired function. The illustrations of the new appliances are chiefly taken from *Keen's Surgery*. Space has been gained by the omission of Dr. E. H. Pool's personal experience of the value of various exercises after appendectomy, which appeared with numerous illustrations in the second edition. This omission, however, does not detract from the emphasis given by the author to massage and movements as a necessary adjunct to post-operative convalescent treatment of parts put temporarily into disuse by grave surgical necessity.

In the chapter on exercise in the treatment of diseases of the circulation the work of Sir James Mackenzie and of the Mount Vernon special heart hospital under Lewis and others during the war is fully appreciated. Reference is also made to the systematic treatment of abnormal heart conditions in the Relief Foundation Hospital, White Plains, U.S.A., as recorded by Dr. F. Brush. In the chapter on the treatment of respiratory diseases Marcus Paterson's observations at the Frimley Sanatorium on the gradual immunization and subsequent recovery in cases of tuberculosis by a series of auto-inoculations produced by progressive exercises find a place. This combination of exercise and rest is also illustrated by the observations of Dr. J. Roddick Byers in the treatment of tuberculous soldiers in military sanatoriums in America. These are the chief additions in the way of new matter in the third edition. Several illustrations have been omitted without

detracting from the value of the book, and as a consequence its size has not been increased, nor has the general character of the book been altered. The first 305 pages, forming Part I, are devoted to exercise in education, and the remaining pages, forming Part II, to exercise in medicine. Part I is mainly descriptive of physical education in schools, colleges, and other institutions in the United States, with accounts of the German, Swedish, and French systems of exercises. With the exception of the additions and modifications referred to above, Part II has retained its original form and matter.

The volume appeals in a special degree to education authorities and their medical officers, but the subjects with which it deals are of importance to the general practitioner and consultant as well, and also to the officers of the combatant services. It illustrates in an authoritative manner the position now held in the scholastic and medical world by what the author designates the Cinderella of the therapeutic family. The work of Professor Tait Mackenzie in America and of Sir Robert Jones in this country has been of infinite value in placing physical training on a scientific basis in connexion with education and medicine, and may thus be said to have revolutionized the attitude of the medical profession towards its teachings.

### THE TREATMENT OF GONORRHOEA.

DR. A. REITH FRASER, lecturer in venereal diseases at Cape Town University, has added yet another book to the flood of literature that has appeared within recent years on the subject of gonorrhoea. It was once said, and with reason, that English medicine had seriously neglected venereal disease, and that anyone requiring information on the subject would perforce have to turn to foreign literature. This accusation can no longer be made, for the English works on the subject of venereal disease and its treatment turned out in the years following the war would form a library of no small dimensions.

Dr. Reith Fraser has, however, struck a new note, and his *Monograph on Gonorrhoea*<sup>3</sup> may in some ways act as a corrective or as an antidote to some of its predecessors. The pith of the gospel that he brings to us is that it is utterly impossible to sterilize the infected urethra by means of the antiseptics at present at our disposal, and that those who endeavour to eradicate the gonococcus by prolonged applications of powerful antiseptic solutions or by intraurethral manoeuvres necessitating the constant passage of instruments are possibly doing far more harm than good. In the words of his preface:

"The added responsibility of incision and scarification of an infected surface, the traumatizing nose of urethral instruments on a fragile mucosa and the extensive cicatrization which follows in the wake of curette and cautery have not been weighed in the balance against accepted principles of sound surgical procedure. Indeed it seems quite reasonable to postulate that in days gone by gonorrhoea was treated much more rationally and successfully than it is at the present time."

The author is equally strong in his condemnation of the abuse of the numerous "scopes" that have been invented for peering into the human vitals, and considers that "With reasonable reservations most of them one day will be relegated to the limbo of forgotten things, and the fact that they ever were perpetrated will be apparent only to those who dabble in museum curiosities, or probe a diligent finger into the pages of history."

The book that follows these introductory flourishes is extremely complete; it starts with the history of gonorrhoea, its literature, the anatomy of the male urethra, and the pathology and bacteriology of gonorrhoeal urethritis. In the later chapters describing methods of treatment the author has endeavoured to keep out stereotyped and reiterated teaching which conflicts with his clinical experience, and advocates only those remedies which he personally has found to be successful. At the end of each chapter is a very complete bibliography, including a very large range of foreign literature. A very useful chapter is that devoted to standards of cure in the male. The aim is to set up a satisfactory and practical standard universally applicable, and within its scope is included both the

<sup>2</sup> *Exercise in Education and Medicine*. By R. Tait Mackenzie, M.D., LL.D. Third edition. Philadelphia and London: W. B. Saunders Co. 1923. (Med. 8vo, pp. 601; 445 figures, 1 plate. 24s. net.)

<sup>3</sup> *A Monograph on Gonorrhoea*. By A. Reith Fraser, M.D. (Aberd.). London: Henry Kimpton. 1923. (Roy. 8vo, pp. xvi + 508; 55 illustrations and plates. 18s. net.)

single and the married man. Dr. Fraser has rightly included gonorrhoea in the female within the scope of his work.

In summarizing the very difficult question of treatment he states that the underlying principle of all treatment is to secure free drainage. For this reason he deprecates the use of styptics and powerful astringent drugs, and employs only those agents which promote a profuse serous exudate and an energetic secretion by the mucus glands. He has apparently found "Milton" (a strongly hypertonic saline solution containing a high proportion of free hypochlorous acid) as useful an application as anything. During the whole course of treatment vaccine therapy is employed in the hope that it may protect the upper genital tract from infection and reduce any likelihood of metastases.

Following the description of his own treatment he gives summaries of methods that have been advocated during the last ten years by various writers on gonorrhoea in women. These summaries are so complete that they leave no doubt that Dr. Fraser has followed very closely the trend of modern opinion.

In spite of the somewhat overburdened state of the market for venereal manuals a welcome must be given to the work under review, since it succeeds in avoiding the beaten track and furnishes a not unneeded corrective to the vast amount of instrumental and mechanical treatment carried out by many workers in this branch of medicine. We recommend it especially to those who have allowed their enthusiasm for "scopes" and other instruments to get the better of their judgement.

#### STERILITY IN WOMAN.

DR. R. A. GIBBONS has collected in a useful small volume the fruits of his ripe experience of the subject of *Sterility in Woman*.<sup>4</sup> Dr. Gibbons has for long given attention to this important subject, and has had exceptional opportunities of studying it in the course of many years in practice. His book shows that in his studies and in his practice he has considered the subject from every point of view, and his statements may therefore be regarded as having a considerable weight of authority behind them.

In his first chapters Dr. Gibbons considers the important aspect of sterility in its relation to the State—the question of the falling birth rate, of illegitimate children, of infantile mortality, of abortion-mongering, of the marriage of near kin, of the compulsory notification of venereal disease, of the use of contraceptives, and so forth. In the following chapters he discusses the physiology of conception, and then deals seriatim with the structural causes of sterility and with the functional and constitutional causes. He also discusses sufficiently for most purposes the causes of sterility in the male. The last two chapters are devoted to treatment, medical and operative.

The volume provides an admirable account of the whole subject. It is sufficiently full for the needs of the family practitioner, and is written in a refreshingly clear and lucid style. It is well illustrated by figures, which are borrowed for the most part from well known textbooks in gynaecology, and these figures are carefully chosen to illustrate helpfully the important points in the text. Lastly, Dr. Gibbons has provided a useful bibliography, which will serve as an introduction to a fuller consideration of the subject for those who require it. We are confident that family physicians and others who are consulted on this important subject will find much to help them in this book, and will appreciate it all the more perhaps in that it is not written too exclusively from the point of view of the gynaecologist.

#### ANNALS OF MEDICAL HISTORY.

From an editorial survey of its position in the concluding number of the fourth volume of the *Annals of Medical History*<sup>5</sup> it is to be feared that this admirably produced quarterly is not receiving the support that it so undoubtedly

deserves. It supplies a very definite want and, as the editor remarks, its discontinuance would make any effort to start a successor a matter of grave anxiety and hesitation. Its cover bears an admirable reproduction of Sir William Beechey's portrait of William Heberden the elder in his 86th year, and in the account of his life Mr. P. B. Davidson compares him with the late Sir William Osler both in personal charm and in showing more interest in diagnosis than in treatment. The frontispiece, a photograph of S. Weir Mitchell, illustrates Dr. C. L. Dana's attractively written Weir Mitchell oration on "Medicine and the Humanities" in which, apropos of that wide-minded neurologist, he says that in medical practice quite two-thirds of efficiency and success depend on conduct and character, and hardly one-third on technique, though he did laboratory work and was the father of the best modern phases of psychotherapy. Dr. Ernest Wickersheimer, of the University Library, Strasbourg, contributes a scholarly note on the *Liber de Medicinis expertis* falsely attributed to Galen, which is remarkable for the long list of medical names, generally bizarre, and therefore exciting much interest among bibliographers.

This issue contains an appreciative sketch of Dr. Wickersheimer, who was librarian of the Sorbonne and general secretary of the Société Française d'Histoire de la Médecine. Dr. F. R. Packard concludes his account of Guy Patin and the medical profession in Paris in the seventeenth century, and it is to be hoped that this attractive life will appear in book form. Dr. M. Charlton writes a short sketch of Christopher Widmer (1780-1857), who went to Canada as an army surgeon in 1812 and settled at York, now called by its original Indian name of Toronto, and played a prominent part in the early medical history of Canada. Dr. Charles Greene Cumston, lecturer on the history of medicine in the University of Geneva, gives an account of the Latin poem on the diseases of nurslings—paedotrophia—written by Scevole de Sainte-Marthe in 1584. This number contains a note on a unique book recently presented to the library of the College of Physicians of Philadelphia, the *Congressiones* (1514) of Francisco Lopez de Villalobos, who gave elsewhere one of the earliest descriptions of syphilis.

#### NOTES ON BOOKS.

DR. D'HERELLE'S book on the bacteriophage<sup>6</sup> was issued last year as one of the monographs of the Pasteur Institute and reviewed in this journal (March 4th, 1922, p. 354). An authorized translation into English now published contains an additional chapter on the nature of the bacteriophage, in which the hypotheses which have been advanced in explanation of the phenomenon of bacteriolysis are discussed and refuted one by one; d'Herelle recalls the old theory of Stahl to the effect that "any body brought to a state of putrefaction transmits very easily this state to another body still free of corruption," and likens his opponents to disciples of Liebig unwilling to accept the researches of Pasteur; the author's views are clearly and simply explained in this volume, which will be welcomed both by medical bacteriologists and biologists.

The lapse of three years has brought a demand for a third edition of Dr. J. A. CROWTHER'S *Molecular Physics*.<sup>7</sup> Like other books written on this attractive subject, it deals with the discoveries on the constitution of the chemical atom made by the physicists who enlarged the work which had come to a standstill in the hands of chemists. While other books have been written on the theory reciting the conclusions established and indicating the methods by which they were reached, Crowther's work is distinguished for the manner in which it takes the reader through the earlier stages of the genesis of the modern theory, the practical difficulties encountered, how these were surmounted, and how sometimes erroneous inferences prevented advance. For the reader who is not a specialist in this branch of physics such a narrative plan is the best, especially when the story is told in the facile manner which is the author's peculiar gift. Full mathematical treatment would not be in

<sup>4</sup> *Sterility in Woman: Its Causes and Treatment*. By Robert A. Gibbons, M.D., M.R.C.P., C.M., F.R.C.S.E. London: J. and A. Churchill, 1923. (Demy, 8vo, pp. x + 244; 44 figures. 12s. 6d. net.)

<sup>5</sup> *Annals of Medical History*. (Quarterly.) Vol. iv, No. 4. Edited by F. R. Packard, M.D. New York: P. B. Hoeber; London: Baillière, Tindall and Co. 1922. (Pp. 323-405; illustrated. Subscription in Great Britain, 42 2s. a volume of four issues.)

<sup>6</sup> *The Bacteriophage; its Role in Immunity*. By F. d'Herelle, Pasteur Institute, Paris. Translated by George H. Smith, Ph.D., and Wilkins Company. 1922. (Med. 8vo, 84.25; other countries, 84.50.)

<sup>7</sup> *Molecular Physics*. By J. A. Crowther, M.A., Sc.D., F.Inst.C. Third edition. Textbook of Chemical Research and Engineering. London: J. and A. Churchill, 1922. (Cr. 8vo. pp. viii + 189; 22 figures. 7s. 6d. net.)

place in a book of this class, but since no description of the phenomena would be clearly intelligible without reference to mathematical relationships, the derivations of these is explained, and for the reader little skilled in higher mathematics the nature of methods by which the relationships are deduced is indicated. The chapter on Planck's quantum theory gives a lucid account of its derivation, and shows how in its application to atomic structure a great field of inquiry remains still unexplored.

Dr. F. A. MAGUIRE has brought together in a small volume entitled *The Anatomy of the Female Pelvis* his notes on pelvic anatomy for students of gynaecology.<sup>8</sup> In so far as this represents an endeavour to relieve textbooks of gynaecology of some of the matter with which they are commonly laden it is to be commended. The teaching is sound and lucid. It suffers, however, from the lack of free illustration which is characteristic of textbooks of gynaecology; and we very much doubt whether publishers would be justified in elaborately, or even adequately, illustrating a little book such as this, the demand for which is likely to be limited so long as the larger textbooks include pelvic anatomy in their purview.

Dr. WALTER GUTTMANN'S *Medizinische Terminologie*<sup>9</sup> has been enlarged and thoroughly revised. Seventy-three new figures have been added and thirty-three others replaced. Though this dictionary will be of use mainly to those who have some knowledge of German, it will be of some service to those who merely seek information as to the country and date of the author in the cases of eponymous diseases, symptoms, operations, instruments, and the like.

<sup>8</sup> *The Anatomy of the Female Pelvis: Descriptive and Applied.* By F. A. Maguire, D.S.O., M.B., Ch.M.Syd., F.R.C.S.Eng. Sydney: Angus and Robertson, Ltd.; London: The Australian Book Co. 1922. (Cr. 8vo, pp. 115; 4 figures. 6s.)

<sup>9</sup> *Medizinische Terminologie.* By Walter Guttman. Sixteenth to twentieth edition. Berlin and Vienna: Urban and Schwarzenberg. 1923. (Roy. 8vo, pp. vi + 1323; illustrated.)

## THE X-RAY DIAGNOSIS OF THE PATHOLOGICAL GALL-BLADDER.

### THE MACKENZIE DAVIDSON MEMORIAL LECTURE.

PROFESSOR A. W. GEORGE of the Massachusetts General Hospital delivered the Mackenzie Davidson Memorial Lecture on May 17th before a large audience composed of members of the Röntgen Society and the Section of Electro-therapeutics of the Royal Society of Medicine. Sir HUMPHRY ROLLESTON was in the chair.

Professor George commenced his lecture with a graceful allusion to Dr. Robert Knox and to other distinguished British radiologists.

There was a large number of cases, the lecturer said, in which indefinite shadows were present on the x-ray plate, only suggestive, so far as shape, size, and position went, of gall stones. By experience they had learnt that very often in such conditions the gall bladder did not contain stones. The shadows were due either to thickening of the gall bladder wall, inspissated bile, or very thick and dark bile. Such skiagrams were indicative of a pathological gall bladder, with or without stones. As time went on radiologists had begun to analyse and classify observations which they had regarded as secondary evidence of a diseased gall bladder. This indirect evidence was of the highest importance.

The normal and healthy gall bladder could not, in the great majority of cases, be rendered visible by x rays. Neither did it cause pressure upon the gastro-intestinal tract made opaque by a barium meal. When such pressure deformity was present it was almost always due to a pathological gall bladder. In the deformity due to a gall bladder there was a definite shadow which Professor George had termed a half-shadow; it was due to a concave or rounded surface pressing against a similar surface, the first part of the duodenum. Hence they found varying degrees of shadow quality in the photographic film. If the edge of the liver, a flat surface, pressed against the duodenum, the half-shadow was lacking. This difference was of great importance in diagnosis.

Why was the diseased gall bladder able to cause this pressure? Perhaps because at some time during the examination or examinations there was a tension within the gall bladder greater than within the barium-filled duodenum. The lateral view gave the position of choice.

Another important structure involved was the second

part of the duodenum. Very constantly in the normal individual this part of the duodenum extended downwards parallel to the vertebrae, till it became the third portion passing up behind the stomach. Frequently in gall-bladder disease the second part of the intestine was directed outward toward the liver, and in quite a number of cases the size of the gall bladder might be outlined by the position of the second part of the duodenum. Again, in pancreatic disease this part of the intestine was of great diagnostic importance. When the duodenum was in this position it was found to be due, save in very rare cases, to gall-bladder adhesions. This was a very definite and important observation.

Burnham of San Francisco pointed out in 1922 that in the lateral position a duodenum passing backward toward the vertebrae and forming an angle passing downward again to its normal position was significant of gall-bladder disease. Post-operative cases came in a category of themselves, and were most difficult to diagnose.

The next observation of importance was the pressure of the gall bladder upon the antrum of the stomach. This occurred as frequently as pressure deformity on the first portion of the duodenum and in a large number of cases the pressure would be found to involve both viscera at once. In this portion also the half-shadow effect must be noted.

Another point of interest was the transposition of the jejunum from its normal position on the left side to the upper right quadrant; this had frequently helped the lecturer in diagnosis. There was, however, one other possibility: peritonitis, especially of a tuberculous nature, earlier in life might be responsible for the condition. It was remarkably easy for the gall bladder to throw out adhesions and pick up adjacent structures.

A fourth observation of relatively common occurrence, but possibly not of such value as those preceding it, was the filling of the ampulla of Vater. In every case in which, through a series of gastro-intestinal plates or films, the ampulla had been demonstrated full of barium, there was disease either of gall bladder or pancreas; and changes in the pancreas often occurred secondary to lesions of the gall bladder.

There was frequently a change in the position of the proximal end of the transverse colon; something akin to a secondary hepatic flexure was formed, and to this the term "pseudo-hepatic flexure" had been given. Very often in the absence of all other signs this change in the transverse colon would be the only diagnostic sign pointing towards disease of the gall bladder.

Another diagnostic point which had been suggested by Carman, Burnham, and others was the so-called spasm occurring in the antrum of the stomach. The lecturer did not feel that this was entirely reliable. Perhaps it should be observed with the fluoroscope rather than with plates.

Many had asked what was the negative value of the x ray. He felt that since they had so much evidence pointing to a positive diagnosis the absence of all these observations should have some value. With a proper examination a diseased gall bladder could be in almost every instance demonstrated on the plate or film. Even cholesterol stones, if present in large numbers, could be shown. It might not be possible to recognize individual stones, but with increased density and some change in the shape of the gall bladder the radiologist could be reasonably certain he was dealing with a chronic gall bladder, with or without stones. Kirkland of Muncie, Indiana, had recently had an opportunity in the Mayo clinic of doing radiological work on cases diagnosed clinically as suffering from cholecystitis or cholelithiasis. Although the lecturer had not the exact figures, it was reported that a correct diagnosis was made by x rays in 92 per cent. of the cases operated upon, well over a hundred in number. He believed that from the moment infection took place there began changes in the gall-bladder wall and in the bile which would have their counterpart eventually on the x-ray plate.

The lecturer concluded with an earnest appeal for young men to approach the subject with enthusiasm and a real desire for technical excellence.

Dr. Knox proposed, and Sir ARCHIBALD REID seconded, a vote of thanks for a very remarkable lecture.

SATURDAY, MAY 26TH, 1923.

### NATIONAL HEALTH INSURANCE FINANCE.

It seems that National Health Insurance cannot touch anything that it does not complicate. The multitude of approved societies and their various types, regulations of all kinds, certification rules and forms, have perforce become familiar to a considerable number of officials, doctors, and insured persons; but it is doubtful whether more than five or six persons all told have explored the ramifications of National Health Insurance finance. Many more than this have essayed to do so, but they have retired dismayed from the task, or have sometimes been led to draw erroneous conclusions from the incomplete character of the materials available for their difficult researches. The Insurance Acts Committee has performed a service to others besides the medical profession by securing from an expert adviser the memorandum on the National Health Insurance Fund which is published in the SUPPLEMENT to this week's issue of the JOURNAL.

This report on the financial position of the fund discloses a number of remarkable facts and results. The first point to emphasize is that, although separate accounts and subordinate funds abound, there is the one fund, of which all these are parts and on which the soundness of the whole insurance scheme depends. It is upon the stability of the National Health Insurance Fund as a whole, and not upon the particular conditions of any of its subordinate divisions at any given moment or in any one year, that hangs the guarantee of the various benefits and payments as they mature. A second point which the investigation has brought out is the vastness of the transactions of the fund. The issues out of the fund since the Act came into force have probably approached 350 millions sterling. A third, and perhaps practically the most important, point is the demonstration of the amplitude of the reserves. It is by no means an easy matter to track these reserves or to make their addition, but it seems evident that the balances in the fund to-day are well over 100 millions.

It is of course essential to any sound insurance scheme that the reserves should be abundant. They have not only to meet all the ordinary liabilities as they become due but ought to be sufficient for extraordinary claims or entirely unforeseen circumstances. It is, too, the business of an actuary to make safe. He is wise if, within the margins of error with which he has to deal, he calculates conservatively. The Government actuary, the approved societies, insured persons, and, we think, insurance practitioners also, are to be congratulated on the present position of the fund. There seems to have been almost a conspiracy to ensure its affluence. In 1911 it would have been quite improper to base calculations on the hope that large numbers of persons would pay their premiums, in the form of stamps, and would then throw their policies, in the form of stamped cards, into the fire; but they did it.

No doubt most of them are wiser now, but stamps still disappear. No actuary could have allowed for the war; but it came, and with it the large number of deaths of which there had been no expectation, thus reducing the liabilities, while the credits given and funds accumulated to meet them remain. The rise in the earning power of money could not have been foreseen; but it occurred, and profits calculated at three per cent. worked out at five or more. No actuary could have relied upon extra Treasury grants to make good particular deficiencies or mitigate the effects of unforeseen circumstances; but they were voted to the extent of millions. Finally, at the beginning the actuarial calculations had to be based upon a sickness incidence gauged from such data as previous experience afforded; whereas in fact the sickness rate has proved to be far less than that legitimately anticipated from these data. This reduction seems to be not fortuitous but abiding, and there can be little doubt that it is largely due to the effects of the scheme itself, and to the accumulated results of the efforts of the medical profession in all its branches—preventive and curative alike. Millions have thereby been saved to the Insurance Fund.

There have naturally been some offsets to these advantages. It is true, paradox as it may seem, that the prolongation of the average life which has occurred does not benefit a health insurance scheme; and war's aftermath of prolonged unemployment has a deleterious effect on both credit and debit sides of the account. All approved societies are not in an equally flourishing condition, but there is no doubt at all that societies as a whole have done very much better than they had any reasonable expectation of doing, and that insurance funds as a whole are in a very healthy state.

The prime purpose for which the memorandum was obtained was that the Insurance Acts Committee and the profession might have reliable information as to the state of the National Health Insurance Fund in connexion with the consideration of the capitation rate of payment for practitioners. The amount of that payment cannot properly be held to be dependent upon the state of the fund; it must be determined on its merits and with regard to other considerations. But if the insurance scheme is to be in itself sound and solvent this charge, whatever it is, should be met from the insurance fund. It is not right or just that practitioners should be placed in regard to any portion of their remuneration in the position of residuary beneficiaries after all other charges have been met. If any priority were proper, the full charge for medical benefit, as the essential foundation of the scheme, should be placed before any other; and, the scheme being regarded as nationally advantageous, any necessary State contribution should be in sufficient proportion to meet all charges for guaranteed benefits. The memorandum shows that the present proportion of two-ninths is sufficient for this, and leaves a secure margin. There need be no talk about using the societies' money for medical benefit. The debiting of seven-ninths to the societies' account has always been in the nature of mere book-keeping; and we are all agreed that the other benefits to which insured persons are entitled and which approved societies dispense should not be endangered; but we claim that all legitimate charges must be met out of a properly constituted fund.

Some recent answers given in the House of Commons by the Minister of Health have a sinister appearance of attempting to belittle the reserves

available. Investigations such as those on which the memorandum by the Insurance Acts Committee's expert adviser is based do not justify any such attempt: the position must be fairly faced. It is certain that no medical service is worthy of State support unless it is a good one. It is certain that a good service must be and ought to be adequately remunerated. Fortunately it appears to be true also that the National Health Insurance Fund is in a position to afford such payment.

### THE COUNTRY PRACTITIONER.

Any attempt to compare the attractions of medical practice in town and country must have regard to the personal equation. If looked at from the financial point of view the prospects in a town must be, on the average, reckoned the better; but there is the other side. It is from every point of view fortunate that the average Englishman and Scotsman retains the love of open-air sport, which for the townsman finds its readiest outlet to-day in golf, or, when money is a little more plentiful, in a shooting syndicate, or both. The superior institutional facilities of the town—the hospitals, laboratories, and dispensaries—the opportunities for scientific intercourse and post-graduate study, and the means for education of a family, will determine the issue for the majority. A minority of young medical men, however, will look at the matter differently. Such men, while not failing to realize that the professional man, whether in law, church, or medicine, commonly makes a smaller income in the country than in the town, will yet find the more natural life, the rural road instead of the city street, the clean air instead of the urban smoke, the country pursuits in hours of leisure, the garden, the river, and the moor, make a strong appeal. Such an one will think that he may enjoy from the first some of those things the townsman promises himself as a reward of many years of toil in uncongenial surroundings. Moreover, in his medical work the country doctor may feel sure that there are opportunities for initiative which are forbidden to the general practitioner who passes his life within easy reach of operating rooms and consultants and specialists. It is to the interest of a patient in rural cottage or hamlet that his doctor should undertake emergency responsibilities and risks which the town doctor may properly pass on to others. And so, fortunately for the general welfare, a fair sprinkling of men who have done well at their university or hospital, and who might count on a successful urban career, yet determine to settle in the country, where, in addition to practice, they may take a large part in local affairs, and win the regard and esteem of a whole countryside.

So much for sentiment and inborn predilection. But to fill his place in the scheme of things the country doctor must have an income on which he can live and bring up his children. Dr. Williams-Freeman in his article on "The Plight of the Country Practitioner" (SUPPLEMENT, April 21st) maintained that the fight for a reasonable existence for the doctor in a country district is becoming more and more difficult. Improved travelling facilities which make it easier for him, by motor car, to get through his work may lead to the invasion of his territory by town practitioners. In this respect he suffers with others who minister to the needs of the country folk. The village shop, for example, is ruined by competition from the market town or the city, and such wealth as the land pro-

duces is not being spent in the place of its production. Moreover, the rural population continues to diminish. These are serious facts, and though it cannot be expected that the whole burden of medical loss due to far-reaching changes of a social and economic nature can be borne by the insurance funds, yet it is altogether right and proper, in the interests not merely of the doctor but of the rural community, that funds should be made available, so far as is reasonably possible, for amelioration of conditions which otherwise will tend gradually to deprive the country folk of the medical aid which is their due; failure to do this must in its turn hasten depopulation and so continue a vicious circle unchecked.

In view of such considerations it is satisfactory to note that at the special conference of representatives of Local Medical and Panel Committees to be held at the Central Hall, Westminster, on June 7th, one of the matters to be considered will be the recorded opinion of the Insurance Acts Committee "that no settlement with the Government would be satisfactory which did not allow of special provision being made for certain rural practices with small panels."

The problem bristles with difficulties; and Dr. Williams-Freeman is not so clear about the cure as about the disease. He suggests, but with some hesitation, increase of salaries under the Poor Law; that is not a very attractive proposition. Scotland is usually regarded as able to look after itself in matters of finance, and by means of the Highlands and Islands Medical Service Act it has achieved a large measure of success in dealing with the most sparsely populated and inaccessible areas in Great Britain. Outside the counties statutorily embraced in that Act there are similar difficulties in remote areas of Aberdeen, Banff, Dumfries, Bute, and elsewhere; the attention of Parliament was called to the position by representatives of these areas, with the result that the House of Commons made a small grant. The motive was to aid the public, not to subsidize the profession, but it is mainly through the profession that aid can be given, and so the doctor benefits indirectly. His lot is made easier by helping him, for example, to maintain a motor car, especially if he undertakes to utilize it for removal to hospital of urgent cases, where no ambulance service is available; or by providing him with a house of call and consulting room with essential equipment in a distant village where he will undertake to attend on certain fixed days, and where perhaps a district nurse can also have her headquarters. Where an arrangement of this sort is in force, and becomes understood by the inhabitants, it helps to save needless visits on successive days in response to messages from different individuals. We have heard of one village which is within range of two doctors resident widely apart, and where a common consulting room is used on one fixed day a week by one man and on another by the other. The control of such schemes is in the hands not of the Local Insurance Committee, but of the Scottish Board of Health, through its medical officers.

Circumstances in Scotland are no doubt somewhat different from those in most parts of England, and the cases mentioned are not just those contemplated by Dr. Williams-Freeman, but the principle is of general application—that a fund should be placed at the disposal of the central authority to alleviate conditions of exceptional local hardship in respect of medical attendance. The lowland Scottish method seems well worth investigation, and no doubt the conference will be glad to consider all feasible proposals which may be brought before it.

## NUTRITION IN ETIOLOGY.

EVIDENCE of the interest the profession is taking in questions relating to nutrition and its disorders is afforded by the fact that the last two British Medical Association Lectures that have come to us for publication deal with various aspects of the subject. Dr. Hugh Thursfield's lecture delivered before the Guildford Division, which appropriately came first (May 19th, p. 841), dealt with disorders of growth in a general way, while Dr. Pritchard's, delivered before the Oxford Division and published this week, was devoted to a consideration of the pathogenesis of rickets.

A great impetus to the investigation of the value of various articles of food was given by the shortage of food and the restrictions on its use which arose during the war, and much light has been thrown on the principles governing healthy nutrition, and on the various ways in which its processes may be disturbed, by recent researches into the action of vitamins and the causes of rickets. The investigations to which we refer have been made partly in laboratories in this country, in India, and in America, partly in hospitals and institutions, and partly, on a large scale, among the children of Vienna from 1919 to 1922 by the mission sent to that city by the Accessory Food Factors Committee appointed jointly by the Medical Research Council and the Lister Institute of Preventive Medicine.

The last annual report of the Lister Institute shows that much of the time of the workers there, and especially those in the department of experimental pathology, of which Professor C. J. Martin, the director of the Institute, is himself the head, has been given to investigations of this order. Not the least interesting of the observations have reference to the effect of light on nutrition, especially the disordered nutrition of rickets. The observations of Dr. Harriette Chick and her colleagues in Vienna were directed to ascertain the relative value of the administration of cod-liver oil, of exposure to the radiation of the mercury vapour lamp, and of outdoor treatment in the sun and shade respectively. Each of the three methods was equally effective in restoring normal calcification of bone and bringing about complete and rapid healing of the bone lesions. On the other hand, no child kept indoors without one or other of these special forms of treatment showed similar steady restoration of the bone to normal. The chief conclusions were: first, that diet and light are factors of primary importance in the etiology of rickets in infants, and that light, especially ultra-violet light, appears to enable the body to deal economically with certain specific food constituents, permitting normal bone development on a diet which, when exposure to light is less, leads to the development of rickets; secondly, that a diet containing an average allowance of milk, with carbohydrate additions, did not include sufficient antirachitic fat-soluble vitamins to prevent rickets in winter. In summer the increased sunlight rendered this diet adequate. And thirdly, that fat-soluble vitamins, as provided by cod-liver oil, play the same important part in human as in experimental rickets. One member of the mission to Vienna, Miss Margaret Hume, made the observation that ten minutes' daily exposure to ultra-violet light enabled rats to grow normally for some two months, even when deprived of fat-soluble vitamin. Subsequently she found that it was not necessary to irradiate the rats directly, but that if empty jars were irradiated and the rats introduced immediately afterwards the

same beneficial influence upon growth was secured. This observation the report rightly speaks of as "rather astounding," but after her return to this country it was twice repeated under careful control conditions. The experiments were so conducted as to ensure that it was indeed some influence temporarily impressed upon the air by the radiations which was responsible for the action. This was found to be the case. No interpretation of the observation is forthcoming at present, but, the report continues, "it is being sought after, for it may be surmised that herein may lie the secret of those subtle changes in climate to which mankind, and certain individuals in particular, are susceptible."

It is now well known that cod-liver oil of good quality may have what almost amounts to a specific action on rickets. Professor Drummond of University College and Dr. Zilva of the Lister Institute have been investigating a large number of samples of cod-liver oil collected in Norway, and have observed a variation in potency of about twenty-fold. It seems to be due to some biological factor still not ascertained. The ultimate origin of the vitamin found in active liver oils was traced to unicellular marine organisms which are consumed by copepods, larval decapods, and molluscs, which are consumed by caplin and squid, which in their turn are eaten by the larger fishes. During last summer Dr. Zilva visited Newfoundland, where facilities were offered by the Dominion authorities for the investigation of the methods of preparation of cod-liver oil there in use. Material was systematically collected from a number of fishing stations in the island, and laboratory investigations showed that Newfoundland oils are of very high and uniform potency, and that the method of preparation prescribed and enforced by the Newfoundland Ministry of Marine and Fisheries has no deleterious effect on the vitamin. The refining processes in use are up to date, and are favourable to the preservation of the vitamin potency. Dr. G. F. Still and Dr. Zilva are engaged in a clinical study of the therapeutic value of certain oils of which the vitamin potency has been experimentally determined. The observations of Professor Korenchewsky seem to be bringing us near to an understanding of the part played by a deficiency of calcium in the production of rickets. His latest results, published recently in our columns (May 12th, p. 802), tend to show that excess of calcium in the diet is not by itself sufficient to prevent rickets. The disease is produced in young rats by a deficiency of antirachitic fat-soluble vitamin alone, even when the amount of calcium and phosphate in the diet is more than sufficient for health. Rickets ensues if the young rats are given the deficient diet from an early age and the mothers are not too well fed during pregnancy and lactation. If, however, the mothers are given cod-liver oil or abundance of animal fat whilst the foetus is forming and the young are being suckled, sufficient stores of the antirachitic vitamin are accumulated by the offspring to carry them over the period of susceptibility to rickets. The suggestion is made that in industrial districts where rickets is prevalent experiments for the prevention of rickets should be instituted by giving cod-liver oil and calcium phosphates to mothers during pregnancy and lactation. Although the interplay of the various factors influencing the satisfactory deposition of calcium phosphates in the growing skeleton is still obscure the knowledge won will be of great service. The problem has existed ever since men took to living in crowded cities, but as long as rickets was regarded by some as an infective disease of unknown origin and

by others as attributable to undefined defects in diet or hygiene, efforts towards prevention were either paralysed or imperfectly orientated. As a result of the concentration of experimental work upon the problem for the short space of three years the main factors in the etiology of the disease appear to have been ascertained. The facts derived from clinical and epidemiological observations and from animal experiments now fit together into a coherent theory, and already provide sufficient sanction for preventive and curative measures against one of the most widespread and most damaging diseases to which an industrial population is subject.

#### THE OCTOCENTENARY CELEBRATIONS AT ST. BARTHOLOMEW'S HOSPITAL.

A PROVISIONAL programme of the series of events by which it has been decided to mark the eight hundredth year of the foundation of St. Bartholomew's Hospital is now published. For variety and interest it well deserves the attention and the personal attendance of every member of this great and famous school. On Tuesday, June 5th, there will be a service at the Priory Church of St. Bartholomew the Great at 10.30 a.m., when the Bishop of Chester will preach. Both the church and the preacher are intimately connected with the hospital—the church as the contemporary foundation, the preacher as the third son of Sir James Paget, one of the most famous teachers in the medical school. At midday there will be a solemnity in the hospital quadrangle which will last from half to three-quarters of an hour, and afterwards the official delegates will lunch with the Lord Mayor at the Mansion House. H.R.H. the Prince of Wales will receive the addresses presented by the delegates in the Guildhall at 3 p.m., and it may be remembered that he, too, has an hereditary connexion with the hospital, for his father, his grandfather, and his great-grandfather have honoured the hospital by acting as president, and have in similar manner shown a personal interest in its welfare. On Wednesday, June 6th, the Lord Mayor will open Bartholomew Fair according to ancient custom, causing the proclamation to be read announcing various pains and penalties to be incurred by evil-doers. The fair will be open from 2 to 7 upon payment of 5s. a person, but as the space is limited tickets must be bought beforehand, as no money will be taken at the gate. In addition to the various booths, where the old "shows" will be resuscitated, the Students' Union will maintain a series of stalls where "fairings" can be purchased at a price to suit all pockets to take home to the women and children as was the usual custom when travelling was bad and fairs were occasional. On Thursday also the price of admission to the fair will be 5s., but on Friday 2s. 6d. The fair will be open each day from 2 to 7 p.m. The old students' dinner will be held at 7 p.m. on Thursday in the Merchant Taylors' Hall, Threadneedle Street. The price has been fixed at 27s. 6d.; the secretaries have already given notice that early application for tickets is desirable, because the attendance is likely to be great, and, although the hall is one of the largest and finest in the city, the seating accommodation will be strained. There will be a series of tableaux in the Great Hall of the Hospital on Wednesday and Thursday afternoons, tickets for which will cost 10s. 6d. These tableaux, which have been arranged by Sir Aston Webb, P.R.A., are scenes to illustrate various events in the history of the hospital from its foundation to the present time. Each has been designed by a Royal Academician, the executants being students of the Academy school and of the hospital. The music has been especially composed by Sir Alexander Mackenzie, and will be performed by members of the Royal Academy of Music. At 8.30 p.m. on Thursday there will be a conversazione in the hospital and medical college,

during which Bartholomew Fair will be open to guests. Various interesting exhibits will be on view during the evening, details of which will be found in a souvenir programme to be bought at the bookstall in the fair. On Friday evening there will be a special meeting of the Rahere Lodge of Freemasons at the Freemasons' Hall in Great Queen Street, when those delegates who are Masons will be welcomed in the presence of H.R.H. the Duke of Connaught and the chief officers of the craft. On Saturday, June 9th, a cricket match, "Past v. Present," will be played at Winchmore Hill on the hospital ground, and on the same day the League of St. Bartholomew's Nurses will be "At Home" in the Great Hall from 4 to 6 p.m. A short and well illustrated history of the hospital has been written by Sir D'Arcy Power and Mr. H. J. Waring for presentation to the official delegates. Some extra copies will be on sale at the price of 10s. 6d., but as the number is strictly limited and the plates cannot be reproduced, early application should be made, by those who wish to purchase, to Mr. Geoffrey L. Keynes, F.R.C.S. Eng., addressed to the hospital. A memorial medal has also been struck by Mr. John Pinches from the design of Mr. Charles L. Hartwell, A.R.A. It will be given to the delegates and to the members of the various committees engaged in the celebrations, but will not be sold. All tickets for the fair and the tableaux must be bought in advance either at the box office just inside the gates of the hospital or from the usual theatre agents.

#### THE INTERNATIONAL SOCIETY OF SURGERY.

THE International Society of Surgery has its headquarters in Brussels and meets once in three years. It has already met in Belgium, in the United States, and in Paris. This year it will hold its sixth meeting in London under the presidency of Sir William Macewen, C.B., F.R.S., Regius Professor of Surgery in the University of Glasgow, and President of the British Medical Association. The Society consists of practising surgeons of consulting rank, who are elected on the nomination of a national committee for each country, the number of members from each country being strictly limited. Members alone can take part in the proceedings. On the present occasion the Society will hold its meetings in the rooms of the Royal Society of Medicine, kindly lent for the purpose by the President and Council, from Tuesday, July 17th, to Friday, July 20th. The proceedings will be opened by H.R.H. the Prince of Wales at 11 a.m. on Tuesday. The subjects for discussion are the surgery of the endocrine glands; arthroplasty; the remote results of operations for wounds and injuries of nerves; serotherapy and shock. The official delegates, on the invitation of the First Commissioner of Works, will be entertained at a luncheon presided over by Mr. Neville Chamberlain, M.P. The members have been invited to the Mansion House by the Lord Mayor; to the Royal College of Physicians, and to conversaziones at the University of London and at the Royal College of Surgeons. Sir William Macewen, as President of the Society, will receive the members at the Royal Society of Medicine on the evening of Tuesday, July 17th.

#### THE FUTURE OF MEDICAL RADIOLOGY.

A DINNER was given last week by the new binary star formed by the Röntgen Society and the Electro-therapeutic Section of the Royal Society of Medicine, mainly to honour Professor George of Boston, who during the afternoon had delivered the Mackenzie Davidson Lecture, an abstract of which is published at page 902. A number of commendably brief and informal speeches were made; Dr. G. W. C. Kaye of the Physics Department of the National Physical Laboratory said that the coming together of the two bodies had seemed a few years ago an impossibility. Dr. G. B. Batten had, earlier in the evening, described how the

original Röntgen Society, founded some twenty-five years ago, underwent a process of fission, the majority of its medical members splitting off to form the British Electro-therapeutic Society, which became the Electro-therapeutic Section of the Royal Society of Medicine, and how from the conjugation with the Röntgen Society many beneficent things were hoped. We are all rather tired of being told that the arts of diagnosis and treatment become every year more complicated, and there are murmurs that the chemists and the instrument makers and users are building a wall of partition between the patient and his physician, but we will all admit that radiology as applied to medicine can only approach perfection through the combined work of the physicist who ascertains the laws, the inventor who designs according to these laws, and the engineer who makes and the medical expert who uses the highly tempered apparatus required to give the final result, which when interpreted by the medical radiologist and the physician in consultation gives relief or cure to suffering humanity. Dr. Kaye, who, as has been said, congratulated radiologists on the degree of combination already attained between the various sorts of specialists who must work together, spoke immediately after Sir Archibald Reid, who outlined a still more ambitious scheme which, after some eighteen months' discussion and effort, is now approaching realization. It is proposed to establish an Institute of Radiology, where all workers may fgather and where they will find a library and museum. It is to be established in London, as the most convenient centre in Great Britain, and it is hoped to have it in working order at the opening of the winter session in October next. Mr. Thurstan Holland proposed a toast to the guests, which was acknowledged by Dr. Heyman, one of the teachers of gynaecology in the University of Stockholm, who has given much attention to the value of radiations in the treatment of diseases of women, and by Professor George, who gave some account of sister societies in America—the North American Radiological Society, which has some thousand members, and the American Roentgen Society, of a more severely scientific complexion.

#### TORQUAY AS A HOLIDAY HEALTH RESORT.

At this season of the year people's minds naturally turn to thoughts of holidays, and the question at once arises, "Where shall we go?" It is a suitable moment, therefore, to point out some facts which are apt to be overlooked. To those who seek a healthful happy holiday no foreign resort can offer greater attractions than those which are to be found on our own shores. Among the many beautiful places to be visited, mention may be made of Torquay. It supplies almost everything that the heart of man, woman, or child can desire; bathing, boating, golf, and tennis can be indulged in under ideal conditions, and for those who enjoy walking or motoring there are innumerable expeditions amid glorious scenery. Starting from Torquay in any direction, as the journey proceeds, one magnificent view after another is disclosed and the fleeting changes from wide-spreading landscapes to free and open moorland and from leafy lane to rocky coast charm the traveller. Torquay itself, set as it is on a hill overlooking Tor Bay, is perhaps at its best in early spring and late autumn, but because of its equable climate it is delightful at all seasons of the year. Mild in winter, and blessed with a high average of sunshine, it offers many attractions to those in pursuit of health and change at that season. In summer excessive heat is rare, for on the peninsula of Torquay cool breezes blow either from the sea or from off the moorland; a temperature of over 80° F., even in the warmest summer, is uncommon. The Corporation of Torquay has within recent years spent a large sum of money upon the Spa Establishment, which is situated on Beacon Hill overlooking Tor Bay. Here all the most up-to-date British

and Continental methods of balneological and hydrological treatment are administered; they include the Vichy and Aix douches with hot sea water, the seaweed bath, and the Dartmoor peat packs. In addition to these specialized forms of treatment there are available the usual pine and vapour baths, Nauheim treatment, concentrated sea-water baths, and a large tepid salt-water swimming-bath. The Electrical Department is equipped with the modern apparatus for the administration of the various forms of medical electricity and diathermy. Torquay also boasts that it has a radium water of high radio-activity, tasteless and odourless; it has a diuretic effect, and is believed to be an excellent solvent of uric acid. The equipment in the Spa Establishment is on the most up-to-date scale, and the dressing rooms, corridors, and cooling lounge are well furnished. No holiday or health resort is complete unless there are facilities for golf, and Torquay is blessed with two courses, a nine-hole course at Walls Hill and an eighteen-hole course at Pettitor. The latter belongs to the Torquay and South Devon Club, and is undoubtedly the better course; from the point of view of picturesque surroundings it must be hard to beat. Deep-sea fishing is to be had at all times of the year, and in season trout and salmon can be caught by those skilled in the art at various parts of the Teign and Dart. The Corporation of Torquay entertained during the week commencing May 14th representatives of the press from various parts of the country, and trips were arranged to the places of interest which abound in and around Torquay. A new marine drive is in course of construction, and will afford magnificent views of coastal scenery; when completed it will certainly prove to be one of the main attractions both to the resident and the visitor. The Mayor, Corporation, and other officials are to be complimented upon their enterprise, and their venture in this respect is bound to reap its reward. An excellent train service is provided by the Great Western Railway Company, and the journey between Paddington and Torquay, already rapid and comfortable, is to be further speeded up during the summer.

#### THE NEW SCHOOL OF HYGIENE.

THE Minister of Health, with the concurrence of the Trustees of the Rockefeller Foundation, has appointed a Transitional Executive Committee in connexion with the proposed School of Hygiene. The functions of the committee will be to appoint a Director, to arrange for amalgamation or co-ordination between the School and other institutions working in similar or closely related spheres, to prepare plans for the new School, and to begin building, unless in the meantime it has been possible to set up the permanent Governing Body. The members of the committee are: The Right Hon. Neville Chamberlain, M.P. (Chairman), the Right Hon. the Viscount Burnham, C.H., Captain Sir Arthur Clarke, K.B.E. (a member of the Port of London Authority since 1910, and an Elder Brother of Trinity House), Sir Walter Fletcher, K.B.E., M.D., F.R.S., Lieut.-Colonel Fremantle, O.B.E., F.R.C.S., M.P., Sir Harry Goschen, K.B.E. (banker), Sir George Newman, K.C.B., M.D., Sir Cooper Perry, M.D. (Principal Officer of the University of London), and Sir Arthur Robinson, K.C.B., C.B.E. (First Secretary to the Ministry of Health), with Mr. L. G. Brock, C.B., of the Ministry of Health, as Secretary. It will be remembered that at the end of February last year the Rockefeller Foundation offered to provide a sum of two million dollars (£400,000) towards the cost of building and equipping a School of Hygiene in London, subject to the condition that the British Government would accept the responsibility of providing for the staffing and maintenance of the school when established. The Government, through the Minister of Health, undertook to provide £25,000 a year. A small committee was set up to advise the Minister on the preliminary steps to be taken in regard to the site and planning of the school; a site was

acquired in Bloomsbury and sketch plans prepared. It will be noted that the Transitional Committee now appointed is authorized to begin building, and also to arrange for amalgamation with other institutions providing facilities for education in hygiene and public health, using those terms in their widest sense. The establishment of a school or institute of state medicine was recommended by the Athlone Committee, which proposed that the new school should be associated with the University of London.

#### THE JENNER CENTENARY IN FRANCE.

BRITISH appreciation of the work of Pasteur has its counterpart in French appreciation of the work of Jenner, and no finer tribute to the English pioneer in preventive medicine was paid during the recent celebrations than by the great meeting of the Académie de Médecine on January 23rd, as noticed in the BRITISH MEDICAL JOURNAL of February 3rd. A charming souvenir of that great gathering has now been issued by the Académie in the form of a small volume containing a full account of the proceedings. It is illustrated by eight beautifully executed plates, of which the subjects are Hobday's portrait, a bust of Jenner presented to the Académie by the Saint-Yves-Ménard family, an engraving after Boilly's picture showing the vaccination of a child in the middle of its anxious family, a series of Jenner medals, two autograph letters, an engraving presented by Sir StClair Thomson of the picture of the twenty-one founders of the Medical Society of London, into which a portrait of Jenner was painted in 1802, and a photograph of the centenary exhibition at the Académie. The souvenir does not seem to have been placed on sale, but it will be treasured by everyone who is fortunate enough to receive a copy. Its issue is a gesture of international courtesy and friendship in medicine which will be warmly appreciated here.

#### TREATMENT OF GENERAL PARALYSIS BY MALARIA.

THE fact that a remission of a chronic disease may occur after an attack of an acute specific fever has led to a number of attempts, made chiefly in Vienna and extending over the last fifteen years, to apply the principle to the treatment of general paralysis of the insane. Various fever-producing substances and infections have been used, but the best results have been obtained with benign tertian malaria. The method is described by Dr. W. L. Templeton, a member of the staff of the City of London Mental Hospital, Dartford, in this issue. The general paralytic is inoculated with the blood of the malarious patient, and in due course develops malaria. He is allowed to have ten or twelve attacks of fever, and is then treated with quinine; he is apparently always cured of his malaria quickly and safely. In more than half the cases so treated the symptoms of general paralysis disappear to a greater or less degree, and in more than a third of the cases completely, some of these for so many years that the patient may almost be regarded as cured. Cases of malaria are uncommon in this country, but benign tertian does occur, and we understand that the staff of the hospital at Dartford will be grateful if any practitioner who has such a case to treat will inform them; and explain to the patient the object with which he is asked to give blood, which must be obtained before quinine treatment is begun.

#### REMOVAL OF THE SPECIAL CONDITIONS OF SALE OF INSULIN.

ON April 21st, 1923, (p. 695), we published a statement by the Medical Research Council, setting forth the steps that had been taken to make insulin available for use in this country. At that time the supplies of insulin were inadequate to meet the demand that might be expected, and it became necessary to secure that the limited quantities

available should be distributed to the best advantage. The question was submitted by the Council to the Minister of Health, who appointed a committee composed of Sir George Newman (chairman), Dr. R. A. Bolam, Sir Walter Fletcher, Sir Humphry Rolleston, Dr. Alfred Salter, M.P., and Dr. McCleary (secretary) to advise him on distribution. On the advice of the committee the manufacturers were directed during the period of restricted production to supply insulin for use in this country only, and to those hospitals and to those registered medical practitioners who undertook to observe certain defined restrictions upon the use of insulin. The following additional statement can now be made. During the past four weeks the productive capacity of the British firms has considerably increased, and it is no longer necessary to maintain the restrictions upon the supply of insulin, which, therefore, may now be obtained from the manufacturing firms through the ordinary commercial channels. The Medical Research Council, however, considers that it may be advisable again to remind the members of the medical profession who desire to use insulin, of the great importance of making accurate blood sugar determinations, of correlating the diet, the blood sugar changes, and the insulin dosage in each case, and of avoiding the danger of giving insulin in cases of renal glycosuria or other non-diabetic conditions.

#### EARLY EDITIONS OF SIR THOMAS BROWNE.

It is a pity that Professor Monro did not put together his notes on the early editions of Sir Thomas Browne a few years ago, for they should have appeared amongst those contributions to medical and biological research with which his friends sought to honour the seventieth birthday of Sir William Osler. The notes would have appealed to him in his double capacity as a true lover of Sir Thomas Browne and as an ardent bibliographer. But even though late in time they are more than welcome, for they supplement and add to the work of Charles Williams. Professor Monro tells in simple words the difficult story of the early years of the *Religio Medici*; points out some additional means of distinguishing between the two editions issued in 1645; and shows that all the copies of the 1656 and 1659 editions are not alike. After a consideration of the different editions published in English to the time of Simon Wilkin, he turns to the translations and Continental editions. He records details of the different translations into Latin, Dutch, French, and German, thus showing how well it was known and how much it was appreciated by the scholars of the seventeenth century, when there was a real commonwealth of letters. Professor Monro then considers the treatises on *Vulgar Errors*, *Urn Burial*, the *Garden of Cyrus*, and the *Lesser Tracts*, including *Christian Morals* and the *Letter to a Friend*. The whole essay is a piece of sound spade work for which every friend of Sir Thomas Browne will be grateful. It appeared in the *Records of the Glasgow Bibliographical Society*, and the copy before us bears the imprint of Maclehose, Jackson, and Co., publishers to the University.

#### A MANCHESTER GIFT TO THE MEDICAL BENEVOLENT FUND.

DR. W. F. DEARDEN, writing on behalf of the trustees of the Manchester Medical War Financial Assistance Fund, instituted by the late Manchester Medical War Committee, has sent to the Financial Secretary of the British Medical Association a cheque for £230 to be paid to the treasurer of the Royal Medical Benevolent Fund. The donation is made through the British Medical Association because the Manchester War Committee was really a British Medical Association committee. The trustees of the Manchester committee have also sent £229 to the Royal Medical Benevolent Fund Guild through the Manchester Branch

Guild. The trustees have disposed of the surplus funds of the trust in this manner with the full approval of the original guarantors and subscribers. The cheque for £230 will be paid over to the treasurer of the Royal Medical Benevolent Fund, 11, Chandos Street, Cavendish Square, W.1, together with other sums collected through the British Medical Association.

## Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

### Serious Illness of Mr. Bonar Law.

MR. BALDWIN SUCCEEDS TO THE PREMIERSHIP.

SERIOUS illness compelled Mr. Bonar Law on May 20th to tender his resignation of the Premiership, and on May 22nd Mr. Baldwin was asked by the King to form a Government and consented to do so. It is the custom when a new Prime Minister is appointed (though of the same party) that all his colleagues shall hand in their seals of office so that he may be free to reconstruct the Ministry.

The news of Mr. Law's retirement was received everywhere with profound regret in the circumstances. It is significant of goodwill in British politics that leaders of all groups united in expressions not only of sympathy but also of personal regard for Mr. Law, one of the warmest tributes coming from Mr. Ramsay MacDonald, leader of the Labour party, and therefore official leader of the Opposition in the Commons. Messages from abroad also manifested the appreciation of Mr. Law's sterling qualities of character by all nations with whom he had as British Prime Minister had relations.

Mr. Baldwin, before becoming Chancellor of the Exchequer last year, was President of the Board of Trade (1921-23), and was previously Secretary to the Treasury (1917-21). Still earlier he was Parliamentary Secretary (unpaid) to Mr. Bonar Law.

### National Health Insurance.

In reply to Mr. Jarrett and Mr. Hurd, who asked whether an independent inquiry would be held to ascertain how best to remedy defects revealed in ten years' working of the panel system, the Minister of Health said, on May 16th, that he was aware of recent criticisms of the panel system, which, in a service of this magnitude, were, he feared, inevitable. The revision of the terms of service of insurance practitioners, with a view to securing a more efficient medical service under the Insurance Acts, had been fully examined in consultation with the Insurance Consultative Council and the Insurance Acts Committee of the British Medical Association, and he did not consider that any useful purpose would be served by such an inquiry as was suggested.

Sir Kingsley Wood asked if the Minister was considering the very large number permitted to be on doctors' panel lists. Mr. Chamberlain, in reply, said he took it that this matter was being considered by the Insurance Consultative Council and the Insurance Acts Committee. Mr. Mardy Jones asked whether representation would be given in this inquiry to the medical aid societies which had been ignored up to the present, and which, he said, represented a very large proportion of the insured persons in this country. Mr. Jarrett also wanted to know when the result of the inquiry by the Consultative Committee would be made known. Mr. Chamberlain was unable to say when any decision would be reached. It would, he thought, probably have to be delayed for some little time.

In answer to Mr. Rhys Davies, Mr. Chamberlain stated that out of the disposable surpluses of approved societies in England, following the first valuation, the aggregate amount set aside for provision of the benefits under the scheme during the five years covered were as follows: Dental treatment, £495,000; optical treatment, £106,000; hospitals and convalescent homes, £979,000; medical and surgical appliances, £164,000; and nursing, £207,000. As regards the third item it was not possible to say what portion of the figure of £979,000 was allocated to convalescent home treatment, this benefit being included under the schemes with hospital treatment; but in addition the amount of £60,000 was set aside for the leasing and maintenance of convalescent homes by certain societies.

Mr. Chamberlain, replying to Sir K. Wood on May 16th, said that notice of intention to make a regulation reducing the amount of the administrative expenses of approved societies was given in the *London Gazette* on May 11th. The regulation would not be laid before Parliament until forty days after the date of the notice, but a draft copy would be placed in the library.

### Dangerous Drugs Bill.

The Lords' amendments to the Dangerous Drugs and Poisons (Amendment) Bill were considered in the Commons on May 16th and were all agreed to. On the same day the Royal Assent was given to the measure.

### Dangerous Drugs in Medical Prescriptions.

Sir E. Stockton asked, on May 15th, whether, in view of the increase of the drug habit, the Home Secretary was in possession of any information to show that there was any abuse of medical

prescriptions containing drugs, which prescriptions did not contain words prohibiting repetition. Mr. Bridgeman said that the regulation made under the Dangerous Drugs Act expressly provided that the drugs should not be supplied more than once on the same prescription, with an exception for cases in which the prescription explicitly directed that the drugs might be supplied at specified intervals on not more than three occasions; and in view of this the committee which considered the Regulations thought it unnecessary to require that the words "Not to be repeated" should be inserted in the prescription. To obtain or supply drugs on a prescription otherwise than in accordance with the regulation was an offence against the Act, and he had no reason to think that the regulation in question was not observed.

### Dogs' Protection Bill.

During a break in business near eleven o'clock on the evening of May 16th, when the orders of the day were read, and the Dogs' Protection Bill was called amongst them, Sir Frederick Banbury moved that the measure be then given a second reading. Lieut.-Colonel Nall began to speak on the measure—in its support—when Mr. Adamson claimed to move that the question be now put. The Speaker, however, refused the closure. Mr. Jack Jones then once more asked that the question be put, but the Speaker again withheld his consent, and it then being eleven o'clock the debate on the bill stood adjourned. Sir Frederick Banbury named Monday, May 28th, for the resumption.

**Small-pox Outbreak.**—Mr. Chamberlain, in answer to Mr. Becker on May 16th, said he was advised that the recent increase of small-pox might be attributed to the widespread neglect of vaccination and revaccination and to the fact that small-pox was a disease of seasonal prevalence, the maximum incidence usually occurring at the end of the first quarter of the year. The number of cases notified in April was 139, as compared with 215 in the previous month.

**Tuberculosis in Children.**—At the instance of Mr. Foot, Mr. Wood stated, on May 17th, that the relevant statistics of tuberculosis in children were divided into two categories—those of children ascertained at medical inspection to be suffering from pulmonary tuberculosis, and those of children suffering from crippling due to tuberculosis. According to the latest returns furnished by local education authorities, the number of children in the first category was approximately 20,000, of whom about 2,000 were in special schools, 11,000 were in public elementary schools, and 7,000 were attending institutions not certified by the Board or were not at school. In the second category there were 13,000 children, of whom 1,700 were in special schools, 6,500 were in public elementary schools, and 4,800 were attending institutions not certified by the Board or were not at school. Such of these children as were in attendance at public elementary schools were not suffering from tuberculosis in an infectious form. Provision was made in the code for the exclusion from public elementary schools by the school medical officer of any child whose presence might involve the spread of the disease.

**Disability Pensions.**—In answer to questions, on May 17th, the Minister of Pensions said that the pension regulations required that a man who had been on the pension list four years or more should be considered for final award; medical boards were instructed to furnish an assessment for the purpose of such final award, unless the man was likely to get materially better or worse within a period not exceeding two years. The boards were advised that cases of tuberculosis would, generally speaking, be found unsuitable for final awards, but that each case should be considered on its merits. The form in which the records were kept did not render it possible readily to distinguish between valvular disease of the heart and other forms of heart disease. The instructions relating to making of final awards recognized the probability that cases of valvular disease of the heart would deteriorate. Medical boards were, in fact, advised that cases of this nature would ordinarily be found unsuitable for final awards, but that each case should be considered on its merits.

**Water Supplies.**—Major Kelly inquired, on May 9th, whether the water supplies of the country are now sufficient to meet requirements in the event of another dry summer this year, and whether any national survey of water resources had been completed. Mr. Chamberlain said that the situation was such as to give no ground for anxiety at the present time. A survey of the water resources of the country was proceeding as rapidly as possible having regard to the staff available.

**Poison Gas: Experiments on Animals.**—The Under Secretary for War, replying to Mr. Lansbury on May 14th, gave the following particulars as to the animals which had been employed in the gas poisoning experiments at the Porton Experimental Station near Salisbury since February 23rd, 1922, when the last statement was made: cats 66, goats 48, guinea-pigs 118, mice 148, monkeys 23, rabbits 139, rats 209. None of the experiments had consisted in dropping bombs containing poisoned gas among these animals. They were always under an anaesthetic if it was in any way possible, and they were destroyed as soon as the objects of the experiment had been attained.

### Answers in Brief.

Out of 318 local education authorities in England and Wales, 297 have established clinics for the medical treatment of school children found to be suffering from physical defects. There are about 500 blind or partially blind children and about 6,300 crippled children for whom provision is not yet made in recognized schools or educational institutions, but it is hoped to make provision in the course of the next few months.

# THE NEW INSTITUTE OF ANATOMY AT UNIVERSITY COLLEGE, LONDON.

BY  
PROFESSOR G. ELLIOT SMITH, M.D.Syd.,

F.R.C.P.Lond., F.R.S.,

PROFESSOR OF ANATOMY IN THE COLLEGE.

In a previous article I gave an account of the circumstances in which the Rockefeller Foundation endowed the Department of Anatomy and provided for the extension of the Department of Physiology and also explained the general ideas that inspired the design for the new building. I propose now to give a brief sketch of the measures that have been adopted to give expression to these principles. Of the five floors in the building the lowest is devoted mainly to practical work in anatomy—that is, dissecting and radiography; the next floor to teaching accommodation and museums; the third and fourth to research in anatomy, histology, and embryology; and the top floor to teaching in microscopic anatomy.

The building, designed by Professor F. M. Simpson, F.R.I.B.A., faces Gower Street, and has a frontage of 154 ft. exclusive of the end gateway, which gives access to the south quadrangle. At the back it joins the physiology building. It consists of five floors and a sub-basement in addition, which contains the heating chambers, coke cellars, tank and specimen rooms. The students' entrance is in the south quadrangle at the basement level. On the same level are the large top-lighted dissecting room (55 ft. by 52 ft.), with prosectorium and annexe, the x-ray rooms, injection room, workshop, and cloak rooms for men and women students.

The rooms for the x-ray examination of the living subject and for the study of x-ray plates are close to the dissecting room, so that the students may be able, when dissecting any region of the body, to correlate the x-ray appearance with what they see and handle in their dissections. The x-ray equipment, the chief features of which are mentioned later in this account, has been superintended by Major Charles E. S. Phillips, O.B.E., who has spared no trouble in devising the best possible equipment for teaching anatomy by radiography.

The main entrance from Gower Street is at the ground floor level, and leads by an oak-panelled vestibule to the hall and central staircase which serves all floors. On the ground floor are the museum (52 ft. by 50 ft.) and preparation room, lecture theatre (48 ft. by 40 ft.), fitted with the latest Zeiss epidiascope, demonstration theatre, and rooms set apart for teaching and research in anthropology.

On the first floor in front are the Medical Sciences Library and periodical room, oak panelled, together 66 ft. long by 25 ft. wide, with book-store adjoining, the room for the lecturer in the history of medicine, the private room and laboratory for the professor of anatomy, dean's office, a series of research rooms, including the laboratory for comparative neurology. In the latter will be housed a collection of neurological preparations, the nucleus of which consists of sections made by the late Dr. Page May and Sir Victor Horsley, and others presented by the Central Institute for Brain Research in Amsterdam at the instance of Dr. Ariens Kappers.

On the second floor are located the research laboratories for the professor of embryology; and a lecture room seated for about ninety students, with apparatus for projection of histological preparations. In addition, on this floor are situated the advanced laboratory for histology and embryology, a small chemical laboratory, the laboratory for research in experimental embryology, and the microphotographic and dark rooms, whilst two rooms provide accommodation for the collections of preserved material and microscopical preparations. These rooms are well equipped for all kinds of photographic work, both macroscopic and microscopic. Professor J. P. Hill has made a very rich collection of mammalian embryos and aims at making as complete a series as possible of human embryos. For research in Comparative Embryology the Institute offers unique opportunities.

The main students' laboratory for microscopical anatomy (52 ft. by 50 ft.) is situated on the third floor. It extends across the width of the building and is well lighted by two continuous skylights facing north, as well as by windows facing the south quadrangle on the one side and Gower Street on the other. The laboratory affords accommodation for about ninety students; each student being allocated a

working place provided with a cupboard, water, gas, and electric light. Adjacent to the laboratory are the preparation room, the research laboratory for the assistant in histology, the modelling and aquarium rooms. Accommodation for the keeping of live animals is also provided on the third floor. Provision has been made of facilities for experimental embryology and for the study of degeneration effects in the nervous system.

A room (32 ft. by 24 ft.) is set aside for the cinematographic study of animal movements. For this purpose there is to be installed a cinematographic apparatus (so-

called ultra-cinema) designed by M. Nogues of the Marey Institute of Paris, by means of which it is possible to take up to 300 photographs a second of moving objects. This is perhaps the best method for the analysis of reflex movements and muscular adjustments such as those of posture. The film being projected at a rate of about 16 to 18 a second the whole movement is observed slowed ten to fifteen times, so that it will be possible to make out the different phases of which the movement is composed. Heavy electric leads are carried to this room so that brilliant illumination by arc or mercury lamps may be employed. In the summer months it will be possible to make use of direct sunlight, the flat roof being admirably adapted for the purpose of cinematography.

The x-ray department is equipped with the latest type of apparatus for radiography in all its medical branches. Facilities are provided for rapid work as well as for the study of movement and anatomical structure as revealed by the latest x-ray technique. The appliances include an arrangement specially designed to enable great sharpness of image to be obtained upon the photographic plate or film.

The power unit consists of a 10 kw. transformer x-ray set which supplies energy to the x-ray tubes, either when working from below or above the operating tables, or when used for fluoroscopy, and arrangements are made whereby the portable trolley control may be connected either at a position near the tables or at a separate wall plug adjacent

ELEVATION TO GOWER STREET.

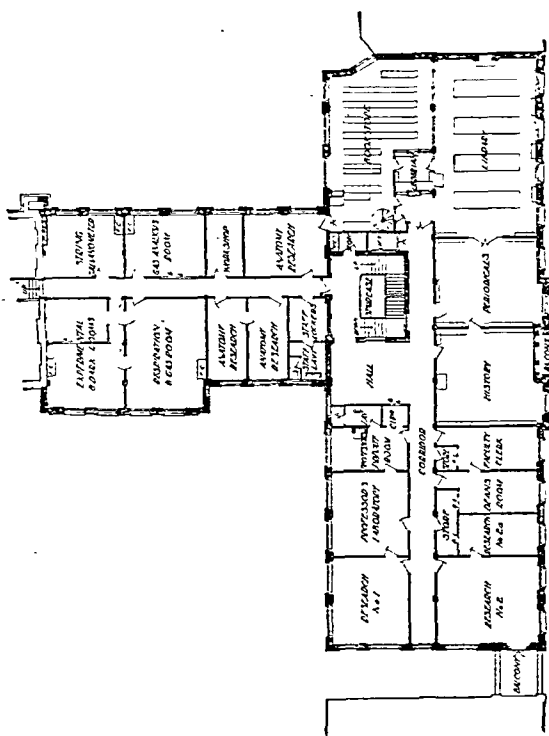

THIRD FLOOR PLAN.

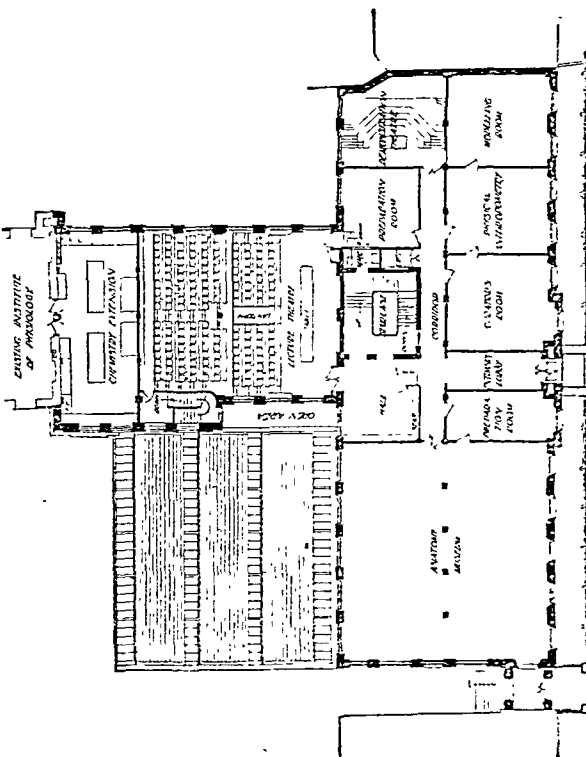

SECOND FLOOR PLAN.

FIRST FLOOR PLAN.

GROUND FLOOR PLAN.

to the fluorescent screening stand at the far end of the room.

One of the x-ray operating tables is fitted with automatically moving plate carriers beneath the top, which itself is hinged so as to render the tube box and diaphragm mechanisms readily accessible. The other operating table is fitted with the Bucky-Potter grid, and is the second table of the kind that has come to this country from the United States. As well as a large screening apparatus there is a heavy type tube stand for general use, and a number of minor accessories. Apparatus for the special radiography of the head is also provided.

The high tension overhead leads are made of nickel-plated tubing of sufficient diameter to reduce the formation of corona to a minimum, and a high tension switch actuated by strings serves to connect the transformer terminals with the set of leads required for each apparatus as desired. The protection of all engaged in the work of the department has been carefully provided for, and stray radiation is prevented from entering adjacent rooms by a covering of lead six feet high upon the walls. The lead sheet, carefully lapped at the joints, is hidden beneath stout boarding which serves to absorb the soft component of any secondary radiation which may be produced from the lead by stray radiation. The floor is covered with rubber. An adjoining dark room and large viewing room together with a plate store complete the department. The installation has been carried out by Messrs. Watson and Sons (Electro-Medical) Ltd., London, who not only did the work of equipping the x-ray rooms but gave Major Phillips the benefit of their experience in designing x-ray apparatus.

The Rockefeller gift has also rendered it possible to effect certain much needed alterations and extensions in the department of biochemistry, pharmacology, and physiology. On the ground floor the general biochemical laboratory receives an extension behind the anatomy theatre, providing additional places for advanced students in biochemistry. The biochemical research laboratories are also enlarged by taking in the whole ground floor of the pharmacology building, providing in this way two additional research laboratories and a private room for the professor of biochemistry. In pharmacology further accommodation for research is procured by dividing the present pharmacology lecture theatre into two laboratories. The pharmacology lectures will be delivered in future in the physiology theatre.

This department receives also two extra laboratories on the second floor of the physiology building in compensation for the laboratories it gives up on the ground floor to biochemistry.

A large part of the first, second, and third floors of the building connecting the present Institute of Physiology with the Institute of Anatomy is used for increasing the accommodation for research in physiology. On the first floor three additional laboratories are provided for research as well as two rooms which will be used as a workshop. On the second floor two laboratories are provided adjoining the main students' laboratory, for the use of advanced students. There are in addition three other laboratories set apart for research. The third floor of this connecting block contains three rooms allocated to the Foulerton research professor, the caretaker's apartment, and the common rooms for the staff of all the departments in the building.

On the three upper floors there is free communication with the Institute of Physiology. From the basement a tunnel leads under Gower Street to connect with the medical school.

The Gower Street front is entirely in Portland stone; the back portions in Arlesley brick with stone dressings to match the existing physiology and pharmacology buildings. The floor of the dissecting room, annexe, and prosectorium is of white mosaic, and the walls of white glazed brick. On the corridors is a strip three feet wide of quarter-inch cork carpet, with margins of white terrazzo in basement, and of oak or pitch pine on other floors. A dado of terrazzo, with green panels and white frames, runs up the whole of the staircase and along the sides of the principal corridors. The floors of most of the working rooms are cement covered

with linoleum. The steps and landing of the staircase are oak on concrete with iron balustrade, and the museum, library, periodical room, and entrance vestibule from Gower Street have oak floors.

A passenger lift runs from the basement to the top of the building, serving all floors, and hand-power lifts are provided from the injection room down to the tank room, and from the tank room up to the annexe of the dissecting room. The whole of the building is steel-frame construction.

It is the unfortunate result of this new development that the department of anatomy becomes separated from that of zoology and comparative anatomy, with the work of which a very intimate association and co-operation have developed. But the hope is still entertained of reuniting these departments by further extension of the Institute of Medical Sciences along Gower Street. Thus a new department of zoology would be added to the new Institute of Anatomy. In this connexion it is interesting to remember that only four doors away from the new building is the house in which Charles Darwin began the compilation of the notebooks upon which *The Origin of Species* was based. It would be singularly appropriate to erect upon this site a building which would be at once a permanent memorial to the great Englishman who revealed to the world a new intellectual horizon and a home for those subjects—biology, anthropology, and psychology—which were directly stimulated by his work. Professor Richardson, of University College, has given immediate expression to this hope in a sketch now being exhibited at the Royal Academy.

## Scotland.

### THE ASSOCIATION OF PHYSICIANS IN EDINBURGH.

The annual meeting of the Association of Physicians of Great Britain and Ireland was held in Edinburgh on May 18th and 19th, under the presidency of Dr. Byrom Bramwell. The discussions took place in the physiology lecture theatre of the university, and various laboratories were visited. On the afternoon of each day cases of unusual interest were demonstrated in the medical out-patient department of the Royal Infirmary. A dinner was held on Friday evening in the hall of the Royal College of Physicians.

### PRESENTATION OF PORTRAITS OF DR. BYROM BRAMWELL.

At a meeting of subscribers and friends, numbering some 200, held in the hall of the Royal College of Physicians of Edinburgh on May 19th, a portrait was presented to Dr. Byrom Bramwell. The portrait had been painted by Mr. David Alison, A.R.S.A., commissioned by over 250 of Dr. Byrom Bramwell's old students and friends. Dr. F. N. Kay Menzies, the honorary secretary and treasurer of the committee of subscribers, announced that as a much larger sum had been subscribed than was necessary for the original portrait, the committee was enabled to commission the artist to execute a replica, and hoped further to be able to issue photogravures at a later date to the subscribers. The original portrait was presented to Dr. Byrom Bramwell by Sir David Drummond, a former colleague in the Infirmary at Newcastle-on-Tyne. The replica was presented on behalf of the subscribers by Sir Humphry Rolleston, K.C.B., President of the Royal College of Physicians of London, to the Royal College of Physicians of Edinburgh, and was acknowledged by its president, Sir Robert Philip, who occupied the chair at the meeting.

### LECTURE BY DUTCH PROFESSOR IN EDINBURGH.

Professor H. R. Kruyt, who occupies the chair of physical chemistry in the University of Utrecht, last week gave a lecture upon the electric charge of colloids in the medical chemistry department of the University of Edinburgh. Professor Sir James Walker presided over a large audience. After paying a tribute to the fundamental researches of the English school of colloid chemists from Graham, its founder, to the present time, Professor Kruyt took as his central idea the proposition that the electric charge is the most important property of colloids, whether suspensoid or

emulsoid. Professor Kruyt gave an account of his own work on the stream-potential between two electrodes when water is forced through a capillary tube connecting the two electrode vessels; with pure water 25 volts can be obtained at moderate pressures; addition of very small traces of salts affects the potential and may even reverse the charge. In conclusion, he protested against the view of physiologists that proteins, and emulsoids generally, form true solutions which obey the solution laws.

#### THE ST. ANDREW'S AMBULANCE ASSOCIATION AND THE V.A.D. COUNCIL.

The Army Council recently extended a cordial invitation to the St. Andrew's Ambulance Association to nominate a representative to serve on the Central Joint Voluntary Aid Detachment Council. The Association has nominated Colonel Donald J. Mackintosh, C.B., M.V.O., of the Western Infirmary, Glasgow, and this appointment practically completes the constitution of the Council, which is now representative of every important ambulance organization in the country; it has been set up for the purpose of reviewing the Voluntary Aid Detachment organization.

#### END OF AN EDINBURGH MIRACLE WELL.

The members of the Greater Edinburgh Club last week made one of their excursions to the old church of Restalrig and the adjoining miraculous well of St. Triduana. The Rev. William Burnet, incumbent of Restalrig parish church, mentioned that he frequently received letters asking for bottles of the water, not only from all over Scotland, but from India and other parts of the world. St. Triduana was a Saxon saint, and her well has been a place of pilgrimage for persons afflicted with eye diseases for over a thousand years. The well building is a fine piece of fifteenth-century architecture, with groined roof supported on a massive central pillar. The water has now been completely dried up by the new Edinburgh sewer through the adjacent Craigintenny meadows, over which houses are being rapidly built.

#### THE CENTRAL MIDWIVES BOARD FOR SCOTLAND.

The examination of the Central Midwives Board for Scotland, held simultaneously in Edinburgh, Glasgow, Dundee, and Aberdeen, has just concluded with the following results: Out of 95 candidates appearing for examination, 87 passed. Of the successful candidates, 27 had been trained at the Royal Maternity Hospital, Edinburgh; 20 at the Royal Maternity Hospital, Glasgow; 3 at the Maternity Hospital, Aberdeen; 9 at the Maternity Hospital, Dundee; 7 at the Queen Victoria Jubilee Institute, Edinburgh; 4 at the Cottage Nurses' Training Home, Govan, Glasgow; and the remainder at various recognized institutions.

## England and Wales.

#### POST-GRADUATE COURSES IN LONDON.

THE Fellowship of Medicine has been proceeding with the suggested scheme of post-graduate teaching outlined in our issue of April 21st and already considerable progress has been made. The general non-undergraduate hospitals have taken up very heartily the idea of the suggested grouping for the holding of short refresher courses and in some cases spontaneous offers have been received from special hospitals wishing to be included in these groups. Dates have been agreed upon for these courses for a year hence, and there will be a course lasting for two weeks during each month of the year.

Such response has been received from the special hospitals with regard to courses in the various specialties that it has been no light task to fit them all in, but the dates have been so arranged that no two special courses in the same subjects shall be taking place at one time. The complete programme for the year will be published shortly, but a preliminary announcement is made here of the courses arranged for next month, namely:

A refresher course at the Prince of Wales's General Hospital and affiliated hospitals from June 11th to 23rd and a course on gastrointestinal diseases of children at the Children's Clinic, Western General Dispensary, from June 11th to July 5th. Copies of the syllabus and full particulars of both these courses can be obtained from the Secretary to the Fellowship of Medicine.

For those desiring work in ophthalmology, neurology, and dermatology, should a sufficient number of entries be received, courses beginning on June 11th and continuing for about four weeks will be available at the Royal London Ophthalmic Hospital, the West End Hospital for Nervous Diseases (provisionally), and St. John's Hospital for Diseases of the Skin respectively.

Application for particulars regarding these and future courses should be made to the Fellowship of Medicine, 1, Wimpole Street, London, W.1.

#### PUBLIC HEALTH OF THE CITY OF LONDON.

The report by Dr. W. J. Howarth, C.B.E., M.O.H. for the City of London, on the work carried out by his department during 1922, testifies to the progressive policy of the Corporation. A comparison of the report with that of one of his predecessors, say of twenty-five years ago, is an interesting study. Such questions as the prevention of tuberculosis and venereal diseases, the verminous condition of children, the fly nuisance, the inspection of hairdressers' establishments, the manufacture of ice-cream, are only a few of those dealt with by Dr. Howarth, but to which we find no reference in the reports of Dr. Sedgwick Saunders, who was M.O.H. during the final years of the last century.

The resident population of the city in 1922 is estimated at 13,363. The birth rate was 11.1 per 1,000, and the death rate 14.1 per 1,000; the infantile mortality rate was equal to 61 per 1,000 births. The vaccination statistics are instructive, for only 28 per cent. of the children whose births were notified to the vaccination officer were successfully vaccinated. In 1899 this percentage was 63, and in that year there were 10 conscientious objectors compared with 65 in 1922.

#### Tuberculosis.

The city tuberculosis dispensary at St. Bartholomew's Hospital is under the charge of Dr. F. H. Young, O.B.E., who is assisted by a tuberculosis nurse. During the past year 351 new patients attended the dispensary, of whom 133 were resident in the city; of the latter, 23 were found to be suffering from tuberculosis. Of the 218 patients resident outside the city, 75 were found to be tuberculous. Patients resident in the city are supervised and treated at the dispensary; those who are non-resident, but who work in the city, are informed that they can be treated and advised at the dispensary or transferred to the tuberculosis officer of their own district. The majority decide to remain patients at the dispensary. All non-residents who do not work in the city are transferred to their own tuberculosis officer. With regard to sanatorium treatment, Dr. Howarth says:

"Experience shows that when the disease is active, residence in an institution more quickly and certainly brings about arrest than when treatment is attempted at home on sanatorium lines, and that the lessons learnt in the sanatorium are sometimes put into practice by the patient on his return home to his permanent advantage."

"The principal difficulty encountered occurs on the discharge of a patient from a sanatorium with the disease arrested. The home environment to which he returns is often unsatisfactory; suitable occupation near his home may be practically unobtainable, even when remuneration is not the main consideration, and a very considerable benefit gained in some cases soon lost and the treatment in the sanatorium largely wasted."

#### Venereal Diseases.

At the venereal diseases treatment centre, the medical officer of which is Mr. Kenneth M. Walker, there was a considerable decrease in the number of new patients. In 1922 there were 583 compared with 758 in 1921 and 1,053 in 1920. Of those suffering from syphilis, 64 discharged themselves before completing the first course, and of the 320 patients with gonorrhoea, 132 gave up attendance before the end of the first course. A few beds are provided at the centre for in-patient treatment, and the number of days of such treatment totalled 170.

#### Smoke and Atmospheric Pollution.

In the year 1914 a critical examination of the air of the city was begun: an apparatus consisting of a large rain gauge is mounted upon the roof of one of the corporation's buildings in Golden Lane, and the rain water from a known area of surface is collected monthly. In June, 1922, the amount of deposit registered as falling in the city amounted to about 54 tons. Of this mass of dirt approximately 18 tons were soluble and 36 tons were insoluble, consisting of tar, carbon, and grit.

*Inspection of Meat.*

During 1922 the record amount of 463,074 tons of meat passed through the central markets at Smithfield, an average of about 1,800 tons a day. Thirty per cent. of the pork was supplied by British feeders, but Mr. Dunlop Young, veterinary surgeon to the corporation, considers this amount could be greatly increased if more attention were paid to scientific feeding, etc. He advises the pasteurization of all food which could convey tubercle bacilli to pigs in order to avoid the destruction of carcasses or portions of carcasses on the market. One ton in every 320 tons of meat paying toll in the central markets was condemned in 1922, compared with one ton in 169 in 1921. Of the fish delivered at or near Billingsgate Market during 1922, one ton in 107 tons was condemned compared with one ton in 88 tons in 1921.

*Milk Regulations.*

In discussing the provisions of the Milk and Dairies (Amendment) Act, 1922, Dr. Howarth expresses the opinion that the clause which gives power to a local authority to refuse to register a retailer will require attention with regard to the desirability of permitting basements to be used for the storage of milk; the practice of permitting churns to stand on the footway outside milkshops, and the means of safeguarding churns and lids; and the practice of keeping small milk receptacles containing a reserve supply on shop floors.

*Ireland.**TYRONE COUNTY HOSPITAL.*

DR. EDWARD THOMPSON, F.R.C.S.I., medical officer of the Tyrone County Hospital, in the course of his report recently published for the years 1921 and 1922, states:

"At present in Ireland and Ulster the condition of the hospitals and the whole Poor Law system is appalling. For years past the British Government had this question continually brought to their notice. A Viceregal Commission was appointed; the whole question was carefully investigated, and an admittedly admirable report was issued, which was immediately pigeon-holed, and nothing has resulted. A year or so ago another Hospital Commission took the place of the Viceregal Commission. It, also, has reported and urged the necessity of hospital reform. I understand the Northern Irish Government have the question under serious consideration . . . and that the result will be the abolition of the boards of guardians, who have always proved themselves unfit for their responsibilities . . . regardless of the general experience that no improvement can possibly take place without an increased expenditure, which, although considerable at the start, will result in increased efficiency, and a lowered cost in the future. . . .

"I wish particularly to refer to the table detailing the list of operations in the two years. There have been 127 operations for appendicitis alone, with 9 deaths. Considering that 75 per cent. of these cases were abscess cases—that is, the appendix had ruptured before admission to hospital—the result is surprisingly good, quite as good as in any hospital anywhere, and yet there are some doctors in the county, I am sorry to say, who cart off their unhappy patients long distances to some city hospital, and ignore the efficient surgical hospital at their doors for the treatment of these and similar acute abdominal complaints. The total mortality after all operations was 23, representing rather less than 4 per cent., which is about the average in all surgical hospitals. The annual expenditure is still too high, but is absolutely dependent on the contract price of provisions. When these fall the cost will be lowered and vice versa."

*FREE STATE ARMY MEDICAL SERVICES.*

The Irish Medical Secretary has made representations, with regard to complaints made by medical practitioners that they were called upon to afford gratuitous medical treatment to soldiers serving on outpost duty and to their dependants, to Major-General Francis J. Morrin, M.D., Director of Medical Services, who, in the course of his reply, stated:

"One medical officer is appointed to every 500 men, with extra assistance in the larger battalion areas. It is his duty to inspect and to care medically for these men. This scheme has been completed for all Ireland, and the Army has now, in proportion to its members, more doctors than any army in the world.

"Prior to April 1st it was the custom to employ 'part-time' medical practitioners at a rate of 10s. 6d. per diem. This meant an enormous financial involvement for the Army, as nearly every medical officer in the country was doing part-time work. This arrangement had to cease; it was uneconomic and most unsatisfactory from a military standpoint. The position of civilian medical practitioners now is: If engaged by the Command Medical Officer to do part-time work, for example, visit outposts, etc., he is paid 10s. 6d. for such days on which he arranges to visit. The appoint-

ment must be sanctioned by this office. If a doctor is urgently called on he receives 10s. 6d. for such call; of course, the necessity for the call has to be vouched for by the Command Medical Officer. Further, medical practitioners are requested to furnish all claims against the Army monthly.

"The capitation rate appeared to me as employing a professional man to do work by contract. I prefer to pay a minimum fee of half a guinea to any doctor employed. I am having instructions circulated to the Army that when men or officers consult, on their own account, civilian medical practitioners, they are liable for the fee. I am particularly anxious to see the medical services independent, but I am equally desirous of treating fairly the civil medical officers. Consequently any information or complaint you may receive I shall be most pleased to investigate at any time, when they shall have my very careful consideration."

*Correspondence.**IONIC MEDICATION AND THE CONSTANT CURRENT.*

SIR,—It is a pleasure to see that you have drawn attention to this subject by a leading article in your issue of May 19th. May I be permitted to comment on it?

First of all the constant current in a wire and in the tissues are two different things. In a wire the current consists of a movement of electrons; in the tissues it consists of a movement of ions. Ions may be defined as particles derived from salts and composed of atoms or groups of atoms showing an excess of positive or negative electricity as the case may be. The tissues and fluids of the body are in part composed of salts and consequently of ions, and when the current—so called—flows there is a movement of ions, and an exchange takes place between adjacent compounds. This is put forward as a suggested possibility in your article. It is the basic fact in ionization. To quote Professor Leduc, "Il n'y a pas de courant simple, il n'y a que des actions électro-ioniques."

The exchange of ions is accompanied by a movement of water from the positive to the negative electrode, and this is believed to be largely the explanation of the benefit resulting from ionization in cases where there is exudation as in a sprain, and also in cases where the exudation is becoming organized into scar tissue. In these exudates there is absence of vessels, or, at least, defective circulation. The fluid brought by the current is not immediately carried off, but the exudate is made more soluble and therefore can be more readily dispersed by movement or massage. There is abundant clinical evidence of the beneficial results which follow ionization in these cases. It is a pity that when the value of this treatment is being discussed, both from the theoretical and practical aspects, the evidence brought forward should be taken from cases of deeply seated disease, in which the condition existing is surmised rather than accurately known; and from cases in which this form of treatment can be applied only in an imperfect and unsatisfactory manner, in theory at any rate; whilst the evidence derived from cases to which in theory and in practice it can be satisfactorily applied, is passed over in silence. To proceed in this way is the very negation of the "experimental method" which aims at making the answer decisive by arranging that the conditions of experiment are simple and clear.

It is, I think, admitted on all sides that ions such as strychnine, chlorine, salicyl and iodine, which form soluble compounds with ions in the body, are carried away by the blood and lymph stream, and are not carried by electrical action to the deeper parts. This, however, does not imply that the action of the constant current in promoting an exchange between the normal ions of the fluids and the normal ions of the tissue cells does not take place. Ordinary nutrition implies exchange, and it is claimed that electrical action favours this exchange. Ions introduced electrically undoubtedly act on cells placed superficially—for example, cocaine so introduced produces anaesthesia. Why should we hesitate to believe that the normal ions of the fluids which are situated at a depth enter the cells with which they are in contact, when subject to electrical action?

No reference is made in your article to ionic medication in certain surgical conditions. The evidence there of benefit is convincing by its simplicity and decisiveness.

In conclusion, may I point out that it is comparatively

easy to gain a reasonable knowledge of the physical, chemical, and electrical factors involved in ionization, but it is hard work to unravel the conditions present in a disease labelled "sciatica," for instance, when presented for treatment. Until the factors in each case are recognized it is empiricism, perhaps quite justifiable empiricism, to treat the patient by any method whatever, including ionization.—I am, etc.,

London, W., May 19th.

A. R. FRIEL.

### THE EDUCATION OF MYOPES.

SIR,—The good common sense of Mr. Harrison Butler shown in his Middlemore lecture on refraction of the eyes<sup>1</sup> breaks down at one point, when he makes his favourite tilt against current theories of myopia. No one would wish to deny him that pleasure, but it is a pity he carries his hostility to a theory to such a length that he would (if he could) injure practical measures established for the benefit of myopes and proven to be of benefit to them.

He speaks of the myope school as "an inferior system." That is a libel on these classes. They are in no way inferior to the general school. They are placed in the elementary schools, and have the same trained teachers, who themselves receive special instruction in their particular duties and additional pay because of the heavier work entailed. The myope classes differ only from the general school in that class books, pens, and paper are not found in them, for these are replaced by charts, blackboards, screens, and chalk, by means of which the pupils read, write, and draw at arm's length in large size. A living teacher is better than a book, as Mr. Butler himself recognizes in his remarks on the teaching of retinoscopy. In the days when books were rare, was there no good teaching, and did no one learn?

Mr. Butler objects to the disbaring of myopes of more than 3D. from State school scholarships. On my evidence this disbaring is right and good. In a recent issue of the JOURNAL<sup>2</sup> I gave the facts upon which this practice is based. Between the ages of 20 and 60 years myopes of more than 3D. who did habitual close eye work were found to suffer breakdown from eyestrain or disease to the extent of 53 per cent., whereas myopes who did not engage in habitual close work suffered only to the extent of 9.4 per cent. The higher the degree of myopia the greater the rate of breakdown: those over 10D. suffered to the extent of 77.4 per cent. On these facts it is right to divert young myopes from scholarships which are generally introductions to lifelong careers of habitual close work. The limitation does not apply to certain trade scholarships.

Mr. Butler says he forbids music to myopes. I wonder why? Most instrumental music requires reading at no nearer distance than arm's length and with the eyes looking straight forward; under these conditions, with a good score and good light, music is a harmless and delightful means of extending the interests of these children; further, the cultivation of the ear is a diversion which saves the eyes.

Mr. Butler's strong common sense shown in so much of his lecture makes me think that once he has put his favourite "cock-shy" in its proper place he will appreciate the practical advantages of educational methods for myopes calculated to train them in the way they should go for the safety of their frail eyes.—I am, etc.,

London, W., May 19th.

N. BISHOP HARMAN.

### THE COASTAL MOSQUITO NUISANCE.

SIR,—Considerable attention has been directed to the mosquito nuisance at Hayling Island by J. F. Marshall, Esq., M.A., F.E.S., who has been making a special study of the subject for the last three years. Mr. Marshall has discovered that although a total of fourteen species of mosquito have been located at Hayling, the nuisance is caused almost entirely by one species, the *Ochlerotatus detritus*. The special characters of this particular species are that it breeds in salt, brackish, or non-salt water, it spends the winter in the larval state, it is a prolific breeder, and its larvae are to be found in stagnating sea water in enormous numbers all the year round. It lays its eggs not only in water but on ground in the vicinity of marshes. It seems to know instinctively that such

ground will come under flood, and it has a flight range of from two to four miles.

Mr. Marshall has demonstrated further how the nuisance can be dealt with by drainage and filling in, or where these measures are not practicable by the use of larvicide.

As a sequel to these findings at Hayling Island, investigations were instituted in the Gosport-Alverstoke-Leo districts and very similar conditions discovered. The same species of mosquito has been identified at Weymouth also, where it is no less troublesome. It would be interesting to know what other places along the coastline are affected by it.

As this particular mosquito is not a specific disease carrier, it is not considered incumbent upon the local health authority to expend large sums of money in its eradication. Its bite, however, in common with that of other species, is not only irritating but is at times the cause of boils, cellulitis, or even blood poisoning. I contend, therefore, that it is the duty of the health authority to supply the public with information as to how the nuisance can be abated. If it is sufficiently troublesome to justify active measures, the problem might be taken up, on the lines initiated at Hayling and just recently adopted at Gosport, through the medium of a mosquito control committee, consisting of interested residents assisted by the health authorities concerned.

The salt marsh mosquito nuisance has long been known in America, particularly in the State of New Jersey, and very thorough measures have been taken to deal with it. The Americans have discovered that it is a sound financial proposition, and where the work of eradication has been completed property values have gone up by from 25 to 300 per cent. Although conditions in this country may not yet be as bad as those in America the nuisance is already sufficiently severe to retard the development of certain desirable seaside resorts, and I am convinced that the community would welcome any assistance or advice relative to its abatement.—I am, etc.,

D. H. C. GIVEN, M.D., D.P.H.,

Surgeon Commander, R.N.

May 7th.

### NEW MENTAL TREATMENT BILL.

SIR,—I have never proposed that the rest homes outlined in my letter (March 24th, p. 536) should be uncontrolled. I specially stressed the fact that they would be run and controlled by the health committees (not the asylum committees) of local authorities and would be subject to the approval of the Ministry of Health. For this desirable and necessary purpose, grants in aid could be obtained from Parliament. Any risk of "the exploitation of such homes by unscrupulous and designing persons" can be effectually countered by the provisions of Section 315 of the Lunacy Act, which impose a penalty on any person detaining "an alleged lunatic" except in strict compliance with the requirements of the Act. However insane a man may be said to be, he cannot legally be deprived of liberty without judicial sanction. Health committees are every whit as competent to run hospitals for "uncertifiable" people (which are free from detention) as are asylum committees, and have a better right. The places will be free from "stigma," and on that account likely to be much more successful than homes under lunacy in preventing early cases becoming certifiable.

Since it is admitted that no bill is needed to permit a person to enter a hospital where detention is not practised, it is clear that the new Mental Treatment Bill is meaningless, unless detention is in view. But detention without check of judicial inquiry and appeal is in essence improper. If the boarder enters a mental institution on an absolutely "voluntary" footing, and has the right to leave it within forty-eight hours, why is there mention of a period of six months, which can be extended by the Commissioners to a year? If truly voluntary, he can stay as short or as long a time as he wishes. There is, moreover, no safeguard against his being secretly certified at any moment.

It is noticeable that in the new bill, which is confessedly designed to "supply machinery to deal with doubtful cases before passing them on to the machinery allowed by the present law," the safeguarding provisions of Section 315

<sup>1</sup> BRITISH MEDICAL JOURNAL, May 19th, 1923, p. 913.

<sup>2</sup> Harman: Standards of Vision for Scholars and Teachers in Council Schools. Ibid., January 13th, 1923.

will be liable [Cl. 6 (6)] to be suspended or annulled at the will of the Board of Control. The Board is also to be given power [Cl. 4 (3)] to discountenance or close down any rest home or hospital not under its own jurisdiction. This is a very serious matter. There can be no justification for extending the jurisdiction of the Board over harmless and uncertifiable people to their damage, and the throttling of any prospect of providing for them the kind of homes which they so greatly need for their speedy recovery.

The new bill will give short shrift to cases designated as "incapable of volition." The authorization of a minister of religion suffices for their committal after joint (not independent) examination by two doctors, one being a nominee of the Board, whose opinion will, of course, carry the greater weight. The large majority of these "no-volition" cases are due to toxic causes (puerperal, influenzal, etc.). These ought never to be sent to asylums. A more effective way of shielding them from "stigma" is to enforce upon infirmaries, hospitals, and maternity homes the obligation of providing means to retain and deal with their own delirious cases.

The provision of hostels run on a hospital footing for uncertifiable mental cases, quite apart from lunacy, will furnish an example of tackling the beginnings of insanity on the sound principles of preventive medicine; and no legislation is needed to bring about the desired end. By intercepting these cases on their way to asylums, it would tend to a very material reduction in our expenditure on lunacy administration, now amounting to £7,900,000 per annum.—I am, etc.,

London, E., May 12th.

S. E. WHITE.

#### BLOOD PRESSURE AFTER OPERATIONS.

SIR,—In an article recently published<sup>1</sup> by Professor Lehrnbecher on the changes in blood pressure resulting from operations of various kinds, he stated that the recording apparatus was affixed to either arm indiscriminately, as it made no difference from which side the readings were taken. Now although it is quite true that the blood pressure in the two arms is identical under normal conditions, my observations have convinced me that this does not hold good in cases of unilateral conditions, whether from operation or trauma. The results of a first series of 819 observations were published (after a preliminary communication in the *BRITISH MEDICAL JOURNAL*, 1918, ii, 132) in the *Quarterly Journal of Medicine* for 1920 (xiii, 148), and they showed that as regards the maximum pressures, differences of 10 to 18 mm. are found in about 83 per cent. of all cases, and above 20 mm. in about 12 per cent., the figures for the minimum pressures being respectively 81 and 20 per cent. Later on I confirmed these results by a second series of 1,897 observations,<sup>2</sup> and my brother, Dr. R. J. Cyriax, has also found that these differences were often present in pulmonary phthisis.<sup>3</sup> Professor Lehrnbecher appears, however, not to have had his attention drawn to the above articles, and thus did not exclude the source of error in drawing conclusions from observations on the blood pressure of only one arm. I sent a short notice to the journal in question, pointing out the fallacy, but the editor returned it regretting that he was only enabled to publish articles by its collaborators. I trust therefore that you will be able to insert this communication of mine in order that workers on blood pressure may once again be reminded that it is quite wrong in unilateral conditions, as well as many bilateral ones, to draw conclusions from unilateral blood pressure observations.—I am, etc.,

London, W., May 16th.

MESSRS. BAILLIÈRE, TINDALL, AND COX have issued a list of books on medicine and the allied sciences showing the net prices and the cost of postage. The list is classified and has an appendix containing a list of periodical publications. Copies can be obtained from the firm at 8, Henrietta Street, London, W.C.2.

#### Obituary.

LIEUT.-COLONEL JAMES CURRIE ROBERTSON,

M.B., C.M.G.,

Indian Medical Service.

LIEUT.-COLONEL JAMES CURRIE ROBERTSON, C.I.E., C.M.G., C.B.E., Bengal Medical Service, died at Simla on May 14th, aged 52, of heart failure following pneumonia. He was the son of Alexander Robertson of Kilmarnock, and was educated at Glasgow, where he graduated M.A. in 1890, M.B. and C.M., with honours, in 1894, and also B.Sc. with honours. He entered the I.M.S. in January, 1896, attained the rank of lieutenant-colonel in 1915, and was placed on the "selected list" for promotion in November, 1921.

Within a year of entering the service he had his first experience of active service, taking part in the Sudan campaign of that year, the Dongola expedition, for which he received the medal and also the Khedive's medal. Soon after his return to India he was deputed on special plague duty, and spent the whole of the rest of his service in sanitary work, for it was in such work that he was chiefly employed, even in the two campaigns in which he afterwards served. In 1901-2 he served in South Africa, where he was on special duty under the Director of Burgher Camps, and also took part in the operations in the Transvaal, receiving the medal with two clasps. In 1901 he was appointed to be a Deputy Sanitary Commissioner in the North-West Provinces, now the United Provinces of Agra and Oudh; in 1912 he was promoted to be Sanitary Commissioner with the Government of India, the highest post in the Sanitary Department. In February, 1915, he returned to military duty for service in the recent war. In 1916 he was at Malta, in charge of measures taken to deal with an epidemic of plague in that island, in which he was so successful that the Governor and Commander-in-Chief, Field-Marshal Lord Methuen, specially thanked the Indian Government for his services. In the following year, 1917, he was sent to Italy, and posted to Taranto, with the acting rank of colonel. The Italians had considered Taranto unsuitable for a military cantonment owing to the excessive prevalence of malaria in the town and surrounding province. But Robertson's antimalarial measures were so successful that Taranto was used as a British base for the movement of troops intended to take part in the operations further eastwards.

After his return to India he was appointed, on August 9th, 1920, to be Director of Hygiene and Pathology at Army headquarters, Simla. He had recently been granted furlough, and when attacked by his fatal illness was on the eve of leaving India, probably for good.

His services had met with recognition from the Government. He received the C.I.E. on January 1st, 1914, the C.M.G. on August 8th, 1917, and the C.B.E. on June 3rd, 1919. He was also decorated with the Italian silver medal *della saluta pubblica* in November, 1920, and appointed an officer of the Order of the Crown of Italy in September, 1922.

ARTHUR PEARSON, M.B., B.S.LOND.,

Tanganyika, Katanga, Southern Rhodesia.

WE regret to have to record the death by an extraordinary accident of Dr. Arthur Pearson, who, after being a student at Guy's and taking the diplomas of L.R.C.P. and M.R.C.S. in 1901, became a medical pioneer in Central Africa. He met his death on his farm, Long Meadow, twenty miles from Bulawayo, in an attempt to rescue a native boy who had been overcome by carbonic acid gas generated in a tank containing mealies. Dr. Pearson was trying to get the boy out by a rope which he lowered through the manhole, when he disappeared inside the tank. The turmoil set up by the natives attracted Mrs. Pearson, and as soon as a larger hole had been cut with hammer and chisel she put a ladder inside and herself went down into the tank, to find her husband lying on the mealies. She secured the rope about him and had him raised to the air, but artificial respiration was useless as he had broken his neck in his fall. The native who was lying beside him senseless was also got out, and recovered almost immediately.

Dr. Pearson had become well known to a great number of people from the Congo to the Cape. He first went to South Africa during the Boer war, and in 1903 took a position in the Congo as medical officer to the Tanganyika Concessions; later he became chief medical officer to the Union Minière du Haut Katanga. In addition to his ordinary medical work he devoted special attention to enteric fever and to the construction of native compounds, and wrote books on the subjects in conjunction with Dr. Mouchet. Of recent years his opinion as a consultant came to be valued over a very wide area.

His manifold activities carried him into fields outside his profession. Always a keen rifle shot—as a student he captained the Guy's team, and was a member of the Artists' Volunteers—he did much big-game shooting in Africa, but the hunting instinct was gradually supplanted by the wish to observe, his rifle gave place to field-glasses, and for many years past he was never happier than when, armed only for defence, he could watch the movements and habits of the fauna which teemed in his country. He came, too, to feel an ever-growing interest in the problems involved in bringing wild land under cultivation. It was, therefore, no real break in his life (though to some of his friends it seemed otherwise) when eighteen months ago he left the Congo and settled on a large farm which he bought in South Rhodesia, retaining only a consultative connexion with the Union Minière.

He was a man out of the ordinary, as this short record of his life shows. Of great height and powerful muscle, he had an almost feminine gentleness about him. His manner, though quiet and unassuming, was never allowed to mask the determination behind it, or to interfere with his quickness of decision and action. He was honest in mind and deed, and had no great patience with those whose methods are shifty. Perhaps it was this trait which made him prefer the more natural conditions of life which he found in Africa. Not that he was himself simple; he had an almost unerring insight into human character and motives, but he was happy among simple surroundings, and, with no great ambition for personal advancement in position or means, he found satisfaction in giving his best to that which came to hand each day. This gained him friends in plenty, and there are many who found that to see him was to trust him, and to know him was to love him.

He was born in 1876 at Cheltenham, and was educated at Berkhamsted School, and graduated M.B., B.S. Lond., with honours in medicine, in 1906. In 1911 he married Miss Horwood, of Tunstall, Suffolk, and leaves three children.

Dr. HENRY WILLEY, whose death on May 16th is announced at the age of 84, was in practice for some twenty-five years near Beckenham, Kent, and for many of those years was the trusted doctor of Charles Darwin, who was living at Down, near Beckenham. Dr. Willey, who received his medical education at King's College, graduated M.B. Lond. in 1864, and became a Fellow of the Royal College of Surgeons of England in the same year. After a most successful career in practice, he retired to Reigate. He is survived by his widow, a son, and three daughters.

## Universities and Colleges.

### UNIVERSITY OF LONDON.

Dr. JAMES CALVERT has been appointed to represent the University of London at the ninth annual conference on the Prevention of Tuberculosis to be held at Birmingham on July 12th and 13th.

Dr. James Fawcett has been reappointed the representative of the University on the council of the Lister Institute of Preventive Medicine for the period 1923-33.

### ROYAL COLLEGE OF SURGEONS OF EDINBURGH.

The following 22 successful candidates out of 41 entered, having passed the requisite examinations, have been admitted Fellows:

B. V. Abhyankar, F. G. Beatty, I. J. Block, S. Bolton, Surgeon Commander H. F. Briggs, R.N., C. C. Bryan, A. F. Cowan, U. N. Das, G. C. Dixon, N. McO. Dott, J. Dunlop, R. S. A. Graham, J. B. Ifance, F. C. Hutchison, J. F. Jefferies, C. E. McQuade, A. G. Ord, D. S. Pracy, Major A. H. Proctor, I.M.S., J. Z. H. Rousseau, W. O. Stevenson, A. Watson.

The Bathgate Memorial Prize, consisting of bronze medal and set of books, was, after a competitive examination in *Materia Medica*,

awarded to Mr. D. B. Craig, and the Ivison Macadam Memorial Prize in Chemistry, consisting of bronze medal and set of books, was awarded, after competitive examination, to Mr. H. W. Bambridge.

### CONJOINT BOARD IN SCOTLAND.

The following candidates have been approved at the examination indicated:

D.P.H.—J. M. Blair, J. A. C. Guy, G. L. Johnston, Elizabeth C. Loudon, F. MacCallum, P. J. McDiarmid, D. O. Macdonald, K. D. Murchison, G. F. B. Page, A. G. Petrie, Ruth J. D. Ritchie, Marion Smellie, G. D. Steven, Marjorie Thomson, Ruby Thomson, P. Veyra, W. H. Wallace, Enid A. Williams. *Part I:* Marion B. Armstrong, Catherine McL. Buchanan, Helen Campbell, W. Campbell, A. C. Dewar, Kathrine Dunn, Margaret A. Galbraith, J. S. McL. Gray, Katharine J. Guthrie, J. L. Halliday, Mary N. Hendry, Catherine Hill, A. R. Lester, W. McKie, Peggy L. Mitchell, J. T. Moffat, G. W. Murray, D. T. Richardson, R. G. Shaw, C. M. Smith, Elizabeth N. Thomson, Sarah B. H. Walker, R. H. Williamson. *Part II:* G. Buchanan, J. G. Tait.

## Medical News.

A LETTER protesting against the false hopes raised by certain persons who make extravagant assertions that wireless is capable not only of relieving but in some cases of actually curing deafness has been issued by persons interested in the education and treatment of the deaf. It is signed by Lord Charnwood, president of the National College of Teachers of the Deaf, Mr. Richard Lake, F.R.C.S., Sir William Milligan, M.D., and Mr. Macleod Yearsley, F.R.C.S. The letter states that at present there are no indications that wireless is likely to be a cure for real deafness, though it may yet be proved that permanent improvement attends its systematic use in hard-of-hearing cases. Until systematic experiments have been conducted and trustworthy evidence is forthcoming that certain types of deafness can be alleviated by wireless, the recent reports of improvements must, the signatories consider, be disregarded; they add that the need for investigation is obvious.

THE Sharpey physiological scholarship tenable at University College, London, is vacant. Applications must be received by the Secretary of the College not later than June 23rd next. The value of the scholarship is £200; it is tenable for one year but is renewable; the scholar will be a member of the academic staff of the College, and will work in the department of physiology under the direction of Professor A. V. Hill, F.R.S., the newly appointed professor of physiology.

THE Dean and Professors of the Madrid Faculty of Medicine have recently paid a visit to the Paris Faculty of Medicine. On May 1st, the dean, Professor Recasens, gave an address on the new applications of radiotherapy in gynaecology, and Professor Cardenal discussed the treatment of acute diffuse peritonitis. On May 2nd Professor Aguilar dealt with general infections of dental origin and Professor Goyanes lectured on vascular surgery. On May 3rd Professor Hernandez gave an address at the Hôtel Dieu on the action of certain drugs on the secretion of gastric juice.

THE United Services Fund has erected a hospital on a site near Ascot for cases of surgical tuberculosis among children of ex-service men. The building provides accommodation for 150 patients in three wards, for babies, girls, and boys respectively. The hospital, which will be known as the Heatherwood Hospital, will be opened by Field-Marshal Earl Haig on Tuesday next, May 23th, at 3.30 p.m.

THE annual dinner of the Harveian Society of London will be held at the Connaught Rooms on Thursday, June 14th. Particulars can be obtained from the Honorary Secretary of the Society, Dr. W. E. Falconar, 40, Cleveland Square, W.2.

AT the annual meeting of the Röntgen Society, to be held on Tuesday, June 5th, at 8.15 p.m., in the Institution of Electrical Engineers, Savoy Place, Victoria Embankment, Sir Oliver Lodge will be proposed for election as president, in succession to Sir Humphry Rolleston; papers will be read by Professor Sidney Russ, D.Sc., on the effects of x rays of different wave-lengths on animal tissue, and by Mr. T. Thorne Baker, F.I.C., on the establishment of a definite relationship between exposure and density in an x-ray plate.

IN the BRITISH MEDICAL JOURNAL for February 24th a review was published, under the title "The Virtues of Sea Water," of a book by Dr. J. Jarricot. Drs. George Barford, Dorothea Tudor, and L. A. Clutterbuck write to state that there exists in London, at 225, Euston Road, a sea-water dispensary which is a direct offshoot of and is conducted on precisely the same lines as the Dispensaire Marin founded in Paris by M. Quinton. The treatment is carried out by subcutaneous injections of sea water rendered sterile and isotonic; the members of the honorary medical staff will be pleased to demonstrate the methods employed to members of the medical profession.

THE Home Secretary has, by a regulation dated May 16th, revoked No. 1 of the Dangerous Drugs Regulations, 1922 (S.R. and O. 1922, No. 1087), which provides that a prescription for dangerous drugs may not be given for the use of the prescriber himself.

MR. HENRY CURTIS, F.R.C.S., on the occasion of his retirement from practice and resignation as surgeon, has been elected a consulting surgeon to the Metropolitan Hospital, London, E.8.

A DEPUTATION consisting of representatives of the British Medical Association, the Society of Medical Officers of Health, the National Association for the Prevention of Infant Mortality, the National League for Health, Maternity, and Child Welfare, the National Baby Week Council, the Association of Infant Welfare and Maternity Centres and its London Federation, the National Society of Day Nurseries, the Central Council for Infant and Child Welfare, the Central Committee for the Care of Cripples, the National Health Society, and the National Housing and Town Planning Association, was received on May 14th by Lord Onslow, on behalf of the Minister of Health. The deputation was introduced by Dr. F. E. Fremantle, M.P., and submitted the views of these societies with regard to the effect of an undue amount of smoke on the child life of this country. Lord Onslow, in reply, said that a bill dealing with the subject was at present being drafted, and he would be glad to have the observations of the societies upon it when it was printed.

DR. T. GERALD GARRY has severed his connexion with the Czecho-Slovakian spa, Pistany.

THE second congress of French-speaking pediatricists will be held in Brussels in September, 1923, under the presidency of Dr. Pechère. The subjects to be discussed are pneumococcal infections in childhood, the diagnosis and treatment of intestinal obstruction, and the treatment of abnormal children.

## Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

IN order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Aitiology, Westminster, London*; telephone, 2630, Gerrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate, Westminster, London*; telephone, 2630, Gerrard.
3. MEDICAL SECRETARY, *Mcdisceara, Westminster, London*; telephone, 2630, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus, Dublin*; telephone, 4737, Dublin), and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: *Associate, Edinburgh*; telephone, 4361, Central).

### QUERIES AND ANSWERS.

"M.D." would like to know if any reader has had experience of marked depression caused by tobacco.

#### TOMATOES.

"H." asks why it is sometimes stated that tomatoes should not be given to young children.

\* \* The objection seems to rest chiefly on the risk of intestinal irritation by the pips. The skin also is hard and indigestible, but can easily be peeled off if the tomato is dipped for a moment in boiling water.

#### INCOME TAX.

"A. K." has paid interest for some years on a loan for the purchase of personal effects and inquires what allowance, if any, is due (a) for interest paid, and (b) for past repayments of the amount borrowed.

\* \* a) An allowance and repayment in respect of the three previous years can be claimed on the amount of interest paid

on an advance from a bank—Income Tax Act, 1918, Sec. 36. No allowance can be claimed for other loan interest; "A. K.'s" right to recoup himself for the tax is to deduct income tax from the interest as he pays it. (b) No allowance is due.

#### Car Transaction.

"C. O. M." purchased a car in 1919 for £175 and sold it in 1920 for £200, buying another for £303; he has since bought a "second" car for £650, the £303 car being retained for use when required. If the car purchased for £303 was no better in type and condition than the first car was when "C. O. M." purchased it, he can claim the net cost—£303—£220 = £83—as expenditure incurred in renewing a car in the year 1920. No allowance is yet due for the last car purchased.

"J. M. D.'s" car transactions have been as follows:

1911 bought N. for £550.  
1916 sold N. for £100 and bought second-hand A. for £220; income tax allowance £120.  
1919 sold A. for £76 and bought F. for £250; income tax allowance £174.  
1922 sold F. for £60 and bought H. for £600, and the inspector offers an income tax allowance of £140.

\* \* This case raises a point of some interest, inasmuch as the type and quality of car was reduced and has since been raised again. Obviously if "J. M. D.'s" earlier allowances were restricted—as they rightly were—to the out-of-pocket cost because some portion of the original capital expenditure was not being replaced, that unreplaced value must be allowed for on the last transaction when for the first time it is replaced. Assuming that the H. was not, allowing for the difference in period, a superior car to the N., we are of opinion that the allowance should be as follows:

Gross expenditure, excluding the original car:	£
£220 + £250 + £600	= 1,070
Deduct receipts: £100 + £76 + £60	= 236
Total expenditure (net) on car renewals	834
Allowed on first two renewals: £120 + £174	= 294
	£540

The above shows the matter as a whole; an alternative mode of statement is that the criterion of value to be replaced is £550—not £250—and that to replace that value "J. M. D." now has to spend £600—£60. The inspector's method of calculation is open to attack by *reductio ad absurdum*; suppose "J. M. D." sold his car and for a year used a cycle and hired cars, would the inspector refuse him an allowance altogether for a similar car bought the year after?

### LETTERS, NOTES, ETC.

A CORRECTION.—In the article entitled "A Coroner's Attack on the Panel System," published last week (p. 875), it was stated by inadvertence that Dr. Burges was a member of the Insurance Acts Committee.

#### CUPPING.

DR. W. JOHNSON SMYTH (Bournemouth) writes: I would like to refer those interested in cupping to the BRITISH MEDICAL JOURNAL published September 28th, 1918, wherein my invention for very efficient cupping is explained. Recently I have used a small motor to "run" the machine, leaving both hands of the operator free. The vacuum is well maintained and the cupping most effective. Messrs. Aish and Co., Electricians, Bournemouth, will supply the apparatus.

#### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 27, 30, 31, 32, and 33 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 28 and 29.

A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 215.

### SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Six lines and under	...	...	0 9 0
Each additional line	...	...	0 1 6
Whole single column (three columns to page)	...	...	7 10 0
Half single column	...	...	3 15 0
Half page	...	...	10 0 0
Whole page	...	...	20 0 0

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded. Advertisements should be delivered, addressed to the Manager, 429, Strand, London, W.C.2, not later than the first post on Tuesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive *poste restante* letters addressed either in initials or numbers.

## A Clinical Lecture ON THE PREVENTION OF HEART DISEASE.

DELIVERED AT THE HOSPITAL FOR SICK CHILDREN, GREAT  
ORMOND STREET,

BY

F. JOHN POYNTON, M.D., F.R.C.P. LOND.,  
PHYSICIAN TO THE HOSPITAL, AND TO UNIVERSITY COLLEGE HOSPITAL.

IN this lecture I will consider a question which I believe to be at present the most practical in the whole range of the study of heart disease—the possibility of preventive measures. Curative treatment for the moment is almost at a standstill. Cardiac tonics have been studied with the greatest industry; we are not likely to learn more of the value of the salicylates in heart disease than we do now, and serums and vaccines are not yet effective.

There is, however, another line of attack, opened up by recognition of the fact that, excluding congenital affections, the major part of the heart disease we meet with in the young is infective in its origin. These infections may attack the whole heart, or predominantly the valves, pericardium, or myocardium. Their relative frequency in the young is very different. Some are rare—for example, the tuberculous. Others vary in relation with epidemic waves—the diphtherial, the influenzal, and that associated with scarlet fever. Pneumococcal and staphylococcal cases are unusual in this hospital, as also the syphilitic, but rheumatic heart disease is very frequent and very constant in its occurrence. This is particularly the case in London, and it is with London I shall be dealing. At this hospital we only see children up to 12 years of age, and many cases, it is known, occur between that age and 15, so that not even here do we get a complete picture of the frequency of rheumatic heart disease in the young.

### *The Gravity of Rheumatic Heart Disease.*

It is possible to give a clear idea of the havoc acute rheumatism causes in childhood, because in 1919-20 we had a bad outbreak, and with Dr. J. C. Spence and Dr. D. Paterson I made an analysis of the cases.

We have 100 medical beds, and these are for practical purposes almost always fully occupied. The average stay of a medical case is twenty-eight days, and the cost of each child £2 9s. a week. The number of cases of rheumatism admitted in the year 1919-20 was 172, and if they are imagined as one long case it would have occupied a bed in the hospital for twenty-nine years; or putting it in another way, all our medical beds (100) would have been filled for fifteen weeks. The average stay of each case instead of twenty-eight days was sixty, and in maintenance the outbreak cost the hospital £4,589. This expenditure is, after all, the least serious result. What arrests attention is that 66 per cent. of these children had signs of organic disease of the heart, 22 cases died, and 38 became complete invalids. Undoubtedly this was an outbreak of unusual severity, but each year we have many cases, and in every London hospital where children are admitted in any numbers there is the same story.

If we study the age incidence we are struck by the early commencement of the heart disease. In this attack the limits were 2 years and 12 years, which is our age limit; thirty examples of first attacks occurred at the age of 7. As soon as the school age is reached we find a steady increase in the frequency of incidence.

On the other hand, acute rheumatism is infrequent among children, of school age, of parents who are in better circumstances than the hospital class.

### *Cardinal Pathological Facts.*

There are some points on the pathological side of infective heart disease which are simple but yet outstanding. If the poisons attack the noble tissues—the muscles and nerves of the heart—these cannot be replaced if destroyed, and if they are partially damaged can only recover completely if that damage be slight. When the fibrous tissues of the heart's framework, the valves and the pericardium, are attacked

and destroyed they are replaced by scar tissue, and if they are the seat of prolonged irritation short of destruction they thicken and contract, sometimes shutting in small areas of necrotic tissue. There are two problems before us at the bedside; one, What evidence is there of active infection? the other, To what extent are the symptoms the result of scars due to healed lesions? With these two problems in mind we rapidly come to the conclusion that in the young some degree of active infection is almost constant. It is an axiom that the chief cause for a cardiac breakdown in a child is active—I do not say fresh—infection.

Diphtheria when virulent kills the noble tissues but does not produce scarring. Contrast with this a chronic relapsing rheumatic pericarditis, where as a result a grossly thickened pericardium is densely adherent to the heart and possibly to the surrounding tissues; a still more striking example of this type of change is seen in chronic tuberculous pericarditis, which may literally strangle the heart in its grip.

Here, then, we have two extreme examples: on the one hand the destruction of the noble tissues, and on the other scarring of the fibrous tissues; but in rheumatism we frequently see a certain grade of damage produced in both—there is myocardial weakness and scarring of the valves. I do not think we can ever get a real grasp of the problem of prevention unless we keep these two classes of injury before our mind, for it is injury to the muscle of the heart which particularly calls for prolonged supervision in convalescence, and the scarred valves disturb the work of the heart as a mechanical pump.

### *Diphtheria under Control.*

When we consider diphtheria—dangerous though the cardiac infection is—we recognize that it is a contagious and notifiable disease due to an accepted microbic infection. It is a disease on the whole as well under control and supervision as we can expect in a great community. Methods for detection and for treatment may no doubt advance, but already there is general recognition of the importance of careful supervision of the heart. It is, for example, well known that dangerous symptoms are particularly likely to develop in the third to the fifth weeks, with exceptions at either limit, and we recognize that most of the tragedies occur in cases in which the nature of the infection has not been recognized and the child for that reason has escaped from supervision. These missed cases must always occur in human endeavour, and in no way alter the fact that heart disease due to diphtheria is well supervised. Tuberculous heart disease is so uncommon in this country that though we recognize it in children's hospitals it bears no relation in frequency to other tuberculous lesions, and great efforts are, we know, made to keep tuberculosis under supervision.

Scarlet fever stands in the same category as diphtheria, for it is notifiable, and every effort is made to get the cases under supervision, but much of the heart disease connected with scarlet fever has, in my experience, arisen after the child has left the fever hospital, and it must be considered in the main under the same heading as rheumatic heart disease, to which I now come.

### *Rheumatic Heart Disease.*

We are now confronted with some obvious difficulties. Acute rheumatism is not notifiable, and I am not prepared to advocate that it should be at the present juncture. The cause of acute rheumatism is still under dispute. Many consider the problem unsolved and the infection unknown; some look upon rheumatism as non-infective, though likely to be complicated by infections which determine the manifestation, and some believe with me that it is a definite infection and a definite disease. Whatever view we may take we shall do well, in my opinion, to look upon rheumatic heart disease as infective, for it behaves in every way like an infective lesion. It is not necessary for the purpose of prevention to commit ourselves to a specific infection, for the moment that rheumatism is admitted to be an infective process the importance of prevention is manifest.

### *Prevention Often Can be Only Partial.*

Unfortunately the prevention of rheumatic heart disease can be attained only in a modified degree, for frequently the patient has already been damaged, and the most we can do

then is to stave off further attacks. This limitation it is essential to recognize, for at present we are unable to control rheumatic heart disease with any certainty. Some may demur at this and point to the specific action of the salicylates, but the present history of rheumatic heart disease in childhood does not bring to me any conviction upon this point.

My views are humbler, and they rest upon the belief that there are some obviously weak points in our general management of rheumatic children which can be much improved. If this improvement is a practical undertaking we shall, I hold, prevent much severe heart disease and many deaths from that cause, and further make many lives more useful to the State and much happier for the individuals. I believe also that with improvement we shall incidentally learn more of the life history of infective heart disease, and very probably in the future discover as a result valuable data which may lead to further advances. It must be remembered that year by year ceaseless investigation is in progress throughout the world of medicine, which may at any moment lead to some new discovery in therapeutics.

#### DEFECTS IN MANAGEMENT OF HEART DISEASE IN CHILDHOOD.

I shall now attempt to justify the main theme of the lecture by referring to what appear to me the weak points in our present management of heart disease in childhood.

##### 1. Imperfection in Medical Education.

The first point concerns our own profession. There seems to me some difficulty in the pathways of students who desire to gain a real clinical insight into the rheumatism of childhood, and I am speaking as a clinical teacher both at a general and at a special hospital.

Except in the largest general hospital there is no great opportunity for a student during his time in the wards to see many cases of acute rheumatic carditis, and yet there is no doubt that at this age rheumatic heart disease requires unusually careful observation. In the adult the later and closing chapters of heart disease are seen with their alarming and striking symptoms; in the child the detection of dilatation, of early endocarditis and pericarditis—that is, the dawn of heart disease—requires close attention and some special teaching. I believe it to be correct if I say that no one in this audience who has worked in a London children's hospital will deny that he left the hospital with a very much clearer idea of cardiac rheumatism.

Yet no one can appreciate the gravity and difficulties of the problems involved in the dawn of infective heart disease who has not a good clinical knowledge of rheumatism—not only cardiac rheumatism—in childhood. Recently this weak point has been strengthened by the greater attention paid to children's disorders in the final examination, and it will doubtless lead to general progress.

##### 2. Public Ignorance.

A second and very important point is the lack of appreciation by the public of the gravity of heart disease in childhood. This, I think, can only be combated by simple propaganda and instruction. The medical profession would be much assisted by a better instructed public, as one example will show. We all recognize that early heart disease is often most insidious, occurring without pain or any striking symptom. So remarkable is this that we recognize a group of cases of primary cardiac rheumatism which may come first under our observation with very definite organic disease and yet with no data to guide us as to its exact commencement or duration. Even now, although I am well acquainted with these facts I get cases in the wards which astonish me by the severity of the lesions and the absence of striking symptoms. If we recognize that this is a difficulty, how much more doubtful must be the feelings of parents, who see their children lying in bed without pain or distress and are told that convalescence must be slow and carefully supervised! If, however, they recognize that the disease is caused by poisoning due to a microbe and that the poison softens the heart muscle, they are more likely to appreciate the necessary care when emphasis is also laid upon the fact that the entire future of the child depends upon the heart muscle becoming once more firm and strong.

The instructions I picture should be simple and terse, in the form of a printed leaflet, such as has been used in this hospital with success for many other purposes. It would be most effectual if they were issued from some official bureau, but even issued by hospitals, provided they were uniform in character, these leaflets would be very useful. At first they would probably only reach the parents of rheumatic children, but in due course they would doubtless find their way into the hands of many parents with children.

These are some of the instructions that appeal to me:

##### *Specimen of Instructions.*

1. Rheumatism is caused by infection by a microbe and is a frequent disease in large cities.
2. In children rheumatism often attacks the heart, and is the most frequent cause of organic heart disease.
3. Pains in the muscles and joints in children should receive attention as possible warnings of rheumatism.
4. Sore throats are often associated with acute rheumatism.
5. Rheumatic heart disease is often painless and requires a doctor's examination for its detection. Shortness of breath and pain over the heart require immediate attention.
6. The heart when injured by rheumatism recovers slowly from the poisoning, and one of the greatest dangers to a child's future is for it to resume an ordinary life before the heart is firm.
7. Chorea or St. Vitus's dance is rheumatism attacking the brain, and its chief danger is the tendency for the heart to be injured by the rheumatism at the same time.
8. Great nervousness, dreaming of school work, alteration in disposition, and slight twitchings are often seen before the chorea has become definite, and are warnings.
9. Rheumatism often recurs, especially in the spring and autumn.
10. An occupation in life for a child with heart disease requires careful choice.

Needless to say, if propaganda is employed the exact degree of information and the wording would be of the utmost importance. These headings are only some of my own ideas upon the subject. Able minds in this country would soon hit upon the best mode of instruction for the public if they once decided that it was the correct step to take.

##### 3. Chorea and School Teachers.

A group of the public whom I think should be particularly approached by propaganda and simple lectures are the school teachers in the London County Council schools. It is possible that such steps are taken already and have escaped my notice. The reason for this action is the great amount of chorea in London during the school age. Chorea being cerebral rheumatism, it seems very probable that this frequency is in part due to overstrain and lowering of the resistance of the nervous system to infection. Now if in private practice we find a boy or girl at a private or public school flagging in health and becoming irritable and unequal to school life, still more if we find warnings of chorea, we advise a term from school and mental and physical rest. Chorea certainly is very rare among such children.

Fortunately for the children in the Council schools, Sir George Newman has taken up their cause with a large body of skilled assistants, but the enormous machinery required for the education of these masses of children and the frequent ignorance in the homes from which they come must result in many children attending in indifferent health, and even until they have definite chorea.

##### *Possible Steps for the Prevention of Chorea.*

I see very clearly the extreme difficulties of coping with such a problem, in the face too of the continual tendency of parents and children to take advantage of any relaxation of discipline. Yet I believe three steps would help:

1. The education of parents as already indicated.
2. Simple lectures on rheumatism and chorea in children to the school teachers.
3. I venture to think that an investigation on a large scale by the school doctors into the frequency of chorea in London school children, and into their histories immediately before their actual breakdowns, would give the medical profession most useful assistance. We should get a definite idea of the magnitude of the evil, and all of us would learn facts which would stimulate us to warn parents to call attention to ill health more promptly.

I cannot say whether or not some of the actual methods of education at present may not be at fault, but it is quite possible that a careful inquiry into the approved routine and character of the teaching may also lead to some useful suggestions. Rheumatic children are very sensitive, and may feel the strain of some particular kind or way of instruction to an extent which is not realized. If, then, as I believe, it will be found that the incidence of chorea is

much too high in London, it is possible that educational experts confronted by the facts will be able to modify some methods without any serious upset to the general machinery. The subject of chorea is well worth most serious investigation.

The school medical officers carry out valuable work for the cardiac children, and we see many cases caught up by them and sent to us for treatment. In that direction there has been a distinct advance in preventive treatment which has already proved encouraging.

#### 4. A Weak Point in Hospital Treatment.

There is great need for the establishment of an auxiliary hospital near London to which we can send rheumatic children for their convalescence. Our hospital, for example, is needed for acute cases, but we know too well how wrong it is to nurse a child through an acute carditis and then to send it out with a heart still enfeebled by half-healed lesions to a poor home; in consequence we often keep these children for many weeks, and even then not long enough. Yet in private practice we should not dream of choosing a hospital ward in this part of London for a slow convalescence. We need auxiliary hospitals, because skilful supervision is required, and rheumatism is notoriously treacherous. It is not only fresh air and sun that I look for in these hospitals. Rest is a necessary part of the treatment of rheumatic heart disease; but blind unreasoning rest is bad—for there is no better tonic for the young heart than exercise, and convalescence from rheumatic carditis should be a history of graded exertion and not aimless rest. The auxiliary hospital can supervise these graded exercises with every hope of success. The ultimate goal is plain—it is to send the child back to its home with a heart strengthened to the level of carrying on ordinary life; and if that is unattainable to ascertain the limitations and advise the parents. In this country hospital it would be easily arranged in the grounds to have level paths and gradients of different degrees. There would be massage provided, and arrangements would be made for education. Such an institution must be linked with the parent hospitals, and it is essential that the medical officer should be enthusiastic in the cause and realize the essentially practical aim of such a hospital.

#### 5. Suitable Employments for Cardiac Cases.

In America the care of cardiac patients, which since 1911 has been organized on a large scale, embraces adults as well as the young. I am here only dealing with the young children, but it is clear that any undertaking of this kind should not end abruptly at the age of 12 or 14 years, and there is one connecting link with the adult which is obvious. It is evident that though many cases of simple dilatation completely recover, and many slight mitral lesions also leave the heart practically as strong as before, in general terms rheumatic affections tend to lessen the reserve power. There are necessarily all grades of weakness to complete invalidism, and I have already indicated that our endeavour, while cases are under medical care, should be to ascertain these limitations as far as possible. Much of this labour will, however, be wasted if no organized attempt is made to study the various adult occupations in relation to physical exertion, and to make a practical schedule which can be within reach of parents who are placing their children with damaged hearts in the world. I am not discussing an abstract problem as to whether overexertion can strain a healthy heart, but content myself with the obvious fact that a damaged heart may easily be brought to rack and ruin by an unsuitable occupation. We want to prevent as far as possible a boy with a damaged heart becoming a coal-heaver or furniture-mover, and to give the child every chance of being placed in an occupation which will be suitable to his or her cardiac powers. So far as I am aware, in London there has been no organized attempt made to prevent by some accessible information the loss of the skill, time, and money spent on children with acute rheumatism that must follow the undertaking of unsuitable occupations. The suffering, the loss of life, and loss to the State from such mistakes must be very considerable. Parents no doubt do in many cases realize the dangers. I admit, too, that "needs must when the devil drives" is an ever-present obstacle; but there still remain, I believe; many who would be greatly assisted if the impor-

ance of occupation was included in instructions to parents, and better opportunities given to these damaged but active workers to select suitable occupations. In America this has been carefully investigated, and suitable lists provided.

#### 6. A Central Office.

It would be necessary to have a special central office, in touch with hospitals and country hospitals, schools, and parents, where this information would be obtainable, together with propaganda and syllabuses of popular lectures. Looking far forward, it is my hope that eventually the study of rheumatism in its broadest sense will have a centre in London, in which research upon this great subject would be continuous. Divorced from the great hospitals such an institution would be a dead thing; but I can imagine this condition of affairs. A young investigator has decided to take up this subject, and goes with suitable testimonials to this headquarters for the necessary training in technique and knowledge of the literature. This accomplished, he receives an official introduction to the authorities at one or more of the great hospitals, by which he will be enabled to study the special cases upon which he is intent. Whether or not he worked in this or that hospital laboratory or at headquarters would be a matter of detail. The headquarters would be the centre for the arrangement of propaganda, lectures, etc., and would be in possession of the literature on the subject and be itself equipped with suitable laboratories. This control institute would eliminate one of the greatest obstacles to research in this country—the rivalry of the great hospitals. Search for the truth and the best requires no rivalries and no schools where one line of thought is obnoxious and another idolized. Research wants freedom. If I could live again and had a request to be granted, I would ask to be educated on sound lines in technique and literature and then be given opportunities to think my own thoughts and make my own mistakes. Then also a centre for continuous study is far less wasteful than sporadic efforts, which are often lost with the death of the investigator.

#### 7. Local Foci.

Among the factors in the prevention of rheumatic heart disease removal of suspected local foci has not yet been mentioned. Up to a certain point I am a believer in local foci of infection, but I am sure that we still want to know more about the behaviour of infections in the human body before we can be dogmatic upon their exact value. The most important local focus in rheumatic heart disease is most probably the tonsils, and for nearly one hundred and fifty years the clinical importance of tonsillitis in relation to acute rheumatism has been recognized by physicians who have paid much attention to the disease. The following is a short account of the first complete observation that showed this suspicion to be correct.

A man, aged 28, came to hospital in June, 1900, suffering from acute tonsillitis, pains in the limbs, and mitral and aortic disease with dilatation and an excited action of the heart. There was a history of previous attacks of rheumatism.

Dr. A. Paine made a culture from the inflamed tonsils in the acid milk medium we used, and twenty-four hours later a minute strepto-diplococcus in association with other micrococci had grown in the tube. These were plated out on fresh blood agar and the diplococcus isolated. This, injected intravenously into a rabbit, produced acute carditis with endocarditis of the aortic and mitral valves, and the same diplococcus was isolated from these lesions in pure culture.

Even if the conclusions from this investigation are not pushed thoroughly home, it is apparent that from a case of acute rheumatism with heart disease a strepto-diplococcus, isolated by plating from the inflamed tonsils, determined an acute carditis, even to the point of reproducing similar valvular lesions. This result, coupled with later ones from chronic tonsillitis in children and supported by the researches of Fritz Meyer in 1901, when added to the long history of clinical observations laid the foundation of the view of the infective focus which has now such far-reaching application in rheumatic affections.

Nevertheless, caution is required in pressing this point too far, for removal of the tonsils, as is now well known, does not prevent further attacks, though I have no doubt in my mind that unhealthy tonsils should be removed in rheumatic children. It would be, in my opinion, a mistake to suggest the wholesale removal of tonsils in rheumatic children and

the United States and have been so wisely utilized there, it can hardly be doubted that a considerable economic saving would accrue to the community, while to the individual patient there would be given that truest source of happiness—the increased power of exercising an activity.

For much of the information in this paper I am indebted to the kindness of the Secretary (Miss M. L. Woughter) of the Society for the Relief and Prevention of Heart Disease, 370, Seventh Avenue, New York.

## ACUTE PAN-SINUSITIS: A SEVERE CASE.

BY

SIR STCLAIR THOMSON, M.D., F.R.C.P.LOND.,  
F.R.C.S.ENG.,

PROFESSOR OF LARYNGOLOGY AND SURGEON FOR DISEASES OF THE  
NOSE AND THROAT IN KING'S COLLEGE HOSPITAL.

MANY cases of acute suppuration in the accessory sinuses of the nose never apply for treatment, the majority being looked upon as merely part of a severe "cold in the head." Of those that do come under observation some are never diagnosed, and in others the original infection is overlooked or forgotten by the greater claim of the secondary infection to which it may have given origin.

This helps to explain why many illnesses are dated, both by the public and the profession, from "a cold" or "chill." This head-cold, in such cases, may have been the primary infection, causing a sinusitis from which originated (a) symptoms in the neighbouring region (pharynx, eyes, ears, head,

Inhalations of menthol steam were frequently given. The expelled pus, examined bacteriologically by Dr. E. Burnet, produced a growth of staphylococci, streptococci, and pneumococci.

The flow of pus from the region of the frontal sinuses soon diminished and frontal headache ceased; the suppuration from the maxillary sinuses persisted, in spite of lavage; but the most persistent discharge and headache came from the sphenoidal sinuses. The sphenoidal sinusitis not only produced a bilateral parietal headache, but a still more intense ache in the typical situation of the occipital region and nape of the neck. Here the headache was so acute that we were very glad to have the opinion of Dr. Farquhar Buzzard. The sinusitis had persisted for nearly three weeks when he saw the case on November 13th. He decided that there was no invasion of the central nervous system.

During this long-drawn-out suppuration Dr. Giordani and I had been keeping a careful watch for secondary infections, but the eyes, ears, throat, lungs, heart, kidneys, and digestive tract remained unaffected. About the twentieth day the patient complained of pain on the right side of his neck, and we found the thyroid gland swollen and tender. This proved to be the beginning of the only secondary infection which the patient developed.

On November 19th—the twenty-fifth day of illness—both maxillary sinuses were lavaged and found quite clear; there was only a trace of muco-pus from the sphenoids; the headache had disappeared and the temperature was round about 99°. But the pain and swelling in the neck persisted; the temperature rose again in a few days to 103°, and, although

face), or (b) in more distant organs (lower respiratory and digestive tract), or (c) interference with general health (simulating typhoid, malaria, neurasthenia, etc.). Doubtless many a bronchitis or pneumonia, beginning with a "cold in the head," has owed its infection to pus in an accessory sinus.

It is quite uncommon for an acute sinusitis to run a course of any length without some secondary infection becoming the predominant disease. I have published two of my own cases of sphenoidal sinusitis in which death resulted with cerebral and ophthalmic complications, together with forty other cases recorded in literature.<sup>1</sup> All these forty-two cases were verified by a *post-mortem* examination.

But it is so uncommon for a sinusitis to remain acute for any length of time, without secondary infections, that I think it might be interesting to record the most severe and persistent case I have ever met with. The temperature chart alone indicates the length and severity of the resulting illness. The only complication was the rare one of an acute thyroiditis, and this did not develop until the third week of the sinusitis. (See chart.)

On October 31st, 1922, I was called by Dr. Giordani to see a foreign diplomatist. For four days previously his temperature had been raised, reaching even 104°. He looked very ill, complained bitterly of his headache, chiefly frontal, and was sweating freely. There was copious pus in both nostrils; all the sinuses were involved. The maxillary sinuses were lavaged and abundant pus expelled.

This lavage had to be repeated twelve times in sixteen days before the maxillary sinuses cleared. During this time the inflammation in the cavities was so acute that on certain occasions the abundant and clotted pus was uniformly pinkish. Discharge from the sphenoidal sinuses was encouraged by local applications of cocaine and adrenalin.

there was no definite suppuration, Mr. Legg, who had been called in consultation, thought it well to cut down and examine the thyroid gland. This was done on November 22nd—nine days after the first symptoms referable to the neck and in the fourth week of the sinusitis. The right lobe of the thyroid gland having been exposed through a transverse incision, punctures were made in various directions and the gland explored with forceps and dissector—but no pus was found. During the operation it was remarked that the connective tissues of the region were oedematous and the veins very distended. Two drainage tubes were left in place; local symptoms (pain and swelling) improved next day, and a week later pus began to escape from one tube and continued for a week, with a normal temperature (see chart). Cultures gave the same organisms as had been found in the nasal suppuration. The left lobe of the thyroid enlarged for a week—just as the right lobe was subsiding—but it caused no pain and went down in a few days.

On December 2nd, five weeks after I had first seen him, the patient was convalescent, but it was not until the end of January that he was able to come to my study for examination. Except for a little fistula in his neck no local symptoms of his severe illness remained. There was no trace of pus in his nose or throat, and transillumination of the formerly opaque maxillary sinuses showed that they were quite clear.

Although organically sound he was looking very shaky, and no wonder, for he had been a very sick man for three whole months. This prolonged illness, entailing fever, severe pain, and insomnia, had all resulted from an acute pan-sinusitis. Complications had, I believe, been averted because the case was diagnosed early and treated seriously. The local treatment has been described. The regular lavage

of the maxillary sinuses prevented stagnation in these cavities and its consequent back-pressure and reinfection of the deeper sinuses. The frontal sinuses drained spontaneously and were the first to clear. The drainage from the sphenoidal sinuses was encouraged by daily, or twice daily, introduction of strips of gauze (between the middle turbinal and septum) soaked in equal parts of 5 per cent. cocaine and adrenaline. I was very glad that I had refrained from any operative treatment on these deeper cavities. The traumatism entailed might only—in such an acute infection, and in the narrow and sensitive nose—have resulted in further blockage to the outflow and might possibly have spread infection to other areas through the blood or lymph streams. Pain, insomnia, fever, and other symptoms were treated on general principles. Local warmth (by woollen nightcap and radiant heat) gave relief.

I have never seen a fatal case resulting directly from acute sinusitis, diagnosed in good time, and treated on the lines described in this paper. In the two fatal cases of sphenoidal sinusitis which I have referred to, secondary infection of the meninges or cavernous sinus had developed before the patients came under observation.

The care taken of the present case was successful in fending off all complications, except the curious acute thyroiditis. This, I imagine, was an infection via the lymphatics, from the pharynx or tonsil, due to the pus descending from the sphenoidal sinuses.

The moral I venture to draw from this case is that all cases of acute sinusitis should be regarded with much more consideration than they generally receive. If carefully treated there are very few which would not recover completely. Most of the chronic cases seen in practice and requiring operative treatment commenced originally as acute cases. Had they then been treated carefully, they would not have drifted into the chronic infections which entail so much ill health and often demand prolonged attention and sometimes anxious operative measures.

The treatment of acute sinusitis is largely in the hands of the family physician. Except for exploratory puncture and lavage of the maxillary sinuses, operative treatment is rarely called for in an acute case.

## OPTIC NEURITIS OF SPHENOIDAL SINUS ORIGIN: OPERATION: CURE.

(With Special Plate.)

BY

SIR STCLAIR THOMSON.

THERE are various causes of retrobulbar neuritis. I am able to give a very full report of a case in which the onset of this affection was rapid and the cause was undoubtedly suppuration in the sphenoidal sinuses.

*Previous History.*—A young man of 24 reported that, as a boy, he had worn glasses, but that on joining the army, during the war, he was told that glasses were not necessary. He served for three years in the army, chiefly on the Italian front, and during his service he developed a yellow-green post-nasal catarrh with occasional cacosmia. After demobilization in 1919 he noticed that he had more need of handkerchiefs and had to

the left sphenoidal sinus, owing to the prominence of the middle turbinal. There were numerous carious teeth, and the patient was at once sent to Mr. W. Hern for attention to them.

*Ophthalmic Report.*—On the same day he was examined by Mr. Treacher Collins, who reported as follows:

"Has had aching pain in left eye for three days, which then ceased. Eyeball still tender to pressure, but not so much so as at first. Experiences sharp pain on movement of his left eye upwards. Vision of right 6/9 partly; -1 cyl. 120°=6/6; 1 letter. Left 6/60 unimproved. Left pupil acts to light but does not maintain contraction 'hippus.' Ophthalmic examination shows marked swelling of the left optic disc, blurring of its margins, and obscuration of retinal vessels. The swelling of the disc = 6 D. Right optic disc normal. Field of vision in left eye somewhat contracted up and in (vide Chart 1)."

## Treatment.

The same evening the patient entered a nursing home, where he was given radiant heat baths to his head, for twenty minutes three times a day, with steam inhalations of menthol and eucalyptus every two hours, and a few doses of aspirin. The

CHART 1.—Optic neuritis of sphenoidal sinus origin. November 28th, 1922.

wash his nose out. When fatigued he was subject to headache over the left eye.

*Sudden Onset.*—On November 20th, 1922, while on business in Germany, he felt depressed all day, and in the evening was surprised to find that he could not see anything clearly from the left eye. He consulted Professor Römer of Bonn on November 23rd, who found that there was inflammation of the optic nerve of the left eye, negative Wassermann reaction, and that an x-ray photograph showed some opacity of the accessory sinuses. A written report advised that the trouble was serious and threatened the eyesight, and that it was a question for a rhinologist whether the condition would abate with conservative treatment or require operation on the sinuses.

*Nasal Condition.*—On November 28th I found pus on the floor of each nostril and the roof of each choana. Exploratory lavage of the maxillary sinuses showed them to be clear. X-ray examination by Mr. Coldwell revealed marked obscuration of the frontal and sphenoidal sinuses. It was impossible to catheterize

CHART 2.—Optic neuritis of sphenoidal sinus origin. February 17th, 1923.

left eye was kept covered so as to exclude all light. This treatment was continued for three days, but, as there was no improvement in his eyesight, I proceeded to operate on the sphenoidal sinuses on December 2nd.

*Operation.*—The area of the nose was prepared half an hour beforehand with strips of ribbon gauze soaked in equal parts of 5 per cent. cocaine and adrenaline, and tucked in between the middle turbinal and the septum. This rendered the nose so ischaemic that, when placed under a general anaesthetic, it was not difficult to introduce Killian's long duck-billed speculum between the septum and the middle turbinal, so as to snap and prise outward the latter body. This proceeding avoided the removal of a healthy and useful middle turbinal, with the traumatism attendant on its amputation. The ostium of each sphenoidal sinus was then well opened with punch forceps.

*Immediate Results.*—Four days were allowed to elapse for the nose to recover from the inevitable reaction. During this time there was no change in the eyesight, although the treatment

by radiant heat, steam inhalations, and rest was continued. On December 6th both sphenoidal sinuses were washed out with warm normal saline, and the patient at once noticed a remarkable improvement in his vision. Two days afterwards Mr. Treacher Collins reported:

"Vision of left eye = 6/18. Still much swelling of the optic disc. White lines in the retina to the outer side of the optic disc."

**Progress.**—Daily lavage of both sinuses was continued, clotted yellow pus being expelled. On December 20th the radiant heat baths were given up; the patient was sent out into the fresh air, and the washing of the sinuses was continued every two or three days. The discharge was examined bacteriologically and reported to contain—

"a large number of Gram-negative bacilli with a small number of cocci and diphtheroid bacilli. On culture these proved to be the pneumobacillus of Friedländer, *Staphylococcus aureus*, and a diphtheroid bacillus of the Hoffmann type."

Progress was continuous. By January 2nd Mr. Treacher Collins reported:

"Vision of left eye = 6/9 partly. Swelling of optic disc = 1.5 D. Two white dots now only seen in retina."

By January 16th he thought the swelling of the disc was less, and no retinal changes.

**Cure.**—By February 17th his report was as follows:

"Vision of his left eye is now better than that of his right. With -0.5 cyl. 90° he sees part of 6/6 and reads J.1 fluently. His field of vision shows only very slight contraction up and in (vide Chart 2). The swelling of the optic disc has subsided, but it still presents rather ill-defined margins, and has a filled-in appearance, no sign of physiological cup showing. The retina is quite clear."

The sphenoidal cavities had been washed out at decreasing intervals, and their interior had occasionally been painted with 25 per cent. argyrol. All suppuration in them has now ceased; the greenish-yellow post-nasal discharge has disappeared, and, as a result, the patient has gained in weight and feels better than he has done since the war.

In 1906 I published two cases in which I was able to demonstrate by *post-mortem* examination that ophthalmic complications (hazy discs and diplopia in one, with optic neuritis and complete ophthalmoplegia in the other) were due to suppuration in the sphenoidal sinuses.<sup>1</sup> This led me to a study of the literature of the subject, and I was surprised to find no fewer than forty other cases in which it had been shown by *post-mortem* examination that sphenoidal sinusitis had been the cause of cerebral death. Many of these cases had been accompanied by orbital or ophthalmic symptoms, and changes in the fundus had been noted in half of them. Fortified by this research I ventured to urge that "in all cases of apparently inexplicable retinitis, papillitis, and optic atrophy the nose requires exploration."

In the eighteen years which have since elapsed I have had a good many cases referred to me. In the majority, I must confess, I found no symptoms of suppuration in the sphenoidal or other accessory sinuses to explain fundus changes. On the other hand, in cases of affection of the orbit (so-called "orbital phlegmon," unilateral proptosis, etc.) the *causa causans* could, in the large majority of cases, be found in the nose or its accessory sinuses.<sup>2</sup> This led to my forming the opinion that while the nose was frequently the source of orbital affections, yet retinitis, papillitis, and optic atrophy were only rarely caused by sepsis in the accessory sinuses. In this opinion I was confirmed by certain cases of retrobulbar neuritis in which I opened the sphenoidal sinuses and found them free from suppuration. The observation that, in many of these cases, the neuritis disappeared only made me think that the cause of it must have been elsewhere. I did not think of claiming the cure as a consequence of opening a healthy sinus.

But, lately, other views have been put forward. It is now held that "the mere presence of pus in the sinuses may undoubtedly be the cause in some instances, but is by no means the usual or only one"; that "in only a small percentage of cases has pus been found"; and that "deflected septa with crowding of the chronically enlarged middle turbinate are the most usual findings."<sup>3</sup> We are even assured that "poor ventilation and faulty drainage are all important predisposing factors," and that "it is futile to longer believe purulent sinus disease the one and only etiological factor."<sup>4</sup> Quite recently nine cases of retrobulbar neuritis were treated by sphenoidal drainage.

In only one case (sixteen months' duration) no improvement had resulted. Yet in only two out of these nine cases was pus found.<sup>5</sup>

These and similar records would seem to warrant the exploratory opening of the sphenoidal sinuses in cases of retrobulbar neuritis, even in the absence of evidence of suppuration in these cavities or the neighbouring ethmoidal cells—when no other cause for the retinitis can be found, and the patient is threatened with blindness.

To suggest the opening of healthy accessory sinuses is a doctrine not altogether free from danger. I have been associated with cases of retrobulbar neuritis which recovered without operation on an accessory sinus and without any definite diagnosis of the cause of the condition. I would like to learn more of the disease from ophthalmologists and to hear from them what is the usual prospect of recovery. It seems a subject very suitable for a joint discussion from this point of view.

In any case, there can be no question as to our duty in opening and draining suppurating sphenoidal sinuses when associated with optic atrophy. In the case reported above operation was strongly recommended by two distinguished ophthalmic surgeons, and it had a double benefit—it averted blindness, and cured the patient of a chronic suppuration which had been poisoning him for some years.

## CYST OF THE RIGHT SUPRARENAL CAPSULE REMOVED BY OPERATION.

BY

SIR HAMILTON A. BALLANCE, K.B.E., C.B.,  
M.S., F.R.C.S.,

SURGEON, NORFOLK AND NORWICH HOSPITAL.

(With Special Plate.)

AN operation for the removal of a cyst of the suprarenal capsule is a rare procedure, and a cyst of this organ large enough to produce pressure symptoms is very uncommon; the following case, therefore, seems worth recording.

In August, 1921, I saw, with Dr. Wortley Quait of Mundesley and Dr. Burton-Fanning of Norwich, a lady, aged 49, who for many years had suffered from "indigestion." The trouble had been much worse for the last five years and was mainly characterized by pain in the back passing round the waist to the epigastrium. The pain had no relation to meals, and would often come on at night, when a little food would bring relief. Of late the diet had chiefly consisted of fish and milk foods, and there had been much flatulence and some loss of weight. The patient had been back wards and forwards between this country and the tropics for twenty years, and often when abroad she would be quite free from indigestion troubles for six months at a time. For the last six weeks there had been frequent vomiting, but a week might pass without any sickness, and after such an interval the patient would bring up a considerable quantity. There had never been hæmatemesis. Constipation had been very troublesome. The stomach was seen to be distended and visible peristalsis was present; there was no tenderness anywhere and no tumour could be felt. An x-ray examination showed that even after eight and a half hours a bismuth feed had not entirely left the stomach.

#### First Operation.

The abdomen was opened and an old ulcer of the first part of the duodenum, just beyond the pylorus, almost encircling the bowel and narrowing it, was found. The stomach was dilated and hypertrophied. A posterior gastro-jejunostomy was performed and the appendix removed. The gall bladder was healthy.

During the examination of the abdominal contents a large cystic tumour was found in the right hypochondrium occupying the cavity of the diaphragm and pushing the liver to the left and downwards, so that the gall bladder was in the middle line of the body and the edge of the right lobe of the liver on the level of the umbilicus. The kidney was displaced downwards, but the cyst was only slightly attached to the upper pole of this organ. At the conclusion of the gastro-jejunostomy it was deemed advisable to defer the removal of the cyst, and the abdominal wound was therefore closed. The patient made a satisfactory recovery from the operation, and examination of the right side of the abdomen a few weeks later did not reveal any abnormal swelling.

SIR STCLAIR THOMSON: OPTIC NEURITIS OF SPHENOIDAL SINUS ORIGIN.

Skiagram showing condition of sphenoidal sinus before operation. Inset: Sketch showing the relation of the parts. T, Sella turcica. S, Sphenoidal sinus. E, Perpendicular plate of the ethmoid.

SIR HAMILTON A. BALLANCE: CYST OF RIGHT SUPRARENAL CAPSULE REMOVED BY OPERATION.

Fig. 1.—Cyst as seen from the front. The yellow nodules described in the text are seen scattered over the cyst wall, and some of them are marked with crosses. The main mass of the suprarenal capsule is at the upper part of the photograph on the left side.

Fig. 2.—Section of cyst wall, low power. There is a layer of fibrous tissue on the outer and inner sides of the section. In the outer half of the wall are seen the glandular cell elements. The inner surface of the cyst at the bottom of the photograph is lined by a layer of flattened cells. Blood vessels are seen cut across in the wall of the cyst.

Fig. 3.—Section of portion of the cyst wall under a high power, showing adrenal cells; many have degenerated.

SIR G. LENTHIAL CHEATLE: EARLY AND CURABLE DISEASE OF THE BREAST.

Fig. 1.—Photograph of a plugged mammary duct outlet. A is a sebaceous island, the duct of which can be seen opening into the mammary duct outlet. At is another sebaceous gland. B marks the opening of the duct outlet on the surface of the nipple. C is the duct opening into its subject; the lumen of the duct is clearly seen to be quite patent.

Fig. 2.—A lower power drawing from a section showing a mammary duct A, and its outlet on the surface of the nipple. Sebaceous glands are opening into the duct outlet. There is here seen to be a perfectly clear pathway for many kinds of irritating agents. The dilatation at the outlet is normal. B shows another outlet to the subjacent duct C.

in the right hypochondrium. The cyst appeared to be wholly in the hollow of the diaphragm and could not be felt below the costal margin during inspiration.

#### Second Operation.

Three months later the patient was again seen, as she had been complaining of distension and sense of pressure in the right loin, and by this time the right side of the abdomen was distinctly fuller than the left and dull on percussion. A large, smooth, ill-defined swelling could just be detected coming down from under the right costal margin on inspiration, and the right kidney could be felt in the iliac fossa.

With the patient on the left side an incision was made below the twelfth rib and the cyst exposed. To assist in its removal it was tapped, and was then peeled off from the surrounding tissues, to some of which, notably the peritoneum and the tissues in the neighbourhood of the vertebral bodies, it was very adherent, so that enucleation took a considerable time. The cyst separated easily from the kidney and it was not adherent to the liver. A very large cavity was left, occupying the arch of the diaphragm behind the peritoneum, which was not opened. Temporary drainage was allowed for and the rest of the wound closed.

Convalescence was uninterrupted, but at the second operation it was felt that, in view of the very firm adhesions of the cyst wall to its surroundings, it was fortunate that the removal of the cyst had not been attempted at the time of the gastro-jejunostomy.

#### Examination of the Cyst and its Contents.

The cyst contained two and a half pints of thin, amber-coloured, odourless, turbid fluid, which was neutral in reaction and became solid on boiling owing to its albuminous contents. It was estimated that the cyst, before tapping, measured 9 by 6 inches; the wall varied in thickness from one-eighth of an inch to that of a sheet of writing paper. The outer surface was smooth except where the adhesions had been dense, and irregularly distributed on the surface, especially over the lower part of the cyst, were slightly raised yellow nodules varying in size from a quarter to a sixteenth of an inch, which can be seen in the photograph (Special Plate, Fig. 1). Similar nodules have been noticed on cysts of the suprarenal capsule removed by other surgeons.

The inner surface was rather rough, yellowish-pink in colour, and, in places, covered with a white sebaceous-looking material. Some of the fluid from the cyst was forwarded to the Clinical Research Association so that it might be tested for adrenaline. The report received was as follows:

"We have carried out the only tests which, as far as we can ascertain, will assist in confirming the epinephric origin of the cyst. Chemically, the phosphotungstic acid test gives a faintly positive reaction for adrenaline. A similar positive might be given by uric acid. But by other tests both this substance and urea have been proved absent.

"The physiological tests (ciliary reaction and direct application under the microscope to the vessels of the mesentery of a pithed frog) both give a definitely, if weakly, positive reaction when the fluid is used. There is, in both instances, a specific sympathetic stimulation evidently due to some constituent of the fluid. As controls in these last experiments normal saline and a 1 in 5,000 solution of adrenaline were used, and we think there is considerable evidence that adrenaline is present in small amount of the cyst fluid. There are no cytological abnormalities, a few leucocytes and very occasional red blood cells only being present."

Sections of the cyst wall were made through some of the yellow nodules, and I am greatly indebted to Dr. Donald Hutchinson of Lowestoft for the beautiful microphotographs here reproduced. The section of the cyst wall under a low power (Fig. 2) shows adrenal cortical cells embedded in its outer half. There is a fibrous layer in the cyst wall externally and internally, and the inner surface is lined by a layer of flattened cells. The high power (Fig. 3) shows that many of the glandular elements in the cyst wall have degenerated.

Doran, in 1908, described a case of cyst of the left suprarenal capsule, in a woman of 62, which he removed by operation. The tumour was over 4 inches in diameter and contained about half a pint of thick blood-stained fluid. The specimen is in the Royal College of Surgeons Museum, where one or two similar specimens can be seen. He gives references to cases recorded in literature up to that date; further references are found at the end of this paper.

The size of these cysts varies considerably: Rolleston described one of the size of a cherry, and in Hartwell's case three quarts of dark reddish-brown fluid were removed.

#### PATHOLOGY.

Much has been written as to the true nature of cysts of the suprarenal: cystic adenomata, glandular cysts, serous and lymphangiomatic cysts, cysts depending for their origin on a primary haemorrhage into the gland (pseudocysts) have all been described. Terrier and Lecène give a useful classification in their paper. It is difficult to be positive as to the exact method of origin of the majority of these cysts as, when removed, they are often of large size.

Unless haemorrhage takes place into adrenal cysts in the course of their growth, the fluid will be found to be of an amber colour, as in the present instance; but, according to the records, haemorrhage occurs very frequently as these cysts increase in size, and this accounts for the dark reddish-brown contents usually found. Partly decolorized clots are often found adherent to the inner surface of the cyst. Haemorrhages into the adrenals have been found in the newborn, and Beadles has described extensive haemorrhages into these glands among inmates of asylums. Cysts of the suprarenal are found in the lower animals. It is well known that persons can remain in apparent good health in spite of the loss of one suprarenal capsule.

#### SYMPTOMS.

Unless haemorrhage occurs into a suprarenal cyst it may grow until it reaches a considerable size before giving rise to any symptoms which cause a patient to seek advice. There may be only a sense of fullness in the side or vague dyspeptic symptoms without any pain; but, if haemorrhage takes place, then pain may be very severe and the patient may become seriously ill. The rate of growth may be very slow unless haemorrhages recur.

#### DIAGNOSIS.

These cysts are most likely to be confused with tumours or enlargements of the kidney. It is remarkable how they tend to remain under cover of the costal margin in the hollow of the diaphragm until of large size, when they may be detected by palpation during inspiration. The kidney may often be felt below the cyst and then the diagnosis is much less difficult. Mobility from side to side is greater than from above down, and, as the cyst enlarges, it pushes the kidney downwards. A right-sided cyst pushes the liver towards the left; a left-sided one displaces the spleen and the tail of the pancreas. The size of the suprarenal may be so large as to extend across the abdomen to beyond the middle line and to reach downwards to the anterior superior iliac spine; the colon is pushed forwards, and the lower ribs may be bulged outwards. A hydatid cyst of the left lobe of the liver should be easily diagnosed from a right-sided adrenal cyst. One of the right lobe may cause great difficulty in diagnosis unless suppuration in the hydatid occurs, when other symptoms may arise which will make the diagnosis clear. A hydatid cyst of the spleen is much more mobile than a left-sided adrenal cyst. A pancreatic cyst is usually more centrally placed in the abdomen, and pathological examinations of the urine and faeces should aid the differential diagnosis.

#### TREATMENT.

Complete removal of the cyst is the right treatment to adopt and can usually be carried out. Some surgeons have explored these cysts through an incision in the rectus muscle or through one parallel to the costal margin. Difficulty has then been experienced in detaching the cyst wall from the structures in the neighbourhood of the spine, where it is usually most adherent. In these circumstances, after the removal of the anterior portion of the cyst wall, an attempt has been made to drain the posterior part through the anterior incision, with, in some cases, disastrous results because the attachment of the cyst to the edges of the incision has broken away.

Most surgeons who have tried a lumbar incision below the twelfth rib, as used for exploration of the kidney, have been quite satisfied with it, and I would suggest that it is the best to use. It can be extended forwards as far as necessary and, if thought desirable, the twelfth rib can be removed, as is not infrequently done in the course of a difficult kidney operation.

Evacuation of the cyst materially assists enucleation, and the lumbar incision then gives ample room and a full view during the dissecting away of the deeper portion of the cyst wall, which is the part of the operation where serious difficulty may be encountered.

Further, if for any unforeseen reason, such as dense adhesion to very important structures, or a sudden serious

condition of the patient, the deepest part of the cyst wall cannot be removed, then drainage through a lumbar incision presents no difficulty.

## EARLY AND CURABLE DISEASE OF THE BREAST.

BY

SIR G. LENTHAL CHEATLE, K.C.B., C.V.O., F.R.C.S.,  
SURGEON AND LECTURER IN SURGERY, KING'S COLLEGE HOSPITAL.

(With Special Plate.)

SINCE the publication of my article on the proemial breast in the *BRITISH MEDICAL JOURNAL* of June 3rd, 1922,\* I have gained valuable information on the interpretation placed upon it by many of my readers. They have asked whether the breasts of patients whom they have sent to me were in what I termed the proemial state. From them I have been able to select instances of diseased breasts in stages which, under proper treatment, can be saved from becoming examples of the established proemial condition.

The most typical conditions of an early and curable disease are exemplified in one of my own patients. She was 26 years old, single, by occupation a saleswoman. At the time of the consultation her tongue, teeth, tonsils, bowels, and urine were normal. The breast had not been injured by a blow, and her stays were not high enough to touch it in any position which she assumed. The left breast was normal. She had complained of pain in the upper and outer segment of the right breast for three and a half months; the pain was increased at the time of her periods.

Palpation revealed an irregularly swollen duct which could be traced from the ampulla in the areola region to the part towards the periphery, where the gland was more tender than elsewhere. On observation of the nipple three minute raised yellowish dry spots could be seen, situated at the upper and outer margin of the nipple, and I concluded that probably one of them was the exit of the duct which belonged to the affected segment of the breast. I believed them to be points of exit of ducts which were plugged with dry epithelium and excretions, either from the breast or from the sebaceous glands which open into the outlet of the duct (Special Plate, Fig. 1). Acting on this belief I advised the woman to carry her arm in a sling and to put hot fomentations on the breast; but the most important part of my treatment was to make sure that she constantly soaked the nipple with hot sterilized water applied with cotton-wool. This treatment was continued for fourteen days until the plug in the outlet of each duct was macerated enough to enable me to remove it by wiping away the film that covered it, and by gentle pressure to squeeze it out. In two months the breast gradually became normal. I then advised her to keep the nipples clean always, by means of the same process, and to avoid all kinds of soap, powder, methylated spirit, hydrogen peroxide, and so on, for fear of irritating or plugging afresh the outlets. If soap be not properly washed away it dries and cakes and fills the outlet. In addition to this it must be realized that soaps are irritating and some brands more so than others.

My interpretation of the state of affairs in this woman's breast was as follows. The presence of the plug was detrimental in many possible respects—for instance, as an irritant it might have encouraged the local action of non-virulent micro-organisms upon the epithelial lining of the duct outlet, and in consequence the whole duct might have suffered a mild infection, or the products of a mild infection might have been disseminated in the same directions. The observations of Mr. A. J. Walton in 1914 and 1915<sup>1</sup> and those of Dr. A. H. Drew<sup>2</sup> suggest another possible explanation—that the products of epithelial irritation created by the plug in

the duct outlet caused changes in the epithelium throughout the distribution of the duct and acini. My belief is that the change was probably a desquamative hyperplasia of epithelium which distended this duct and caused the woman pain. I further believe that similar treatment applied to the breast in this early stage of disease will prevent it from becoming an established proemial breast. Thus the prevention of disease in the care of the breast can be taken a step further back than the proemial state.

Many authorities seem able to connect changes in a sebaceous gland with plugging at the outlet of its duct, but do not seem able to connect changes in the breast with a plugged outlet of a mammary duct. I do not understand why there should be this difference, and it is all the more incomprehensible when it is realized that many sebaceous ducts open into the outlets of a mammary duct (Fig. 2), so that any detrimental discharge from these sebaceous glands would open direct into the mammary duct at this point. In addition to this anatomical feature, there is this fact: in a previous article on cysts and primary cancer in cysts of the breast,<sup>3</sup> I pointed out the consummate case with which foreign material is distributed throughout the ducts of the breast when once entrance be gained. Further, to show what a definite pathway for entrance there is, I draw attention to the anatomical section in Fig. 2, which shows a complete duct in the nipple and the outlet on the surface. The duct lumen is seen distinctly throughout its course. The duct widens at its outlet, into which enter the openings of many sebaceous glands. To all intents and purposes each duct system of the breast may be regarded as a separate gland. This notion may create a doubt in the minds of those authorities to whom I have alluded.

It is essential that women should keep these duct outlets free from plugs. I say this for another reason: I have in my possession whole sections of a breast affected with the earliest Paget's disease of the nipple I have seen. Only half the top of the nipple is affected by the disease. There is no carcinoma in the deeper parts of the breast. The main focus of the disease is in a plugged duct outlet, from which the process is spreading into the duct and on to the surface of the nipple. Epithelial cells are invading deeper tissues and have entered lymphatic vessels. It is a typical case of Paget's disease of the nipple, and this section, together with many other reasons, convince me that Paget's disease of the nipple is carcinoma from the beginning. This is another investigation, on the writing of which I am at present engaged. I mention it here to emphasize the importance of keeping duct outlets clean and free from irritating agents.

## POLYTHELIA.

BY

R. DOUGLAS HOWAT, L.R.C.P., L.R.C.S. EDIN.,  
L.R.F.P.S. GLAS.

CASES of polymastia (supernumerary breasts) are not uncommon. Goldberger<sup>1</sup> makes mention of some 262 such cases. Williams (Baltimore)<sup>2</sup> says: "Probably one in every few hundred women has one or more accessory breasts," and points out that the condition is usually regarded as an atavistic reversion, though it is not associated with any increased tendency towards multiple pregnancy. Ahlfeld,<sup>3</sup> on the other hand, holds that the distribution of the mammary tissue is to be attributed to the transference at an early period of development, by means of the amnion, of some of the cells which ordinarily go to form the breasts to other

\* See also the *British Journal of Surgery*, April, 1923, p. 436.

portions of the body. When polymastia occurs the supernumerary nipples are usually functionless. In numerous instances an hereditary influence has been traced.

Polythelia is a very much rarer abnormality. In fact, with the exception of occasional allusions to the condition, I have been unable to find any report of an authentic case in medical literature. In November, 1921, I reported in this JOURNAL a case of polythelia, in which the accessory nipple functioned; it occurred in my private practice. Since then I have been fortunate in securing the accompanying plate illustrating the case.

The woman, a primipara, aged 23, first recollected noticing the accessory nipple in early childhood and regarded it as a fleshy mole. It is about the size of a sixpenny piece, and is situated close to the left mammillary line in the inferior half of, and towards the periphery of, the left breast. It resembles the normal nipple of the same breast in everything but size, possessing lactiferous ducts and erectile tissue.

Even Montgomery's secondary areola is faithfully reproduced. There is no macroscopical evidence of a supernumerary breast. The right and left breasts are symmetrical except for the small accessory nipple on the latter, and no

demarcation of the gland tissue could be distinguished by inspection or by palpation. The condition has caused the woman no discomfort other than that, during the period of lactation subsequent to her pregnancy three years ago, there was a very free secretion of milk from the secondary nipple as well as from the normal nipples, the medical practitioner then attending her having dissuaded her from nursing the child.

There is no evidence of any hereditary influence. The woman, who is one of a family of

eleven children, is the only one exhibiting this abnormality.

## Memoranda:

### MEDICAL, SURGICAL, OBSTETRICAL.

#### ACUTE OEDEMA OF THE LUNGS.

ACUTE oedema of the lungs is one of the most striking and terrifying emergencies with which the practitioner may be called upon to deal. The most tragically celebrated case on record is that of Charcot himself. During a journey he was seized with a sudden attack of suffocation, expelled a quantity of frothy albuminous fluid, and died in half an hour. Often the sufferer is dead before the doctor gets to him, and is found lying with an abundant frothy pinkish exudation filling the mouth and nose.

On February 23rd, 1923, on the R.M.S.P. *Desna*, I was called hurriedly about midnight to a gentleman taken suddenly ill. During the evening he had been well, dining in the saloon with the rest of us. I did not know then that he had not been in good health, but learnt subsequently that he was suffering from arteriosclerosis, or what I would prefer to call cardio-vascular breakdown.

On reaching the cabin I found him standing up struggling for breath, and bringing up an enormous quantity of frothy soap-sudsy expectoration, coughing it up, and brushing it away from his nose and mouth with his fingers. There was no time to make exhaustive inquiries; but his wife said he was 56, and that it was his first attack. The pulse was small and rapid, and owing to the râles in the chest the heart sounds could not be heard. Even during this rapid examination he became very much worse, and it was clear that unless something was done quickly the first attack would also be the last. I ran to the surgery for a knife and a bandage, picking up a steward on the way to help me. On again reaching the cabin the patient had fallen back exhausted but was still conscious. We put the bandage round his right upper arm, and cut across the first vein easy to get at. This was probably the anterior ulnar; the branches of the median are best avoided when in a hurry. He bled freely, the blood being at first very dark, although his face was pallid. I bled him well over a pint, and it was most gratifying to watch the change. The vivid colour and dyspnoea disappeared, the expectoration gradually ceased, and his dreadful anxiety passed off. At the end of the bleeding breathing, colour, voice, mental attitude, and pulse were all reassuring. It was surprising how the pulse improved; it was not necessary to inject camphor. Incidentally, why is camphor in oil so much used, when a saturated solution of camphor in alcohol is so much more convenient? I have used the latter for years and never found any disadvantage, and a much larger dose can in this way be given.

The patient did well afterwards; he was kept rigidly in bed on a spare milk diet until Liverpool was reached.

Neither the diagnosis nor treatment was difficult. As to the former, asthma, cardiac dyspnoea, angina pectoris, and pulmonary infarct might occur to one's mind, but the extraordinarily abundant frothy expectoration, coming on quite suddenly, was decisive. The acute oedema is evidently due to a condition of vascular engorgement in the pulmonary area, and partially draining the systemic veins gives the right ventricle time to deal with it.

VINCENT Moxey, M.R.O.S., L.R.C.P.,

Southampton.

Surgeon, Royal Mail Steam Packet Company.

#### SINUS THROMBOSIS FOLLOWING PNEUMONIA IN AN ADULT.

THE following case appears to be of interest on account of the difficulty presented in the diagnosis, and because the condition is unusual in the adult.

A woman, aged 35, was admitted under Dr. A. Stanley Barnes on April 11th, 1923. A letter from her doctor explained that on March 31st she was taken ill with symptoms referred to the respiratory system, and that when he saw her for the first time, on April 2nd, she had a dry cough and pleuritic pain in the left side. Next day it was evident that she had lobar pneumonia affecting the left base. The crisis occurred on April 7th; on April 9th the temperature, pulse, and respirations were normal and the patient felt so well that she asked to be allowed to get up. During the following night, however, she complained of severe headache and vomited several times; early next morning, while sitting up in bed, she had an epileptiform convulsion which left her with left hemiplegia.

On admission, some twelve hours later, she was in a semi-comatose condition, but could be roused sufficiently to speak a few words. The temperature was 97°F., the pulse 48, and the respirations 20. There was left hemiplegia with an extensor plantar reflex on that side, while the other plantar reflex was flexor and both knee-jerks were somewhat brisk. There was complete incontinence of urine. There were no retinal changes suggesting vascular disease, and except for the brachycardia no abnormality in the circulatory system was detected. The lungs also appeared normal.

A diagnosis of cerebral embolism was made, although it was realized that this would not account for the headache and vomiting prior to the convulsion.

On April 12th, about twenty-four hours after admission, she suddenly became worse. The face was flushed, the breathing stertorous, the coma more profound, and some weakness with an extensor reflex appeared on the right side. Lumbar puncture was performed, and 50 c.cm. of fluid under considerable pressure and deeply tinged with blood were withdrawn. On April 13th the temperature had risen to 100.5°, and lumbar puncture again yielded a blood-stained fluid. It was concluded that haemorrhage had taken place at the site of embolism.

The condition of the patient rapidly grew worse, the temperature fell below normal, the pulse rate rose to 136, and death occurred the same night.

At necropsy the heart (300 grams) was found soft and flabby, and considerable fatty infiltration was present in the muscle of the right ventricle. There was a slight degree of mitral stenosis, but no thrombi were present in the auricles and no vegetations on the valves. The aorta was normal. The lungs were intensely congested and oedematous. There was extensive *ante-mortem* thrombosis in all the dural sinuses and in many of the cortical veins, especially near the vertex. The surface of the brain was intensely congested and a considerable amount of free blood was seen in the meshes of the pia arachnoid. On section large areas of brain substance showed the condition of red softening. The largest, on the right side, involved the optic thalamus, the genu of the internal capsule, the lenticular nucleus, and the caudate nucleus, so extending into the lateral ventricle. A second area, 1 inch in diameter, was situated in the right frontal lobe, while yet a third affected

the left caudate nucleus. Small petechial haemorrhages in the substance of the brain and thrombosis of the veins of Galen completed the picture.

## Reports of Societies.

### RENAL INEFFICIENCY.

A MEETING of the Cardiff Medical Society was held on May 8th, with the President, Professor E. J. MACLEAN, in the chair, when Dr. R. CAMERON read a paper on renal inefficiency and its clinical detection.

Dr. Cameron limited the scope of the subject to the inefficiency associated with chronic nephritis, into the pathological and clinical classification of which he entered in some detail. Discussing the diagnosis of chronic nephritis, he pointed out the necessity for investigating the presence, severity, and progress of general clinical signs, renal symptoms, such as dropsy and uraemia, cardio-vascular symptoms, especially high blood pressure, in addition to carrying out examination of the urino and certain renal efficiency tests. The general clinical symptoms to be noted were weakness, loss of flesh—which might be masked by oedema—severe headaches, vomiting, and gastro-intestinal symptoms, recurring attacks of bronchitis and oedema of the lungs, with shortness of breath. In addition, there might be added symptoms indicative of kidney mischief—for example, dropsy, uraemia, and cardio-vascular changes; retinitis was present in 15 to 20 per cent. of cases. While the time-honoured clinical methods were still the sheet anchor in the investigation of the presence and gravity of renal disease, a most important new field had been opened up by the introduction of certain chemical tests—chiefly the diastase test, the urea concentration test, the blood urea test, and the urea concentration factor. In regard to treatment, it was important never to overwork a diseased organ. In renal disease the teaching had been to deny almost entirely protein food, since the kidneys were the organs which were chiefly responsible for nitrogenous excretion. In acute nephritis, where the functions were almost entirely suspended for a limited period, it was reasonable to carry out that rule; but in the chronic interstitial kidney—the azotaemic type—the kidney could excrete its nitrogen so long as not more than 94 grams of protein were taken in a day. Chittenden, the apostle of nitrogenous economy, said that 60 grams were necessary to maintain nutrition, therefore at least 60 grams should be taken, which allowed a balance of 34 grams. Large quantities of protein could be given in the hydraemic type, as it lessened the dropsy, was found to be well borne, and altered the whole outlook in life for the patient, who had hitherto been starved to no purpose. On the other hand, if the patient were dropsical and also showed signs of uraemia, it was safe to have a urea concentration test done repeatedly before loading his blood with amino-acids, the precursors of nitrogenous waste; a certain amount of protein he must have to replace tissue waste, but not too much to overtax his renal power.

#### Cavernous Angioma of the Face.

Mr. D. J. HARRIES showed a large cavernous angioma of the face, in a man aged 24 years.

The condition was present at birth and had it now occupied an area corresponding to the of the third division of the fifth nerve on the left the whole thickness of the left cheek below the level of the angle of the mouth, the left lower lip, and the anterior two-thirds of the left half of the tongue, and there was an offshoot running upwards in front of the ear. In April, 1923, the left external carotid artery and all the veins running down from the left side of the face were ligated; two weeks later the opposite side was similarly treated, and this had reduced the mass to about two-thirds of its original size. Mr. Harries intended to show the case again, after trying the effects of electrolysis. The case was interesting in that it suggested that the growth of the angioma might be controlled by the sensory branches of the third division of the fifth nerve; its extent could not be explained in terms of vascular or vasomotor distribution.

A MEETING of the London Association of the Medical Women's Federation was held at the Elizabeth Garrett Anderson Hospital on May 15th, with the President, Dr. LOUISA MARTINDALE, in the chair. Dr. OCTAVIA LEWIN, in a paper on personal hygiene and its place in school teaching, said that the subject was many-sided, embracing the physical, mental, spiritual, moral, social, domestic, and racial aspects of humanity, and that the problems were different in succeeding

### ATROPHY OF THE SKIN AFTER POLIOMYELITIS.

THE following case of atrophy of the skin is, I think, sufficiently interesting to be placed on record as showing an apparently rare sequel to an old poliomyelitis.

Mrs. S., aged 36, came to see me on account of an eruption on the left leg of several weeks' standing. She gave a history of acute poliomyelitis at 2 years of age, after which the leg below the knee was practically paralysed. At the age of 22 there was some recovery of the calf muscles.

On examination, the calf muscles were considerably wasted, and several scars on the foot showed where operations for tendon transplantation had been done many years previously. On the outer side of the leg, extending from a little below the knee to the ankle, was a diffuse erythema of the skin, and purple and crimson areas. The discoloration completely disappeared on pressure and returned very rapidly—evidently a vasomotor disturbance. The temperature of the skin varied at different examinations, being in a condition of poikilothermos. The affected skin was thin and shiny; the lower parts were swollen with oedema, while other parts were dry and scaly owing to the atrophy of the sebaceous glands. The patient complained of dull aching pain and "tingling" sensation.

I found sensation greatly modified or entirely absent. Epicritic sensation was absent. Protopathic sensation was present for touch, but there was definite thermo-anesthesia. The response to variations in temperature was interesting, as it closely resembled that obtained in a typical case of syringomyelia. There was absolute absence of appreciation between heat and cold. Moreover, stimuli normally giving rise to pain produced little or no response.

Apart from the old poliomyelitis there were no signs of any other disease of the nervous system, and I subsequently asked Dr. MacCormac, dermatologist to the Middlesex Hospital, to see the case. He agreed with me as to the diagnosis, saying: "I think there can be no doubt but that the condition is a trophic one associated with the old poliomyelitis."

Unless the two conditions have no relation to each other, is it not rather strange that a sensory disturbance of the skin should follow poliomyelitis? The former is probably the result of some degeneration in the posterior roots in the lumbar portion of the spinal cord, while the latter is due to a lesion actually in the grey matter of the anterior horn of the same segment. It is noteworthy, moreover, that the skin atrophy should have appeared after such a comparatively long interval of time as thirty-four years.

London, E.

A. ROBERT FOX, M.R.C.S., L.R.C.P.

### RUPTURE OF PERIANAL SKIN CAUSED BY A FALL UPON THE FEET.

THE following note of an accident which seems to be an unusual one in the human subject may be of some interest. A man, while riding upon a fire engine which was travelling at some speed, was thrown violently to the ground, landing upon his right foot. The impact was sufficient to cause a very bad compound, comminuted fracture of the right leg. When he was undressed at the hospital, the nurse noticed that there was something wrong with the anus, although no complaint of pain or injury had been made by the patient. On examination I found that the skin had been torn from its attachment to the mucous membrane throughout the whole circle of the sphincter, except for about a quarter of an inch on the left side posteriorly. The skin, showing all the perianal corrugations, had retracted from the anal margin, leaving the subcutaneous tissues bare for an inch or more from the anus. There was no bruising, and there had been very little bleeding. The trousers were not torn nor was there any evidence of his having been struck by anything in that region. I think the injury may have been caused by the sudden and very violent pressure upon the pelvic floor, due to the man's impact with the ground in the standing position. The muscular structures guarding the pelvic floor were taken unawares and overpowered, and the perianal skin so stretched as to be completely torn from its attachments around the anal margin.

The condition is well known to veterinary surgeons, as occurring occasionally in horses when landing on hard ground after jumping. It would be interesting to know if the condition is recognized as occurring also in men.

Nuneaton.

E. N. NASON.

decades of the individual's life. She gave instances that had come under her notice of inadequate provision of facilities for personal hygiene. These included insufficient lavatory accommodation in schools, absence of handkerchiefs and of the knowledge of their use, overtight clothing, and indiscriminate kissing of children even when suffering from infectious diseases. Dr. Lewin discussed the various sources from which education on personal hygiene might be expected, such as the parents, the teachers, the public libraries, and the press. In the *Encyclopædia Britannica* at the British Museum the pages dealing with disease were so thumb-marked as to be almost illegible. She also showed cuttings of the quack medicines advertised in one issue of a daily newspaper, which were so numerous as to cover a whole sheet of the paper. A discussion followed, in which Drs. JEVONS, PARSONS, FAIRFIELD, WILSON, ELSLIE, HANSON, LANE-CLAYTON, HUTCHINSON, and HANDLEY-READ took part.

## Reviews.

### INDUSTRIAL HYGIENE.

WHEN in 1895 Sir Matthew White Ridley, then Home Secretary, had the courage to depart from precedent and appointed Dr. (now Sir) Arthur Whitelegge, who was then medical officer of health for the West Riding, to be Chief Inspector of Factories, he probably did not fully realize the importance of his action. It was the first step in the practical application of preventive medicine in relation to industrial diseases. Dr. Whitelegge was extremely fortunate in his selection of Dr. T. M. Legge as the first medical inspector of factories; to his painstaking labours the workers in many industries are indebted for decreased incidence of certain diseases, and in some cases for actual immunity. His pioneer work undoubtedly stimulated others to labour in the same direction, and now industrial hygiene is recognized as an integral part of preventive medicine.

Medical officers of health will welcome *Industrial Hygiene and Medicine*<sup>1</sup> written by Dr. E. W. HOPE, M.O.H. for the city of Liverpool, in collaboration with two of the assistant medical officers, Dr. W. HANNA and Dr. C. O. STALLYBRASS. The introductory chapters contain an account of factory legislation in this country, and of the efforts made in the early part of the nineteenth century to improve the conditions of industrial workers. It is significant that legislation was at first directed to the shortening of the hours of work of children and young persons under 18 years of age. Later on efforts were made to prevent accidents by the fencing of machinery and in other ways, and to improve the general health of the workpeople by attention to the ventilation of workshops and to their general sanitary conditions.

Although the conditions had been studied early by a few medical pioneers, it was only in the closing years of the century that definite knowledge was won of the causes of certain diseases found to be incident to particular industries, and with this knowledge, attained by careful and prolonged investigations, it speedily became possible to make appropriate proposals for their prevention. These causes and preventive measures are discussed by the authors very fully and clearly, as will be seen from the headings of some of the chapters—industrial poisonings and their effects; dust as a cause of disease; industrial infection; and occupational affections of the skin and special senses. The chapter on industrial physiology sets out very clearly the present-day views of competent observers on this most important subject—important not only to the individual worker, but to the community generally. As is well known, the study of industries shows that in many a break in the ordinary spell of work has been followed by greater output, and the authors express the opinion that a four-hour spell of work is as long as can be endured without unnecessary fatigue. If, they say, a ten-hour day must be worked, it should either be divided into three spells, or, perhaps better, into two spells, each divided by an interval of fifteen minutes.

In a very informing chapter on industrial welfare schemes details are given of several which have been in existence for some years, and advice is offered as to the best way to

inaugurate and carry on such work. It is rightly insisted that the personality of the welfare supervisor is of the greatest moment. Neglect of this consideration may wreck the most carefully designed scheme. Quite appropriately in a work of this character a few pages are devoted to the question of workmen's compensation, and in an appendix will be found an epitome of British legislation affecting industrial hygiene, and the memorandum issued a few years ago by the Home Office on the duties of local authorities under the Factory and Workshop Acts. The duties of certifying surgeons are also included in the appendix.

A large number of well executed illustrations add to the value of the work. The bibliography at the end of each chapter is very complete and is evidence in itself of the immense labour entailed in the compilation of the volume. It is an excellent example of what can be done by steady team work. Indeed it is marvellous that so much information could have been brought together by three busy medical officers of health engaged in the public health administration of a large city and port. Their reward must be in the knowledge that they have produced a textbook which will take a distinctive place in the literature on industrial hygiene.

### NATIVE COMPOUNDS IN TROPICAL AFRICA.

DR. ARTHUR PEARSON, the circumstances of whose tragic death we recorded last week, had recently written a book in association with Dr. R. MOUCHET on the *Practical Hygiene of Native Compounds in Tropical Africa*,<sup>2</sup> based on experience gained by eighteen years of work in the Katanga. As the authors state in their introduction, it does not profess to deal with tropical hygiene in general, but only with its application to native compounds under the conditions met with in tropical Africa.

The first section, consisting of nine chapters, deals with the various aspects of the hygiene of compounds. It is difficult to assess the degree to which a native increases his risk of life by changing his village home for a compound; the authors believe that in the compounds of most industrial undertakings in tropical Africa the death rate reaches a higher level than that which the village would show if the true figure could be obtained for adult natives of working age, when especially they are tenanted by men who are for the first time brought into contact with Europeans and European standards of work. The degree of increase in risk to which the native is subjected is dependent on a number of factors, some of which it is within our powers to control, and it is these the authors discuss in their opening chapter, which deals with general considerations touching upon the native and compound life. As the result of a very interesting analysis of native life under natural conditions in his village, the authors reach certain general principles, relating chiefly to ensuring that the living conditions of the native are kept up to a certain standard as regards his dwelling hut, and to the importance of providing a diet ample in quantity and of sufficient variety; stress is laid on the necessity for attention to all details which may tend to diminish the pathogenic virulence of a compound environment, or which may serve to prepare and strengthen native recruits against this new environment. It is with the methods of application of these principles that the main bulk of the volume is concerned. Four chapters are devoted to the general situation and arrangement of compounds, to the types of construction, to the latrine arrangements and sewage disposal, and to the water supply. Each of these sections is illustrated by a number of admirable photographs and diagrams.

The authors distinguish between the diet and feeding of natives, because each presents distinct problems; by diet they refer to the composition of the rations issued, and by feeding to the manner in which the issue is made and the arrangements provided for consumption of food. This large and very important subject is treated in considerable detail, and the personal observations made by the authors in the Katanga compared with the results of experience in the Rand.

<sup>1</sup> *Industrial Hygiene and Medicine*. By E. W. Hope, O.B.E., M.D., D.Sc., in collaboration with W. Hanna, M.A., M.D., D.P.H., and C. O. Stallybrass, M.D., D.P.H. London: Baillière, Tindall and Cox. 1923. (Demy 8vo, pp. 766; 123 figures. 21s. net.)

<sup>2</sup> *Practical Hygiene of Native Compounds in Tropical Africa. Living notes from the experience of the first eighteen years of European work in the Katanga*. By A. Pearson, M.B., B.S. Lond., and R. Mouchet, M.D. London: Baillière, Tindall and Cox. 1923. (Cr. 4to, pp. xiv + 183; 49 figures, 44 plates. 22s. 6d. net.)

The next chapter deals with the maintenance of cleanliness. The authors state that a very excellent rough estimate of the cleanliness of a compound may be made by noting the number of flies, and they add: "If we were asked to name the two chief causes of mortality in the Katanga compounds, we would cite pneumonia and flies." Under this general heading such matters as cleanliness of the compound area and of the hut itself, attention to accessory installations, disposal of refuse, and provision for personal cleanliness are discussed. In dealing with hospital organizations, the authors consider the position, construction, and arrangement of the buildings and the organization of care for the sick. In a compound hospital the majority of beds provided should be placed in large wards; a useful method of distribution of beds (for every thousand natives in a compound) was found to be—36 beds in large wards, 12 beds in small wards, and 4 beds in isolation wards, giving a bed ratio to compound population of 5.2 per cent., which is ample in ordinary times. The authors remark that quite early in their work they noted that patients with pneumonia did better on the verandah than in the interior of the comparatively ill-ventilated ward of ten years ago. This conviction led to the design of a special type of ward, the essential feature of which is that the brickwork of most of the wall is not carried more than 1.2 metres above the ground, the space above being protected by mosquito wire gauze, so that the ward is practically an open-air shelter; in order to prevent driving rain from reaching the gauze, the roof is prolonged to provide a wide verandah shelter.

It has long been recognized both in South Africa and in the Katanga that the highest mortality is found among natives who have been recently recruited, and that the danger is greatest when the recruiting is from a race which has not previously worked in a great industrial centre. The various factors conducing to this special susceptibility are analysed and suggestions made with a view to meeting the difficulties which arise.

The second section of the volume contains two chapters: the first deals with the epidemic diseases of tropical compounds and the second contains a few pathological notes.

The book is full of interest, and contains much valuable information, and can be heartily commended. As Balfour states in the preface he has written for it, "there has been an urgent and increasing need for a good book in English, dealing with the sanitation of native compounds," and there can be no doubt that this work will receive the warm welcome which it certainly merits.

### BOTULISM.

UNTIL August, 1922, little active interest was taken in these islands in the subject of botulism. The public health student associated it with sausages on the continent of Europe and with bottled olives and similar articles in the United States of America, especially in California. He never expected to see, in this country at any rate, instances of the disease. The occurrence of eight cases, all fatal, in the Loch Maree tragedy was fully recorded in our columns at the time (August 26th, p. 394, September 9th and 16th, pp. 481 and 527). Dr. GERALD LEIGHTON has now written a book entitled *Botulism and Food Preservation*<sup>3</sup> in which much of the existing knowledge on the subject is well set out. For fuller details he refers the reader to a copious bibliography and to his official report to the Scottish Board of Health (1923). He has written not only for the medical profession but also for those interested in the preserved food industry and for "the intelligent educated general reader."

Before relating the incidents at Loch Maree the author, after stating the nature of botulism, gives its history, cause, symptoms, treatment, and prevention, in successive chapters. Some interesting remarks, based on the valuable work of Professor K. F. Meyer of California, are made on the world-wide distribution of the spores of *B. botulinus*. The part played by the spores, and the two types (A and B) of the bacillus and their toxins, in the causation of the disease is clearly and fully described. Of 64 samples of English soil examined by Professor Meyer—before any case

had been known in these islands—five were found to contain *B. botulinus*. From his researches in California he concluded that the bacillus type A is predominant in virgin soil and that type B is relatively frequent in more cultivated soils. The Loch Maree outbreak was due to type A occurring in a pot of wild-duck paste prepared in England.

The chapter on allied animal diseases, such as "limber neck" in fowls (United States of America), "grass sickness" in horses (parts of England and Scotland), "forage poisoning" in horses (Australia), and "Borna disease" in horses (Germany), is of much interest.

The arrangements made by the Medical Research Council in conjunction with the Ministry of Health to afford facilities in the University of Bristol for the examination of specimens from outbreaks of food poisoning of any kind not only in England and Wales but also, with the co-operation of the Scottish Board of Health, in Scotland, worked well when the Loch Maree outbreak occurred, and the services of the research workers at Bristol and their special knowledge of the causes of food poisoning of all kinds proved very valuable. The co-operation of workers in the Wellcome Research Laboratories on the causes of grass sickness enabled botulinus antitoxins to be obtained for identification of the type of bacillus isolated from the Loch Maree specimens. It is fortunate that types of botulinus antitoxin had already been prepared, though, as it happened, not in connexion with a human outbreak of botulism. For the lay reader especially there is a useful chapter entitled "Answers to questions" based on many inquiries as to the causes and prevention of botulism which have been put to the author.

Dr. Leighton gives the reassuring opinion that if certain necessary and relatively simple precautions be taken by all concerned it is extremely unlikely that other outbreaks of botulism in these islands will occur. He is to be congratulated on having collected so much information on this subject and on having put it into an interesting and readable form.

### BIOCHEMISTRY IN RELATION TO PHYSIOLOGY.

Mr. T. R. PARSONS, in his foreword to the *Fundamentals of Bio-chemistry in Relation to Human Physiology*,<sup>4</sup> explains that the object of his book is to give a short account of the more important principles of biochemistry which have been derived from the study of the chemical changes occurring in the human body. The book, he says, has been written as simply as possible so as to demand a minimum of previous knowledge of pure chemistry and of physics.

Biochemistry is naturally a very difficult subject to explain in a simple manner, but Mr. Parsons has succeeded in setting forth the salient principles of the subject in a remarkably clear and simple fashion. His experience as Demonstrator in Physiology in the University of Cambridge has helped him to adapt his book to meet the needs of students beginning the study of biochemistry and also of those medical men who may have forgotten most of their theoretical chemistry and wish to refresh their knowledge of the general principles of biochemistry. The first eleven chapters give a short account of the chemistry and metabolism of proteins, purins, fats, and carbohydrates; then the more general problems of metabolism are dealt with, and the concluding chapters are devoted to certain problems in physical chemistry.

The book is a short account of what the author considers are the salient facts of the subject. The selection must of necessity be arbitrary and no two writers would make identical selections, but nothing has been included in this volume that is not of real importance.

One of the most interesting chapters is that dealing with the mechanism of muscular contraction. A very clear account is given of the important recent discoveries as to the mode in which carbohydrates are utilized to provide energy for muscular contraction. This chapter concludes with a most interesting comparison between the muscle and an internal combustion engine. The author is to be congratulated particularly upon the clearness and brevity with which he deals with such problems of physical chemistry as

<sup>3</sup> *Botulism and Food Preservation (The Loch Maree Tragedy)*. By G. Leighton, M.D., F.R.S.E., Medical Officer (Foods), Scottish Board of Health. London and Glasgow: W. Collins and Co., Ltd. 1923. (Med. 8vo, pp. xiii+237; 10 plates. 10s. net.)

<sup>4</sup> *Fundamentals of Bio-chemistry in Relation to Human Physiology*. By T. R. Parsons, B.Sc. (Lond.), M.A. (Cantab.). Cambridge: W. F. and Sons, Ltd. 1923. (Cr. 8vo, pp. x+281; 23 figures. 1 plate. 10s. 6d. net.)

polarization, the reaction of fluids, osmotic pressure, and the properties of colloidal solutions. We do not remember ever reading a simpler and more concise account of the elementary facts regarding these difficult subjects.

The two chapters which are, perhaps, most open to criticism are those on vitamins and protective synthesis. The author tries to deal with vitamins in five pages, which is really an impossible effort at condensation. So many facts concerning vitamins are still uncertain that generalization on this subject is very difficult. The statement made on page 185 that the fat-soluble vitamin is present in most natural oils is obviously a slip. This vitamin is either absent from most natural vegetable oils or present only in minute traces. The chapter on protective synthesis in the body is also very brief, and it seems questionable whether it was worth while including so short an account of such a scattered subject.

These, however, are points of relatively small importance, and our general opinion of the book is that it is of a type that deserves a particularly hearty welcome. The present tendency of science seems unfortunately towards infinite subdivision by partitions of special vocabularies and refinements of technique. A book like the one under review, which makes the general principles of a difficult subject available for the first time to a large circle of readers, really plays an important part in the development of scientific knowledge.

### THE SUN CURE IN TUBERCULOSIS.

THE appearance of *Heliotherapy*<sup>5</sup> will be welcomed by all who are interested in what is called surgical tuberculosis, and have heard of its successful treatment by Dr. ROLLIER in his clinic at Leysin on an Alp at the eastern end of the Lake of Geneva. Knowledge of his method of insolation has already been available in numerous articles in Continental and British journals, and in *La Cure de Soleil* (see BRITISH MEDICAL JOURNAL, 1915, i, p. 936), which gave a more complete and systematic account; but in the volume before us the method is for the first time fully described in English. It would be difficult to praise too highly the way in which Dr. Rollier has presented his case. His clear account of the technique of graduated exposure of the body to the sun-rays; the detailed case-records of tuberculosis of every region of the body, illustrated by photographs and radiographs before and after treatment; the careful descriptions of splints and other immobilizing apparatus; the indications for operative intervention (how few they are!); the cases unsuitable for the sun cure; the emphasis on the combination of work and play as an important mental tonic; and finally the presentation of his analysed statistics (over two thousand cases of surgical tuberculosis) from 1903 to 1921—all these different parts of the subject are unfolded in a clear and orderly way which will enable anyone not previously familiar with the subject to grasp essentials, and those possessing a competent knowledge to examine the evidence critically and to draw their own conclusions. There follows a chapter on the scientific basis of heliotherapy which widens into a discussion of the physics of light and its biological action upon human tissues. This is from the pen of Dr. A. ROSSELET, who has long been closely associated with Rollier at Leysin. Finally there are chapters on radiological diagnosis and on radiotherapy and phototherapy.

Dr. Rollier emphasizes the association of good pigmentation with good prognosis, and gives detailed rules for the graduated exposures until the whole body can safely be bared to the sun-rays. He seems to hold that the conditions for this insolation are better in winter than in summer. In winter the whole day, with its brilliant sunshine and cold dry air, is available; while during summer often only the morning hours from six to nine may be used. Both he and Dr. Rosselet admit that besides the action of light other factors may be at work—the tonic effect of cold dry air upon the body surface and the influence of rest; the insistence on the work cure shows that the value of the mental factor is appreciated.

<sup>5</sup> *Heliotherapy*. By A. Rollier, M.D., with the collaboration of A. Rosselet, D.Sc., M.D.; H. J. Schmid, M.D., and E. Amstad, M.D. With foreword by Sir J. H. Gauvain, M.A., M.D., and C. W. Saleeby, M.D. Oxford Medical Publications. London: H. Frowde, and Hodder and Stoughton. 1923. (Demy 8vo, pp. xxii + 263; illustrated. 25s. net.)

The statistics for 1914-1921 are that of 2,167 cases of bone and joint tuberculosis 1,746 were healed.

We could only wish that *La Cure de Soleil* might have been translated into its obvious English, "The Sun Cure" instead of the clumsy pseudo-Greek "Heliotherapy."

### GUY'S HOSPITAL REPORTS.

THE second quarterly instalment of this year's volume of the *Guy's Hospital Reports*<sup>6</sup> is rather unusual in containing contributions on subjects recently much to the fore in its pages from men who are not members of that hospital school. Thus Dr. Adolphe Abrahams provides a note on occult blood in the faeces as a commentary on Dr. J. R. Bell's paper in the last number, which is also supplemented by Drs. Ryffel and Payne's article on the spectroscopic test for blood in the stools based on work in the Laboratory of Clinical Chemistry at Guy's. Professor Harvey Cushing describes the clinical features of intracranial aneurysms as a companion article to that of Dr. C. P. Symonds, who worked under him at this subject at Boston and correctly diagnosed a case before death. There is a joint account of two cases of Addison's anaemia; one with all the characteristic features had gastric carcinoma also, and thus fulfilled Drs. A. F. Hurst and J. R. Bell's anticipation that if subacute combined degeneration of the spinal cord is found in association with gastric carcinoma it would be among the 50 per cent. in which complete achlorhydria is present throughout the period of digestion. The other case is commented on by Dr. William Hunter as an example of septic anaemia rather than Addison's anaemia. Dr. G. W. Nicholson's instalment of his studies on tumour formation is devoted to the argument that so-called renal hypernephromas arise from the renal cells, and not, as Grawitz stated, from displaced adrenals, and that they do not lend any support to Cohnheim's theory of tumours. Like his previous papers this one is rich in original observations, ingenious argument, and knowledge of the literature. Dr. F. A. Knott, bacteriologist to the New Lodge Clinic, shows that hexamine is an active biliary antiseptic and that the bacteria in the bile cause a local rise in acidity around them up to a point at which a small amount of free formaldehyde may be expected, and that then the bacteria cease to multiply and finally die out altogether. Messrs. F. Cook and A. A. Osman have a preliminary report on the acidosis factor in pregnancy and in nephritis. The etiology and treatment of varicose veins are discussed by Mr. Philip Turner. An attractive feature of this number is the obituary notice of the late Sir Frederick Taylor by his colleague, Sir Charters Symonds, who, with sympathetic touches, shows the enormous debt that the medical school owes to its first Dean's work for fourteen years, and brings out his wide activities in other directions. His textbook on medicine held a prominent position for close on thirty years, and passed through eleven editions in his hands, thus surpassing the corresponding works of Bristowe, F. Roberts, and Osler.

### NOTES ON BOOKS.

THE *Textbook for Fever Nurses*<sup>7</sup> by Dr. GRACE H. GIFFEN DUNDAS follows the syllabus of lectures drawn up by the Fever Nurses' Association; it is divided into three parts, the first dealing with anatomy and physiology, the second with the various fevers and fever nursing, and the third with practical instruction and ward work. In an elementary work of this kind illustrations are essential, and their absence in this book considerably detracts from its value. Two of the chapters are merely arid enumerations of the various bones, muscles, and viscera. The description of the various diseases is on the whole clear and accurate though somewhat fragmentary, but must be supplemented by lectures or larger textbooks. In view of the uncertain etiology of scarlet fever, small-pox, measles, rubella, and mumps the writer is too dogmatic in stating that each of these diseases is caused by an organism (vide pp. 93, 127, 134, 139, 140). An index should be added to the next edition.

<sup>6</sup> *Guy's Hospital Reports*. Edited by Arthur F. Hurst, M.D. Vol. lxxiii, No. 2. April, 1923, issued quarterly. London: Henry Frowde, and Hodder and Stoughton. 1923. (Roy. 8vo, pp. 117-25; 1 plate, 21 figures. Subscription: Two guineas post free for volume of 4 numbers; single numbers, 12s. 6d. net.)

<sup>7</sup> *Textbook for Fever Nurses*. By Grace H. Giffen Dundas, F.R.C.S., D.P.H.Camb. Edinburgh: William Bryce. 1923. (Fcap 8vo, pp. xii + 202, 4s. 6d.)

# NINETY-FIRST ANNUAL MEETING of the British Medical Association, PORTSMOUTH, 1923.

H.M.S. Victory at her old moorings.

THE ninety-first Annual Meeting of the British Medical Association will be held next month in the historic town of Portsmouth. On the afternoon of Tuesday, July 24th, Mr. C. P. Childe, F.R.C.S., senior surgeon to the Royal Portsmouth Hospital, will be inducted President in succession to Sir William Macewen. Mr. Childe will deliver his presidential address on the evening of the same day. The meetings of the Sections will begin on the next morning and will be continued on the two following days. The programme of the varied work they will do is published in the SUPPLEMENT to this issue. It will be observed that a Pathological Museum is being formed, to which members are asked to contribute specimens, and also that there will be an Exhibition of Surgical Appliances, Foods, Drugs, and Books.

The Annual Representative Meeting will begin on Friday, July 20th; after formal business it will deal first with the Annual Report of Council, which relates the work done by the Council and Committees of the Association during the past year. On this occasion arrangements have been made which will enable Representatives to make the journey from London to Portsmouth and the return journey also by car. The cars will start from London on Wednesday, July 18th; the route taken will differ on the outward and backward journey, but on both much interesting and picturesque country will be traversed.

Portsmouth, and Southsea its suburb on the east, are one town—Portsmouth being the business centre and the chief base of the Royal Navy, and Southsea a pleasant residential quarter with all the amenities of a seaside watering place.

## SOUTHSEA, PORTSMOUTH.

The Borough of Portsmouth embraces the whole of the Isle of Portsea and a portion of the southern slope of Portsdown, including Cosham. The island is connected to the mainland by one road only over Portsbridge, and by the railway, which crosses the creek a little to the east of the road. The creek joins Langstone Harbour on the east with Portsmouth Harbour on the west at the apical part of the Isle of Portsea, which is roughly triangular in shape. The base or southern border faces the Isle of Wight, from which it is separated by a channel of the sea, called the Solent. The most important portions of the borough on the island are known respectively as Portsmouth, Portsea, Southsea, Landport, Buckland, Fratton, Kingston, Copnor, Eastney, and Hilsea.

Portsmouth Town Station is centrally situated in Commercial Road, opposite the General Post Office. Close to the station on the south side of the railway is the Town Hall and the Municipal College. In the latter building the Reception Room will be provided, as well as the rooms for all the Section Meetings, and the quarters for the meetings of the Representative Body. Behind the College and to the north of the railway is Victoria Park, which can be entered by a gate on the north side of the Town Hall between the War Memorial and the railway. A five minutes' walk across the park brings us to the Naval Barracks, where, in the Gymnasium, will be housed the annual exhibition of surgical appliances, foods, drugs, and books.

Most of the motorists coming to the town will travel along the London Road, or part of it, and so enter the town by the same route that Nicholas Nickleby tramped. They will come through Landport, passing the Halfway House, and so along Commercial Road, with its strange mixture of old and modern houses and shops, and on the way will pass No. 393—the house in which Charles Dickens was born. The motorist will not be able to enter the old town of Portsmouth through the Landport or Town Gate, as described in *Nicholas Nickleby*, as the road has been diverted; from Commercial Road the journey will follow a newer road, past the terraces, which leads directly to the Common and sea front.

The Common and front and the view of the Isle of Wight across the silvery Solent are the charm and attraction of Southsea—a great asset of which the inhabitants are justly proud. The Common is a large open space between the houses and the beach, and is about a mile and a half long. On State occasions it is the site of brilliant military displays. Between the numerous paths that intersect it will be found on many days hundreds of the young men of the borough enjoying games of cricket or football. When standing on the open common in the exhilarating air we have on the west a lovely view of Portsmouth, with its old church tower overtopping the elm trees that hide the Garrison Church; the remnants of the old town fortifications; and, facing the Victoria Barracks, the nicely laid out Pembroke Gardens, open for tennis and croquet.

Here, too, at the west end of the Common is the Clarence Pier, and the Esplanade affords a continuous promenade extending eastwards to Southsea Castle; passing in front of the Castle it continues to Southsea Pier and onwards past Lump's Fort and Eastney Barracks to the Coastguard station—a distance of over three miles. Running parallel with the promenade is a good carriage drive.

Along the front are many memorials, the most important being the anchor of the old *Victory*. It used to stand on the other side of the Clarence Pier and then marked as nearly as can be the spot from which Nelson started on his last memorable voyage. The part of the front between the Clarence Pier and Southsea Castle is always somewhat busy and crowded in summer. In front of the Castle some quiet seats may be found and a good view enjoyed of Spithead, the great anchoring place for the fleets and the scene of the naval reviews. All sorts of craft can be watched passing up and down the Solent—big liners and dreadnoughts, little fussy torpedo boats and racing yachts, all add their share to an ever-changing panorama. Three strange circular structures painted in chessboard pattern rise from the water; they are ironclad forts erected by Lord Palmerston to defend the harbour and dockyard. That nearest Portsmouth is built on the Spit Bank, the next further off on No Man's Land, and the furthest off on the Horse Shoe Bank. The lightship nearest to us is the *Warner*, and beyond can just

\* Previous articles on Portsmouth and its neighbourhood appeared in the BRITISH MEDICAL JOURNAL of December 9th, 1922, p. 1137; January 13th, 1923, p. 77; February 10th, 1923, p. 253.

be made out one of the mystery towers, placed in this position since the end of the great war.

The Common has recently been bought by the Corporation from the War Office and on completion of the purchase schemes will be prepared for adding to its attractions and utility. Continuing our promenade eastwards from Southsea Castle, we come to another busy part of the beach, and Southsea Pier. This pier is the property of the Corporation and was opened in 1908 to replace one that was burnt down. From this pier, as well as from the Clarence Pier, boats run to the Isle of Wight, and during the season many other sea excursions can be enjoyed. Military bands can be heard on both piers, and other musical and variety entertainments are freely provided. Around the pier we shall find the beach busy, with plenty of sea bathing and boating in progress.

Close by the pier is the Canoe Lake Garden, where there are plenty of tennis courts, croquet lawns, and greens for bowls. On the lake are some canoes and swan-like boats for the use of little people; the real live swans were a gift from the late King Edward VII. The sailing of model yachts on the lake is vigorously practised, and is a sport rapidly growing in favour.

Just beyond Lump's Fort—now practically dismantled—is the Corporation miniature golf links. The large brick buildings a little further on are the Eastney Barracks, the home of the Royal Marine Artillery—more familiarly known as the Blue Marines. Passing in front of the barracks we come upon the only stretch of sandy beach the Borough possesses. The promenade stops at the coastguard outlook. The road turns inland and continues to Hayling Ferry, but our walk can be continued along the edge of the sea wall to Fort Cumberland and so round to the ferry, which crosses the outlet of Langstone Harbour and takes us to Hayling Island. The island is noted for its golf links, and here the match for the Ulster Cup will be played.

Southsea streets are somewhat tortuous and confusing. Palmerstone Road, which runs north from Southsea Castle, is the shopping centre. To the west of this road will be found Osborne Road, which is a business thoroughfare leading back to the Common and old Portsmouth. In it, overlooking the Common, will be found the "official hotel"—the Queen's. At the land end of Palmerstone Road by St. Jude's Church is Kent Road, running in the same direction as Osborne Road. It is a residential road, and off it will be found "Dovercourt," a club house kindly placed at the service of the lady members during the meeting of the Association. Grove Road is a continuation of Palmerstone Road and is quite rural, but Elm Grove, to which it leads, has forfeited its title to that designation. It was once the most picturesque road in the Borough, but now the elm trees and rocks are gone and the gardens in front of the old houses covered with shops. Sir Arthur Conan Doyle once lived in this road, and here, whilst in general practice, wrote *Under*

*the Red Lamp*. The continuation of Elm Grove is King's Road, a good shopping centre, and this leads us to the Terraces. Turning to the left and following the Terraces we shall come back to the Common and the sea; turning to the right we shall soon be in Commercial Road, now the chief business quarter of Portsmouth. Continuing straight on from King's Road we shall soon find ourselves at the top of High Street—once the most important of thoroughfares—and from it we can explore the old fortified town. The old fortifications were removed in 1876, and the two recreation grounds formed and levelled.

At the top of High Street on the left we shall see the house in which Buckingham was assassinated by Felton. Behind this house, on ground now occupied by the Cambridge Barracks, is the site of the old theatre, the scene of Mr.

Crummles's successes. On the opposite side is the old Unitarian chapel, which has in its burial ground a monument to John Pounds, the founder of ragged schools. Again, further down on the left, is the George Hotel, where Nelson rested just before he embarked on his last commission which culminated in the glorious victory of Trafalgar. Next the Old Guild Hall claims attention. It is now converted into a museum, which contains some interesting relics of old Portsmouth. Continuing our perambulation round the bend we pass the site of the Old Blue Posts and come to Point, where we can visit the Old Star and Garter and take ferry or floating bridge across the harbour mouth to Gosport, and so visit the great naval hospital at Haslar. A trip round the harbour in a motor launch will be both interesting and instructive, and if time and tide permit the trip may be extended so as to visit the old castle and church at Portchester.

From old Portsmouth we can take our way to ancient Portsea and the Royal Dockyard. In the yard we shall find the latest in steel armoured ships and relics of the old "wooden walls," the glory of the navy in the past; also in dry dock, undergoing internal structural repair, Nelson's old flagship *the Victory*.

The Portsmouth Corporation owns a fairly good service of electric trams that will be found useful for getting about in the town and its immediate neighbourhood. The Corporation electricity supply is one of the first started in England and was incorporated under the guidance of Principal Garnett. The water supply of the borough is very good; the water company obtains its supply from springs at Bedhampton, a few miles out.

For residents and visitors land excursions and sea trips are both numerous and varied. It is hoped to arrange visits for members attending the Annual Meeting to Southampton and the New Forest, Ventnor, Midhurst, Alton, Winchester, Salisbury, Brighton, Bournemouth, Farnham and Hindhead. Each possesses its own particular charm and attraction, and further to dilate on their respective merits would at the present be superfluous.

CHARLES P. CHILDE, F.R.C.S.,  
Senior Surgeon, Royal Portsmouth Hospital;  
President-Elect of the British Medical Association.

## THE SURGICAL CLINICS OF SWITZERLAND.

BY

H. S. SOUTTAR, M.Ch., F.R.C.S.,

DIRECTOR OF THE SURGICAL UNIT, LONDON HOSPITAL.

THERE is no better stimulus for a surgeon than to see how others meet the problems of his art, so when a short time ago I was invited by Professor Gask to join a small party of surgeons in a visit to the surgical clinics of Switzerland I gladly accepted. The party consisted of the directors of the surgical units at St. Bartholomew's, University College, St. Mary's, and the London hospitals (Messrs. Gask, Choyce, Pannett, and Souttar), and Messrs. Girling Ball, Gordon-Taylor, Kenneth Martin, and Morland. We left London on February 28th, and were exactly ten days in Switzerland. During that time we visited Basle, Zürich, Berne, and Lausanne. We spent every available moment in the hospitals and laboratories of these places and in attending lectures and demonstrations given to the students.

I believe it was the first occasion on which a party of English surgeons had visited the Swiss clinics. Nothing could have been more cordial than our reception; we were given every facility for seeing the regular work of the hospitals, and where, as in Zürich, the vacation had begun, special demonstrations were arranged for us. In general we began the day with a lecture demonstration at 8 o'clock and only finished in the wards at a late hour in the afternoon. We saw much that was new and interesting. We believe that the ideas and information we have brought back with us will be of the greatest use in our work, and we hope that they may be of some interest to others.

## Basle.

We arrived at Basle at 7.20 a.m. on Thursday, March 1st, and after breakfast made our way to the hospital, where we met Professor Hotz. He received us most cordially, and we found ourselves seated in the front row of his class of fifty students. The professor is a slight, alert man of medium height, 45 years of age, with a quiet incisive manner which rivets attention, whilst his unfailing sympathy with both his patients and his students marked a most attractive personality. After a few words of greeting to his visitors he proceeded with his regular morning demonstration.

A number of simple surgical cases followed one another into the theatre—a child with a dentigerous cyst, a woman with a sarcoma of the upper jaw, a child with an empyema which had discharged through a bronchus. Three students were called down to examine the cases, and the lecturer directed most of his questions and remarks to them. In the background were four assistants, in addition to the sister and the theatre attendant. For each case there had been provided every possible accessory in the way of photographs, radiographs and specimens, whilst the blackboard and epidiascope were in constant use. An hour later the students retired and the lecture room became an operating theatre. We saw two colloid goitres removed under local anaesthesia, with exquisite technique, practically no bleeding, and no pain. Several operations for appendicitis followed, but in these open ether was given by a nurse.

In the afternoon we visited the wards, where 150 beds are under the direct control of Professor Hotz. The cases were grouped according to diseases in small wards containing from three to ten beds—a most convenient arrangement, as thyroids and gastric cases, for example, could be studied and treated as separate groups. The surgical section included a full range of laboratories, x-ray and electro-therapeutic departments, as well as an out-patient department, all under the absolute control of the professor.

In the evening Professor Staelin, the head of the medical section, gave us an admirable demonstration on the treatment of chronic empyema in adults. It was illustrated by superb radiographs and charts, and a whole series of cases was provided for our inspection. It was a fine example of the class of work which can be produced with the help of a group of highly trained assistants, and it was an object lesson in the close co-operation which exists between the medical and surgical sections.

Next day we made an early start with a lecture at 8 a.m., and when I say that in the course of the day we fitted in five clinical demonstrations, watched two surgeons in their operating theatres, and visited the new Institute of Anatomy, I think it will be agreed that we did not waste our time. We were left with the impression of demonstrations superbly staged, of a great wealth of clinical material organized as is only possible when it is under the control of one head, and of apparatus and accommodation provided for teaching without any regard as to its cost.

For sheer technical perfection it would be impossible to surpass the demonstration given by Professor Hotz to a group of students just entering upon their surgical training. A case of tuberculous spondylitis with severe deformity was shown, and the results of such a deformity discussed from the point of view of anatomy and physiology in terms readily understood by his audience from their knowledge of these subjects alone. The demonstration was illustrated by superb specimens, both dry and bottled, and by diagrams, whilst cases of lumbar abscess and of paraplegia were brought in to illustrate complications. The preparation of such a demonstration must have involved a large amount of work both for the professor and his assistants, but it gave to the students a clear view of surgery as a reasoned science and a high standard for their own clinical study.

In the afternoon we visited the new Anatomical Institute recently erected and equipped by the Canton of Basle at a cost of £100,000. I have seen in England no school for the teaching of any subject that could in any way compare with it. An open position and fine architecture form a prelude to spacious dissecting rooms, research laboratories equipped with every modern appliance, and a lecture theatre which did everything but speak. As teachers ourselves under somewhat different conditions, we found it difficult to imagine what teaching must be like when the pressure of one button brings up a fresh blackboard or a new drawing, and another excludes daylight in a few seconds, where every possible dissection is ready to hand, and where one's voice is never drowned by the roar of traffic.

Near by we saw the foundations of the new maternity wing of the gynaecological clinic. It is to cost £200,000 and when completed will accommodate two-thirds of the women of Basle in confinement. What may not the future of Switzerland be when a small canton is prepared to provide such resources for the health of its children and the training of its medical men?

On Saturday we were privileged to witness a very remarkable demonstration. It is the custom on Saturday morning for the whole medical staff to meet in the lecture theatre of the pathological department. We found all the material from the operations and *post-mortem* examinations of the week neatly arranged on trays. Professor Roessle gave a rapid description of each case, occasionally referring to one of his audience for some clinical detail about his case.

Such a review by the medical and surgical staffs of their week's work must be a wonderful stimulus to efficiency. It supplied us with considerable food for reflection.

## Zürich.

The head of the surgical clinic at Zürich is Professor Clairmont, a pupil of von Eiselsberg of Vienna. He is a man of 47, of dominating personality, and a fine exponent of the minute technique of the Vienna school. We met him in his operating theatre at 8 a.m. on Monday, March 5th, and saw a varied series of operations including Lerich's operation on the brachial artery for Raynaud's disease in a woman of 38, a thyroidectomy under paravertebral anaesthesia, a laminectomy under local anaesthesia, a nephrectomy for tuberculosis, and a cholecystectomy. Each operation was carried out with the most elaborate ritual and extreme minuteness of detail, occupying a very long time in abdominal work. The professor was surrounded by a large number of highly trained assistants, one or other of whom, as a rule, completed the final stages of the operation.

In the afternoon we were shown round the hospital. The patients were grouped in small wards, containing from four to ten beds, largely in accordance with disease. The

most elaborate care was taken in the examination of the cases and in the keeping of records. We saw special rooms equipped for basal metabolism, for continuous bath treatment, and for the making of plaster casts. In one room we were shown a most remarkable collection of models of diseased conditions—for example, carcinomatous ulcers of the breast and face, chronic ulcers of the stomach, and deformities. The specimens were so perfect as to be almost indistinguishable from the original conditions. They were made of wax by an artist who is retained entirely for this purpose, and who uses a process of his own invention. In addition, two artists devote the whole of their time to the drawings of specimens and cases. We saw superb records—photographic, water-colour, and pencil. A small library, well equipped with modern literature and journals, is provided solely for the use of the assistants.

The x-ray department entirely eclipsed anything we had ever seen. For diagnosis there was a large department with many sets of apparatus, all of the most modern type. The rapidity with which extensive examinations could be carried out was very remarkable, the actual time occupied in discovering, examining, and photographing a duodenal ulcer being less than four minutes. It is true that we obtain equally good photographs, but at the cost of enormously greater labour to the staff. The apparatus for treatment was installed nine months ago by Siemens and Halske. It is entirely in duplicate, and so enclosed that injury to the operator is impossible. The transformer has an output of 500,000 volts and is placed in a room beneath. By means of an ionic quantimeter the dosage at any depth in the tissues can be measured with mathematical accuracy. To compare it with any ordinary apparatus is to compare the latest Rolls-Royce with the cars that made the first journey to Brighton.

#### Berne.

Professor de Quervain is a short, thick-set man of 50. He came from Basle to Berne in 1918, following Kocher, who had raised the surgical clinic of Berne to the premier position in Switzerland. Nothing could be greater than the contrast between Berne and the clinics we had just seen. The neat dexterity of Hotz, the irresistible driving force of Clairmont, were replaced by a slow technique and an entire absence of any regard for external appearances. But though the technique looked slow the operations did not occupy an excessive time and the condition of the patients next day was extraordinarily good. We saw two operations for goitre, one for appendicitis, and a resection of the stomach for carcinoma in a man of 59. In each case local anaesthesia was employed, assisted in the stomach case by splanchnic anaesthesia, and in the end by a general anaesthetic.

The Berne clinic differs from the others in that it only controls 100 of the surgical beds of the hospital (600 beds in all). Drs. Arnt and Wildbolz were in charge of the other surgical beds, and were evidently regarded by Professor de Quervain as equal colleagues. To the clinic are attached its own laboratories for clinical and pathological examinations, x-rays and microphotography, a large amount of the routine work being carried out by a sister. As might be expected in the home of thyroid surgery, great stress is laid on the investigation of basal metabolism, and a room was set aside for this purpose. The professor also told us of a series of experiments he is conducting on the effect of thyroid secretion on rats. They are placed under a bell jar and the air aspirated. The normal rat vomits when the pressure reaches 300 mm. of mercury. Rats fed on thyroid, or the blood of patients with exophthalmic goitre, react at 500 mm.; but rats given blood from cretins reach a pressure as low as 250 mm. before reaction occurs. The method is being used practically for testing the strength of thyroid preparations.

De Quervain left upon us the impression of a powerful brain devoted not so much to the technique of surgery as to its larger problems; the problem which at present absorbs him is endemic goitre and the cretinism which accompanies it. The Swiss goitres are of the colloid type; adenomata are uncommon, and Graves's disease is very rare. The contrast with English cases is very remarkable, since with

us enlargement of the thyroid is so frequently accompanied by excess of secretion, whilst in Switzerland the reverse is the case. An interesting attempt to control the disease is the addition to commercial salt of a small proportion of potassium iodide. In this form, or in chocolate tablets, iodine prophylaxis is now being tried in Switzerland on a large scale amongst the school children.

To spend a day in Berne is to realize how grave is the problem for the Swiss nation. A large proportion of the women seen in the street and many of the men have goitres. The two porters who carried our bags to the station were half cretins. A large proportion of the population is of the slow, phlegmatic, hypothyroid type, and big institutions have to be provided for cretins and mongols, unable to care for themselves. Yet even this has its compensations, for, as de Quervain pointed out to us, the Swiss were too phlegmatic to worry about the war. A thyroid secretion has apparently proved an expensive luxury to the other nations of Europe.

#### Lausanne.

We met Professor Roux in his lecture theatre at 8 a.m. on Friday, March 9th. He is a man of 66, with curly white hair and gleaming eyes. His energy is amazing, and from the minute when he began to lecture at 8 o'clock till he finished operating at 1.30 p.m. he never ceased to talk or to be the driving power of the whole clinic.

He starts every morning with a lecture demonstration at 8 o'clock (in summer it is sometimes 6), at which every student must be present. Cases followed one another into the lecture room to be demonstrated by Roux with a wealth of reminiscence and an incisive and apposite wit which I have rarely heard equalled. Two students were called down to examine each case, and for a nervous beginner it must have been a somewhat terrifying experience. We ourselves shared the students' anxiety, for more than once the professor turned to us and asked us in rapid French the views we held in England on some subject. Fortunately he did not press his questions too far, or I am afraid our French, at least, would have been unequal to the occasion. Always courteous, never disturbed by any mischance, we realized that in him there lived a great personality, stimulating all with whom he came into contact, adored by his colleagues and students, and almost worshipped in Lausanne.

The last case was that of a woman in bed with a large pelvic tumour. Having discussed for half an hour every possible diagnosis, Roux wakened up the woman, who had fallen asleep, and asked if she would mind if he made a little incision to see what the tumour really was. As she raised no objection an anaesthetist was called in, the lecture room was rapidly converted into an operating theatre and the patient transferred to a table. A generous incision revealed an enormous mass of carcinoma, apparently arising from the right ovary, and certainly involving everything in the neighbourhood. Nothing daunted, the professor proceeded to separate it from its surroundings with amazing speed and dexterity. He was soon standing ankle deep in swabs and debris, for everything found its way to the floor, but the tumour came out with very little damage to the patient, who was swept away into an adjoining room to have her abdomen closed by an assistant. The floor was swept up with a large besom, and in a breathless stream cases followed one another through the theatre, amongst which I at least noted two goitres, two appendix cases, and a very extensive gastrectomy. When half-past one arrived we were all in a state of collapse, but the professor seemed as fresh as ever. For five and a half hours he had never ceased for one minute to talk and to demonstrate.

Several motors were waiting for us at the doors of the hospital, and we were driven off by Professor Roux to a magnificent lunch. It was my fortune to sit beside the professor, and though he now looked old and tired, he continued to pour out reminiscences, whilst I gathered together all the French I could muster to stimulate him. He spoke of the difficulties of his early boyhood, and of the life of a poor Swiss peasant. He reminded us how Swiss chalets are all built on the side of a hill to face the south, and he told me that it is the custom for the father and mother to live and work in the sunny front room, whilst

the children live as best they can in the cold, dark, airless room facing the hill behind. But, said he, on a cold night they could always sleep with the cows, and many a night he had gone to sleep nestling against his father's cattle.

It seemed to me the finishing touch to a great personality. When the surgeons of to-day were boys at school Roux was one of the giants of surgery—a man whose name will live beside those of Lister and Paget, who to-day is the idol of his country, and yet could speak naturally and simply of his humble boyhood as a happy reminiscence. Professor Roux is a prince among surgeons, but it is not only as a surgeon that he will live in my memory.

#### SOME IMPRESSIONS.

From our short visit we gathered certain impressions which it may be well to summarize.

##### 1. Teaching.

In all the clinics we visited the teaching of the students centred entirely round organized demonstrations in the lecture theatre. In this respect it differs fundamentally from the methods we adopt in this country. In bedside teaching given to small groups of students by individual members of the staff, our students have an opportunity to which the Continental system affords no parallel. We, on the other hand, can give our students nothing comparable to the demonstrations we have seen abroad. We were all agreed as to the value of such demonstrations, prepared by highly trained assistants and perfectly staged with all the resources of the modern lecture theatre. As a stimulus and as a standard, both for the student and the teacher, they are of real value, and in my opinion no educational system can be considered satisfactory in which they do not take a prominent place.

##### 2. The Staff.

At each clinic the professor held a unique position, his assistants being essentially subordinates. Such a system lends itself to a co-ordination impossible for ourselves. On the other hand, the system depends for its success absolutely upon the personality of one man, whilst it greatly limits the opportunities and destroys the initiative of everyone else. If each of our firms had attached to it a paid assistant we should in a large measure obtain the advantages we saw of help for the teachers and training for the younger men without the disadvantages of centralization. The head of each clinic was given full opportunities for private practice. In Basle a private section was run by the hospital for the professor, definitely as a recompense for his services. In Zürich he was accommodated in a fine institution controlled by the Red Cross Society.

##### 3. The Hospitals.

The hospitals belong to the town or canton. So far as we could gather they do not depend on voluntary support. A charge of about 6 francs (5s.) a day is made for each patient, but the whole or greater part is defrayed by a national insurance, to which the whole of the working classes contribute. The fees of the students are for the most part paid from national sources, and the cantons and towns vote large sums for new buildings and equipment, both clinical and educational.

Every hospital we visited was equipped with first-class operating theatres, and with clinical theatres (usually many) far superior to anything of the kind we had ever seen. I have seen nothing in England to compare with the anatomical department just opened, or with the maternity department in course of erection at Basle.

It is most improbable that at the present day such equipment can be provided in England from private sources, and it was our unanimous opinion that our only hope of raising the equipment of our training schools to the level of Switzerland lies in the support of our hospitals by the State. The Swiss have recognized the health of their nation and the care of their sick as primary national duties, not to be left to the vagaries of private enterprise. And they have realized that a highly trained medical service is as valuable an asset as a nation can possess. I hope that we may soon be given an inspired glimpse into the obvious, and follow their example.

## THE SPAHLINGER TREATMENT.

We published three weeks ago (May 12th, p. 830) an article giving a general review of the position with regard to the method of the treatment of tuberculosis at which M. Henri Spahlinger has been at work for the last ten or twelve years. Reference was there made to the complete and partial serums and the complete and partial vaccines that M. Spahlinger had produced and had placed at the disposal of certain physicians, although material has not been made generally available.

It will be of interest to give some further particulars about the various products which, as has already been implied, can be classified under two headings, namely: (1) vaccines; (2) anti-serums. A great majority of the cases of tuberculosis treated are given vaccines. Serum is only used in rapidly progressive cases, or in special emergencies.

#### The Vaccines.

These products are essentially similar to the tuberculins, the use of which from time to time has been advocated. M. Spahlinger has modified and elaborated the methods for the preparation of tuberculin or vaccine, and claims to have obtained products which are more effective than other preparations. Tubercle bacilli are treated by various processes and four vaccines are made. The complete course of vaccine treatment consists of successive courses of injections of each of these four vaccines.

#### Preparation of the Serum.

What is called the complete anti-serum is made by mixing a large number of (partial) anti-serums, each obtained from a horse which has been subjected to some particular course of injections. The serum of each horse which is added to the mixture is called a partial anti-serum. The partial anti-serums are of different kinds; some are obtained by injecting tubercle bacilli or products of tubercle bacilli into horses, some by injecting other varieties of bacteria which are found associated with the tubercle bacilli in cases of mixed infections. The former group is further divided into bacteriolytic serums and antitoxic serums. The antitoxic serums are prepared by injecting products which are called toxins. These products are obtained from tubercle bacilli by somewhat elaborate methods.

The methods imply nothing new in principle and are essentially those which have been tried sometimes with and sometimes without success in other bacterial diseases.

It is sought (1) to produce active immunity against the tubercle bacillus and its toxins in the patient by the injection of a vaccine, and (2) to make an anti-serum which has antitoxic and bacteriolytic properties and to use this anti-serum to confer passive immunity on a human being.

These are the general principles which have inspired every worker from the times of Pasteur and Behring. The only novelties relate to the technical details and exact methods of preparation of the substances which make up the vaccine and of the various products which are used to inoculate the horses. The exact methods employed are secrets; at any rate the full details which would be needed by anybody who wished to work at the method have not been published. As regards the vaccine, an attempt is made to produce an active immunity by the injection of a series of substances obtained from tubercle bacilli. We do not know of any published experimental data which show that animals inoculated with these vaccines develop immunity against the tubercle bacillus. There remains the evidence to be derived from clinical observations on cases treated with these vaccines. On this point it is not yet possible to form an opinion; it is notoriously difficult to obtain satisfactory evidence unless a very large number of cases are treated and observed under strict experimental conditions, which are difficult to maintain in the ordinary course of medical work.

#### Effects of the Anti-serums.

It is claimed that the mixture of serums, which is called complete serum, contains both bacteriolytic and antitoxic serums. Antitoxic serums are prepared by injecting horses with preparations which are called ecto-toxins and endo-toxins. We have not seen any published experiments which

show, or attempt to show, that these substances are toxins in the sense in which bacteriologists use the word "toxin." In the case of diphtheria bacilli and the tetanus bacilli, as everybody knows, it is possible to prepare a bacteria-free toxin which when injected into animals produces the characteristic features of the disease in question. Nobody has ever succeeded in making a potent ecto-toxin from tubercle bacilli, and M. Spahlinger has not published any experiments which would support the claim that he has been more successful than other workers. The serums which he calls antitoxins are so called because they are obtained from horses which have been injected with substances which he calls toxins. We do not know of any published work which shows that these serums contained antitoxins, and as there is no evidence that M. Spahlinger has ever prepared an extracellular toxin, in the ordinary sense of the word, from the tubercle bacilli, it is difficult to say how such evidence can be forthcoming. The claim for the antitoxic properties of the serum is based on the fact that cases of rapidly advancing caseous tuberculosis have been arrested by the use of the serum. As to the value of such clinical evidence it is not possible, from the material so far published, to express any opinion. It is common knowledge that many cases of acute caseous tuberculosis do survive the acute stage and reach a chronic stage, when the patients are able to resume a more or less normal life. The cases of pulmonary tuberculosis showing the signs of large dry cavities, which may be seen in any out-patient department, are sufficient evidence of this.

It is, of course, possible that the elaborate and complicated methods which M. Spahlinger employs may possess advantages, but there is no laboratory evidence that they are any better than what has been done before, and the only evidence there is rests on the observations of some clinical observers who have been favourably impressed by the results which they are obtaining.

## THE DANGEROUS DRUGS AND POISONS (AMENDMENT) ACT, 1923.

### STATEMENT BY THE HOME OFFICE.

We have received from the Home Office the following statement, dated May 28th, 1923:

The Secretary of State desires to draw attention to the provisions of the above Act, which received the Royal assent on the 17th instant and came into force at once. This Act amends and amplifies the Dangerous Drugs Act, 1920, and amends Section 17 of the Pharmacy Act, 1868; but it should be noted that it does not vary the drugs to which the Dangerous Drugs Act, 1920, applies, and does not in any way alter the Raw Opium Regulations or the Dangerous Drugs Regulations which are now in force. The effect of its provisions may be summarized as follows:

*Section 1* gives increased powers of search. It empowers a Justice of the Peace to grant a warrant to search any premises and any persons found on the premises, in any case where he is satisfied that there is reasonable ground for suspecting that drugs are being kept illicitly, or that a transaction in drugs which will be contrary to the Dangerous Drugs Acts or the "corresponding law" in a foreign country ("corresponding law" is defined in Section 6) is being carried out or is in contemplation and that documents relating to the transaction are to be found on the premises; and the constable who makes the search may, on reasonable suspicion of any offence, seize any drugs found or any documents relating to a transaction of the character referred to. It also makes it clear that the existing powers of inspection in Section 10 of the Act of 1920 cover documents as well as books.

*Section 2*, Subsection (1), substitutes two new subsections (1) and (2) of Section 13 of the Act of 1920. The first re-enacts the existing Subsection (1), with the addition of two new offences, viz. (1) the making or using of false statements with a view to obtaining a licence or other authority under the Act, and (2) the aiding, abetting, procuring, etc., of the commission outside Great Britain of any offence against the "corresponding law" (see Section 6) of that country, or the doing of any act preparatory to or in furtherance of any act which if committed here would be an offence against the Dangerous Drugs Act. Under the second of these provisions, it should now be possible to deal effectively with persons in this country who organize the smuggling of drugs from the Continent to the Far

East, the United States of America, and other countries, but do not themselves handle any of the drugs in this country. It will be noted that the powers of search given by Section 1 extend to such cases.

New Subsection (2) increases the penalties under the old Act. It enables proceedings to be taken on indictment by or with the consent of the Attorney-General or by the Director of Public Prosecutions, in which case the penalty may be as much as a fine of £1,000 or 10 years' penal servitude, or both, and substitutes for the graduated penalties fixed by the Act of 1920 for first and subsequent offences on summary conviction a uniform maximum penalty of £250 or 12 months' imprisonment, or both. An exception is made for offences committed through inadvertence in connexion with the keeping of records or the giving or dispensing of prescriptions if not connected with any offence or intended offence against the Acts. In these cases the maximum penalty is a fine of £50. Persons attempting to commit, or soliciting or inciting another person to commit, an offence are made liable to the same penalties; and directors and officers of companies are made personally liable for offences committed by their companies, unless they can prove that the offence was committed without their knowledge or consent.

Subsection (3) of Section 2 makes clear two points about which doubt had been felt: (a) that in a prosecution under the Act it rests with the defendant to prove that he had a licence or other authority to do what he is charged with doing, and that the onus is not on the prosecutor to prove that he had no licence or authority; (b) that a term of imprisonment for non-payment of a fine imposed in addition to a penalty of imprisonment may be ordered to commence *after* the expiration of the sentence of imprisonment. Sections 3 and 4 are amendments of Section 17 of the Pharmacy Acts.

*Section 3* relates to the sale of poisons to registered medical practitioners, registered dentists, and registered veterinary surgeons. Under that Section purchasers of poisons included in Part I of the Schedule of the Poisons and Pharmacy Act, 1908, are required to sign the poison book. This provision had been very much neglected in the case of sales to doctors, and after consultation with the British Medical Association and the Pharmaceutical Society an alternative procedure has been laid down in the Section. This procedure is as follows:

(a) The doctor, etc., must furnish a signed order, bearing his name and address, and stating the nature and amount of the poison required.

(b) The chemist must be reasonably satisfied that the signature is genuine, and is that of a duly qualified doctor, etc.

(c) The poison, if sent by post, must be sent by registered post.

(d) The chemist must himself make an entry in the poison book, and must keep the original signed order for at least two years.

Special provision is also made for the supply of a poison to a doctor in an emergency.

This procedure will apply to sales to registered doctors, dentists, or veterinary surgeons of the dangerous drugs; and either this or the signature of the poisons book should be required to be observed. It should be noted that the provisions of Section 17 of the Act of 1868, and of Section 3 of this Act, apply equally to sales by wholesale dealers to doctors, dentists, and veterinary surgeons.

*Section 4*, Subsection (1), dispenses with the entry by a chemist in his prescription book of the particulars of medicines containing poisons dispensed by him as medical prescriptions issued under the National Health Insurance Acts, as these prescriptions are preserved by the Insurance Authorities, and are available for examination if required by the authorities. Subsection (2) strengthens the provisions of the law with regard to the labelling of poisons. The label must in future state the name of the poison (not merely, as previously, the name of the article, which might give no indication of the nature of the poison it contained), and, where the poison is only one of the ingredients, the proportion it bears to the other ingredients. An Order-in-Council will be issued describing the particulars to be given as to the proportion.

*Section 5* gives statutory sanction to the existing practice in calculating the percentage of a solid ingredient in a liquid preparation. It is the method used in the *British Pharmacopoeia*.

DR. KLEIWEIG DE ZWAAR, professor at the University of Amsterdam, has instituted a triennial prize of the value of 2,500 francs, which will be awarded for the first time in 1924 for the best work in physical or prehistoric anthropology during the preceding three years. Candidates should apply before November 1st, 1923, to the Secretary, École d'Anthropologie, 15, Rue de l'École de Médecine, Paris.

# British Medical Journal.

SATURDAY, JUNE 2ND, 1923.

## THE BRITISH MEDICAL ASSOCIATION.

THE British Medical Association, various and mutable, takes for its province all that concerns the medical profession—science, clinical medicine, public health, and material interests. The vast majority of its members are, in the nature of things, general practitioners, but from its earliest small beginnings in 1832 it has gone on the principle that, representing the profession as a whole, it was under an obligation to contribute to the advance of medicine. In the Memorandum of Association its objects are defined; we read there that the Association was established to promote the medical and allied sciences, to maintain the honour and interests of the medical profession, to circulate such information as may be thought desirable by means of a periodical journal, and to grant sums of money for the promotion of the medical and allied sciences. Another object is to hold periodical meetings of the members of the Association, and this has been fulfilled through the meetings of Branches and Divisions, and through Annual Meetings, which have been held without any intermission save that caused by the great war.

The Annual Meeting this year is to be held in Portsmouth, under the presidency of Mr. C. P. Childe, F.R.C.S., senior surgeon to the Royal Portsmouth Hospital, who will deliver his address on the evening of Tuesday, July 24th. The Sections, of which there are as many as sixteen this year, will meet on the three following days and will debate a large number of subjects of current clinical or scientific interest. Thus in the Section of Medicine there are to be debates on diabetes and on heart disease in early life. In the Section of Surgery there will be, among other discussions, one on the treatment of acute primary infections of the hand. One of the discussions in the Section of Neurology and Psychological Medicine, that on the sequelae of lethargic encephalitis, will be followed by a demonstration. In the Section of Diseases of Children there will be discussions on acidosis and alkalosis, and on summer diarrhoea. Modern methods of investigation of diseases of the stomach, the value of serological tests in diagnosis, and the part played by fungi in disease are the subjects selected for discussion in the Section of Pathology. There will also be a Pathological Museum, and it is hoped that many members will lend specimens, particularly if they have a bearing on the subjects for discussion in the various Sections. A full programme of the work of the Sections is printed in the SUPPLEMENT for this week.

The Annual Representative Meeting, which will begin on Friday, July 20th, has a full agenda paper. In the current issue of the journal of a certain professional organization a member complains that, whilst the provisional programme of his association's annual meeting has been published practically *in extenso*, the delegates are still in the dark as to the work that lies before them. The fact that detailed reports on the more vital issues of policy to be dealt with at Portsmouth have from time to time been circulated to the Divisions according to established custom is alone

sufficient to defend the British Medical Association from a similar charge. With the Annual Report of Council in his hands a representative would be better justified in reversing a familiar request and pleading for less matter and more art; but even so he would probably admit upon reflection that the art which can reduce the record of the year's activities to the volume even of the present report is by no means to be despised. For the Annual Report shows that while the Association continues to grow in membership, as indicated by an increase of over 700 in 1922, and in extent, with the formation of new Branches in St. Lucia and in Tanganyika, its vitality, as tested by the work actually performed and its ability to meet the changing needs of the profession, is amply sufficient to maintain that growth. Amongst the matters covered by the report a few may be distinguished as of more than ordinary interest.

We will place foremost among them the coming visit of the President of the Association to the first session of the Australasian Medical Congress to be conducted under the control of the Federal Committee of the British Medical Association in Australia. Sir William Macewen will, we know, receive a very warm welcome, and the augury is a happy one for the future relations of the central body of the Association and its Branches in the Dominions. At home the Guildhall conference between representatives of various bodies interested in National Health Insurance, and the consequent appointment of a standing committee to consider the various questions involved, maintains the tradition of co-operation in public service, while in another sphere the evidence given before the Lord Chancellor's committee on the law affecting insanity in connexion with criminal cases is of like significance. The successful parliamentary campaign for the withdrawal of the Dangerous Drugs Regulation prohibiting prescription of the drugs by a medical practitioner for his own consumption, and the excision from the Dangerous Drugs (Amendment) Bill of the distinction between a doctor "in actual practice" and other registered medical practitioners, shows the advantage of a close central scrutiny of all legislative and administrative proposals affecting the profession, and the possibility of speedy and effective co-operation in such matters between the Divisions, the central office, and the medical members of Parliament.

Amongst the matters for deliberation and decision two stand out as of primary importance: the hospital policy of the Association, and the proposed scheme for co-operation between the Association and the Society of Medical Officers of Health. The hospital policy is, in its essentials, that which was before the Representative Body last year at Glasgow. The work of the year has been mainly that of consolidation and definition, and while the need for decision as to the vital question of the staff fund in relation to payments made by or on behalf of certain classes of patients remains as urgent as it was twelve months ago, and not less controversial, it will at least be debated with less chance of misapprehension as to the actual point at issue.

Three years have passed since the Representative Body at Cambridge declined to accept the scale of public health salaries submitted by the Society of Medical Officers of Health, and the policy now submitted as agreed between the council of that Society and the Council of the Association is the fruit of three years' experience and deliberation. That experience covers both the short day of reconstruction and inflation and the succeeding period of economic depression and retrenchment; the resulting proposals

should therefore stand the test of the searching criticism to which they will rightly be subjected at Portsmouth. But, after all, the salary scale, though an essential portion of the policy to be considered, is not its only or indeed its chief feature. Neither the Association nor the Society is solely or even primarily interested in remuneration. The development of the powers and obligations of local authorities in regard to public health, abnormally accelerated by war conditions, no less than the continuous growth of preventive medicine, calls for a more authoritative and comprehensive expression of professional opinion than any yet promulgated. That an agreed statement of policy with regard to the development of public health services is presented to the Representative Body together with the new salary scale is in itself sufficient earnest of the future. Finally, the recognition by the Society that all medico-political work should, subject to certain safeguards, be left to the Association, together with the provision for direct representation of the public health services on the governing bodies of the Association, suggests a constitutional solution of a difficulty which at one time threatened a disastrous division.

The Association, through its Naval and Military Committee, keeps in touch with members serving in the Navy, Army, Air Force, and I.M.S. During the war and the years that immediately succeeded the armistice the work of the Committee was heavy, and many matters of importance to each service as a whole were dealt with, as well as a very large number of cases affecting individuals. The value to officers of all services of having a strong organization to take up their grievances when it has been found impossible to obtain redress through the ordinary channels is inestimable. The high-handed action of the Admiralty in retiring compulsorily Senior Surgeon Commanders before the age of 55 was strenuously opposed, but the means by which the rulers of the Royal Navy can be resisted are restricted by law and usage, even when their action amounts to a breach of agreement, which in the case of a private firm would be good warrant for legal proceedings. The Admiralty was not willing to receive a deputation from the Association, and memorandums stating the case for the officers met with a blunt refusal. As the Admiralty remained obdurate it was informed that the Association must advise medical men that if they entered the Royal Naval Medical Service they must realize that so long as the present policy is maintained the Admiralty could not be trusted to keep any engagement it might make with its medical officers.

An Army Order amending the Pay Warrant was issued in 1920, and it was found that Majors were to lose rather than gain in the amount of their retired pay as a result of the revision; some of them, indeed, stood to lose £44 a year. The matter was taken up with the War Office, and the net result was a further revision of the retired pay, which amounted to a gain of £75 all round. By this the Major of twenty years' service got back his lost £44 and received an additional £31 per annum. By the revision in 1920 of the pay of officers of the Indian Medical Service certain increases were received, and this improvement was due to years of persistent work by the British Medical Association. Owing to political and economic conditions the future of this fine service is uncertain, and the uncertainty, which is reflected in the recruiting, is in part due to the way in which the Government of India has played fast and loose. The difficulty all the medical services experience in obtaining recruits is well known, and the Association loses no oppor-

tunity of expressing its views on the reasons for the shortage. It is understood that army pay generally is about to come under review, and the Association will take steps to ensure that the pay of medical officers shall be dealt with satisfactorily.

The Association has been officially recognized as the mouthpiece of postal medical officers by the Postmaster-General, and in November, 1921, set up a special subcommittee to deal with matters of concern to them. Something has already been accomplished; it has, for instance, been decided that itinerant postal servants shall as far as is feasible be placed on capitation lists. The fee for such itinerant servants has been raised, and the rule fixing a maximum number of visits to be charged for has been abolished. The fee for emergency cases has been increased, and the half-yearly maximum of 13s. per case has been replaced by a 12s. maximum per quarter. The form of report for candidates for the postal service has been simplified, and the fee for making it raised, as has also the fee for special consultations. A strong effort has been made to obtain equal pay for whole-time post office medical officers, whether male or female, but it has not been possible to induce the authorities to depart from their established custom of paying a lower rate for its women employees than for its men.

Of the work which has fallen to the British Medical Association since the armistice none is more difficult, more complex, more subject to delay and disappointment than that on behalf of the members of the profession scattered amongst the various colonies and dependencies of the Crown, most of them working as whole-time or part-time servants of the several Colonial Governments. True, there has been some advance; but it has not been possible, notably in the case of the West Indian colonies, to consolidate the position which seemed to have been attained in December, 1920, when, after the repeated protests of the Association and the exclusion from the *JOURNAL* of advertisements of vacancies in these services, the report of the Egerton Committee was published and satisfactory assurances were received from the Colonial Office that effect would be given to its more urgent recommendations. Substantial concessions were then secured as regards pay and conditions of service, particularly in the West and East African groups, but, even in these more favoured areas, the immediate outlook is dark. We have recently called attention to the reduction of personnel in the Kenya Colony Medical Service and to its implications, more especially as regards security of tenure and the licensing of partially qualified medical practice. Now we learn, from the reply of the Under Secretary of State for the Colonies to a question by Dr. Fremantle in the House of Commons, that ordinances have recently been allowed which reduce the standard required for medical registration in British Honduras, the Turks Islands, and St. Vincent.

It is difficult to believe that the position now reached is exclusively determined by the financial difficulties of the several colonies. Indeed, there is available direct evidence that this is not the case. Other considerations are involved, and amongst these we would give a prominent place to the defects in the central machinery for dealing with the affairs of the Colonial Medical Services. Whilst agreeing with the Egerton Committee that a unified Colonial Medical Service, recruited by examination and administered by its own Director-General, is an ultimate rather than an immediate objective, we regret that more advance has not been made along the lines recommended by the Committee and urged by the Association; we are forced to

the conclusion that the existing expedient of a medical advisory committee is an insufficient safeguard for the interests of these services. A day will come when the medical and sanitary services will be generally recognized, in deed as well as in word, as productive services, and the successful development of agriculture and industry amongst a population crippled by preventable disease will be realized as dependent upon the adequate application of the principles of hygiene and sanitation. But the time is not yet, and until provision is made by the Colonial Office for the review of all matters affecting its medical and sanitary services by a medical department with a responsible professional head, those services must continue to depend in the main upon the British Medical Association as a means of bringing their needs and the needs of the communities which they serve before the distant authority which has the ultimate voice in determining the conditions of their development.

### PREVENTION OF HEART DISEASE.

IN a summary of Sir George Newman's memorandum on Recent Advances in Medical Education in England (BRITISH MEDICAL JOURNAL, May 5th, p. 772) we quoted the General Medical Council's recommendation "that throughout the whole period of study the attention of the student should be directed by his teachers to the importance of the preventive aspects of medicine." The idea of prevention of disease is to be a pervading influence guiding all clinical study and practice. In other words, the "cure" of health, using the word "cure" in its now almost obsolete meaning of care, is to be the ideal rather than the cure of disease. A feeling has crept into the profession, perhaps unconsciously, that the control of certain specific infections in greater or less part by the public health authorities signified that these diseases alone were considered to be preventable, and perhaps less has been done in the way of prevention of other diseases than might have been the case. Janeway, in the Shattuck lecture in 1916, said: "By as much as the proverbial value of prevention exceeds that of cure does the importance of study of the causes of disease surpass that of its manifestations, its results or its treatment." An attempt to discover the causes of disease has not been wanting in this country, but often any systematized attempt to make use of that knowledge has been absent.

In the case of disease of the heart it is noteworthy that the most that has been attained is not the cure of the disease but its care, and comparatively little is heard of its prevention. The natural history of diseases of the heart has been the subject of much study and already much is understood; the mechanism of the heart has been investigated in a way that has rid the symptomatology and the semeiology of many of their traditional inaccuracies; the pharmacopoeia of the cardiologist, after investigation and experiment, has been very much depleted, and the few drugs that remain to him are useful in the treatment of symptoms or of complications, but have little or no effect on the underlying disease. The futility of attempting cure is very generally accepted for most cardiac diseases, and it would appear that the ground has been sufficiently well explored to make practicable the adoption of preventive measures.

Dr. Poynton deals with a very important aspect of this subject (p. 919) in a lecture delivered at the Hospital for Sick Children, where the rheumatic type of disease naturally attracts most attention. The summary of his argument follows very closely the lines

that have been adopted by the Society for the Prevention and Relief of Heart Disease of New York, to which Dr. Moon refers when dealing with another side of the same subject (p. 922). The magnitude and importance of the problem are very vividly presented in some of the figures which have been collected by that society. Thus of 5,000,000 men examined for military service in the United States, over 200,000 were rejected on account of heart defects; in one of the largest insurance companies 2.4 per cent. were rejected for the same cause; of 250,000 children in New York schools 1.6 per cent. were found to have heart defects. In England and Wales, of 366,000 school children examined about 1 per cent. were found to have organic heart disease. Mortality tables present a similar picture, and place diseases of the circulation in an unenviable position at the head of the list of causes of death. In 1919 the total deaths in England and Wales from all causes were 504,203, and of this number 51,530 are registered as organic disease of the heart, while pericarditis, acute endocarditis, and angina pectoris account for other 3,112, and diseases of arteries, embolism, rheumatic fever, and chorea add an additional 15,671 to the list. For comparison one may note the figures in the same year for tuberculosis (all forms), 46,312; bronchitis, 45,543; cancer, 42,144; pneumonias, 38,949. Owing to the incidence in different age periods the comparative wastage from these diseases cannot be drawn from these figures alone, but it is obvious that the economic problem is one which demands serious consideration, particularly when one takes into account the years of invalidism that antedate the fatal issue in most cases of heart disease. With a causal condition that in the majority of cases is frankly infective something should be possible to mitigate the extent of these diseases, and in the rheumatic cases the limitation of reinfection would of itself be of immense value. Sufficient has already been done by the New York society to warrant an extension of their experiments. Thus a limited number of so-called "potential cardiacs," children who had had rheumatic fever, repeated tonsillitis, or chorea, but in whom there was no evidence of heart infection, were cared for and watched for an average period of four and a half years. In the rheumatic or throat cases there was no instance of heart involvement, while in the cases that had chorea, either alone or with rheumatic fever, 39 per cent. developed heart lesions, and this occurred in each case in association with a further attack of chorea. It would appear that the more general rheumatic manifestations could be controlled, but when the nervous system was implicated there was less chance of stamping out the infection. This so far supports the contention of Dr. Poynton that "the subject of chorea is well worth most serious investigation." The education authorities in different parts of the country should be in a position to supply valuable statistical information on many of the points with regard to the incidence of heart disease and some of the etiological factors in its production in those of school age, and the incapacity as regards school attendance that results from it. Much good could also be done by arranging to give definite advice to parents of such children on leaving school as to employment suitable for their physical capacity. In one of his reports Sir George Newman writes: "Recent inquiries have furnished abundant evidence of the fact that many children employed for the first time after leaving school break down physically from heart trouble. . . ." In later years a similar condition

obtains. The cardiac cripple, after a period of treatment in hospital which is frequently too short, goes back to his former unsuitable employment only to prepare for a subsequent and possibly last breakdown. No one will deny that years might be added to many lives by adapting work to incapacity, and while with the present amount of unemployment it would be difficult if not impossible to find alternative work for the cardiac cripple, the problem is one which in more normal times ought to be faced.

In any scheme for the prevention of heart disease there will be room for the co-operation of many forces, and practitioners, school medical officers, hospital physicians, venereal disease specialists, throat and dental surgeons, and district nurses would have to be enlisted. Additional auxiliary hospitals or convalescent homes would be required, as residence in ordinary hospital is necessarily too short and most convalescent homes object to the admission of cardiac cases; in any event there would need to be strict supervision of exercise and recreation.

Dr. Poynton outlines some avenues of attack while dealing more particularly with heart disease in the young. The attention of the student should be drawn immediate and remote effects as they affect the child so that he may appreciate the difference in their immediate and remote effect as they affect the child or the adult. The education of the public, and specially school teachers, in the causes that operate to produce these effects would lead to the earlier enlistment of medical aid when prevention would be most efficacious. In New York much good has resulted from the institution of cardiac clinics, where patients and potential patients are looked after and periodically examined, from the segregation of cardiac cripples in special schools or departments, and from convalescence hospitals, where those recovering from recent attacks have a prolonged period under daily observation.

The subject is to be brought before the Section of Medicine at the Annual Meeting of the Association, and the arguments and information contained in the papers by Dr. Poynton and Dr. Moon will serve a useful purpose by preparing the way. Sporadic and isolated attempts at dealing with a subject of this magnitude would probably prove very ineffectual, and some central controlling or advisory body would almost be necessary for efficient organization.

### THE SPHENOIDAL SINUS.

As recently as the last decade of last century there was to be found in a work on surgical anatomy—we have unfortunately mislaid the reference—a statement "that the surgical relations of the sphenoidal sinus might be dismissed in a few words, as it was evident from its situation in the depths of the head—in the very base of the skull—that it was not and never could be reached by surgical measures." This prophecy was almost as unhappy as Erichsen's *obiter dictum* that surgery had reached its final and ultimate limits, uttered in 1873, when Lister was still in Edinburgh working at the development of the antiseptic system.

Since the beginning of the present century the opening and draining of the sphenoidal sinus has come to be recognized by expert rhinologists as a proper operation in suitable cases. Moreover, growths have been removed from the sinus, and it has been traversed by the surgeon as a means of approach in attacking disease of the pituitary gland. But the wide possi-

bilities of disease which may result from septic invasion of this cavity are still perhaps not generally known, and the two articles by Sir StClair Thomson in the current number may well give food for thought. It was in this JOURNAL that, in 1906, he published an article in which the cerebral and ophthalmic complications of sphenoidal suppuration were illustrated by the records of no fewer than 42 *post-mortem* examinations. One of his articles in our present issue is of particular interest to the physician and general practitioner. It shows how suppuration in the accessory sinuses of the nose, and particularly in the sphenoidal sinus, may be the sole cause of an acute illness of several weeks' duration. The other throws light on the association of retrobulbar neuritis with nasal suppuration. It adds one more to the list of cases proving that the cause of an optic atrophy may be found in a suppurating accessory nasal sinus, and be prevented by draining it. Such records have appeared in this JOURNAL before.<sup>1</sup> How frequent this association may be has still to be ascertained. It has been suggested that retrobulbar neuritis may be caused by simple want of ventilation of the ethmoidal and sphenoidal cavities; that "the mere presence of pus in the sinuses is by no means the usual or only cause"; and that these cavities should be opened and ventilated in certain cases, even in the absence of suppuration. Even should a retinitis clear up after the opening of a healthy sinus, this is no definite proof that the condition of the sinus was the cause. The doctrine is not free from danger, and Sir StClair Thomson, though he quotes, does not support it. He is concerned with cases of undoubted suppuration.

Surgical treatment has been energetically criticized by Harvey Cushing, who states that "many unhappy consequences of indiscriminate and ill-advised operations on the accessory sinuses" have come to his attention, as he is often urged to see patients in *extremis* from meningitis the result of operation by inexperienced hands on the ethmo-sphenoidal cavities. These technical disasters should not occur, and are, we believe, unknown or rare in the hands of well experienced rhinologists. But Cushing also doubts the frequency of the association of sinus affection and visual disturbance, and protests against the latter being attributed to a cause in the nasal accessory cavities simply because other possible causes can all be excluded. As he observes, "when a retrobulbar neuritis is said to be accompanied by 2 or 3 diopters of swelling we are certainly dealing with something which a hyperplasia of the mucous membrane lining the accessory sinuses is not capable of producing."<sup>2</sup>

Surely this matter is one which might be advanced, if not settled, by ophthalmologists and rhinologists discussing it conjointly. The former can tell of cases where causes other than nasal were at work; of cases where no clear cause could be determined; and of cases which recovered spontaneously. The rhinologist can tell of cases in which he appeared to succeed, of others in which he failed, and of the local conditions he met with in the suspected accessory nasal sinus.

Such an investigation might be expected to bear fruit in London now that we possess the finest collection in the world of specimens of nasal anatomy. The Onodi collection, which was secured and presented

to the Royal College of Surgeons through the public spirit of British laryngologists, should go far in helping to settle this question. One valuable clinical point has already been learnt by all who have looked at these beautiful dissections—namely, in all cases of retrobulbar neuritis, even when unilateral, if a sphenoidal focus is suspected, both cavities must be opened and drained, for anatomical abnormalities are so common that the sphenoidal sinus on one side may be in contact with the opposite optic nerve. This illustrates one of the many lessons ophthalmic and nasal surgeons may learn from this unique collection, which is full of interest when studied in connexion with the results of clinical observation.

### THE APPEAL FOR CANCER RESEARCH.

We publish elsewhere (p. 947) the text of an appeal to the public to subscribe to a fund established by a body newly organized with the title "British Empire Cancer Campaign." It is addressed to the people of this country and of the Dominions. There is a proverbial saying that he who sees the end sees the means, and we are prepared to believe that it applies in this instance, but we confess to some hesitation, due, in the main, to the terms of the appeal itself.

Cancer is an implacable disease, and the dread of it is present somewhere at the back of the mind of many men and more women who have reached middle age, especially if they be at all introspective. About its cause we as yet know little, beyond the facts that it sometimes follows long-lasting irritation, and that some irritants seem more apt than others to produce it. But there are a multitude of cases to which this explanation can be applied with difficulty, if at all. In fact, we do not know that all the cases to which the term "cancer" is habitually applied are due to the same class of cause. This is one of the reasons which render the problem difficult even of approach. We cannot be sure that frontal attack is the right strategy. In the heart of man the time is ripe and over-ripe, but has scientific medicine reached the stage when the attack can best be delivered in this way? Have we advanced far enough in biochemistry, in cytology and immunology, and, it may be added, in the study of the invisible viruses, to be sure that the line of progress is not along the roads they open? The conclusion of some German investigators who entered on the quest with much enthusiasm was that scientifically the time was not ripe.

It is for reasons of this order that we hesitate to accept some passages of the appeal; they are no doubt guarded by other passages, but they may easily be read to promise too much and too quickly; before now enthusiasts speaking in the name of medicine have promised more than could be fulfilled. This is not to carp at the excellent aim of the promoters of the appeal, to which we do not doubt the public will make a generous response; there is no question that more avenues of attack can with advantage be opened up and larger forces employed in developing statistical and epidemiological as well as laboratory methods; and if we are content with a cure, as to-day well we may be, the help of the new and vigorous science of pharmacology, which already holds some hopes, must be enlisted. And there is radiology—radium and the intensive x rays. All this means money; it means men also, and wise direction. But from the money aspect alone the public has a right to be assured that the funds it supplies will be wisely expended. Here again we cannot help a certain hesitation; the signa-

tures of the appeal, many of them, are highly qualified to allege the seriousness of the problem, but, speaking quite frankly, we cannot think that they are equally competent to direct the measures that can best be taken for its solution. That perplexing task should be resigned to persons tried in the direction of research, well experienced in what has been picturesquely described as its "growing edge"—where, for instance, to continue the metaphor, the individualism of the living cell, and its power of maintaining itself and multiplying in an unwonted environment, is being watched and tested. There is no lack of such experienced advisers, and there is also, as is enumerated elsewhere (pp. 947-950), a respectable number of leaders experienced in this particular department of research.

The first duty of the promoters of this campaign is, no doubt, to obtain money by a fair statement of our present disastrous position to the public. The second, which should at once be undertaken, is to apply to the Imperial Cancer Research Fund, the Medical Research Council, and the Ministry of Health, asking them to take steps for the appointment of an advisory committee composed of men experienced in general medical research, reinforced by others specially skilled in this particular matter. Otherwise money, and what is vastly more important, time and energy, will be wasted.

### THE HISTORY OF BART'S.

"The history of St. Bartholomew's Hospital from its foundation in 1123 to the present day is a part of the history of England which has never before been written at length." With these words Sir Norman Moore opened the preface to his monumental *History of St. Bartholomew's Hospital*, which was published early in 1919 in two large volumes, of some 1,600 pages in all, with a wealth of sumptuous illustrations. The writing of it occupied his spare moments during more than thirty years of a life of remarkable activity. His son, Sir Alan Moore, says in an interesting memoir in the April issue of the *Dublin Review*: "The hospital records include many hundreds of mediaeval charters, each about the size of a half-sheet of notepaper, containing usually ten or twelve lines of contracted mediaeval Latin. All these he read, besides many others at St. Paul's, the British Museum, and elsewhere. He printed in full, or gave extracts from, more than five hundred belonging to St. Bartholomew's alone. Cartularies, journals, ledgers, and many other manuscripts had to be perused and their contents weighed. . . . Moore read the old records till, for him, mediaeval London lived again. He visited many places mentioned in the charters, talked with the inhabitants and discovered links with the past. His book is worthy of the great hospital and ancient city of which it tells so much." Norman Moore died six months before the octocentenary celebrations of the great foundation whose history he wrote, and it has fallen to other hands to prepare for this occasion a shorter chronicle and an anticipation of future progress bearing the title *A Short History of St. Bartholomew's Hospital, 1123-1923*.<sup>1</sup> The greater part of this handsome volume—well written, well printed on good paper, well illustrated, and well bound—is from the scholarly pen of Sir D'Arcy Power, whose intimate knowledge of the subject is known to all Bart's men and to every student of the history of medicine. There is no man better fitted for this labour of love, and his outline of the past and present of the hospital gives

<sup>1</sup> *A Short History of St. Bartholomew's Hospital, 1123-1923*. Past and Present, by Sir D'Arcy Power, K.B.E., F.R.C.S. The Future, by H. J. Waring, M.S., F.R.C.S. London: Printed for the Hospital, 1923. (71 x 9½ pp. xv + 201; 52 illustrations.) Copies may be had for 11s. (including postage) from Mr. Geoffrey Keynes, F.R.C.S., St. Bartholomew's Hospital, E.C.1.

a clear and graphic account of the progress of an institution which has remained for eight hundred years on the exact site where Rahere placed it in the reign of Henry I. As our readers must be well aware, Rahere established his hospital and his priory at the same time, and the neighbouring church of St. Bartholomew the Great—described by Dean Inge as “still the most beautiful parish church in London”—which held its own celebration in March, is participating in next week's ceremonies. The relationship between the kindred foundations is mentioned in the present volume, but the progress of the hospital naturally forms the leading topic. Sir D'Arcy Power's review of the past, based on original records, carries us rapidly but pleasantly down the centuries, beginning with the earliest days of the hospital and the objects of its founder. He discusses in turn the various features, functions and functionaries, and the customs and possessions, which helped to make St. Bartholomew's what it was and what it is. Next comes an account of the organization of the hospital and its medical college at the present day. Mr. H. J. Waring follows with a forecast of future developments, which puts vividly before the reader two alternative schemes of reconstruction; in this he has been ably assisted by a profusion of architectural plans by Mr. T. A. Lodge. So far as can be judged in the twenty-four hours between the receipt of the book and the time of going to press, this commemorative volume for next week's celebration is a work which all Bart's men and many others whom it concerns will wish to possess. A hasty turning of the pages gives us the idea that it is one of those few books which are worthy, in the words of Bacon, to be chewed and digested—that is, to be read wholly, and with diligence and attention. The pictures are of exceptional interest, and reproduced with great skill.

#### THE UNITED STATES AND THE OPIUM CONVENTION.

IN the issue of the JOURNAL for April 7th attention was directed to the reawakened interest of the United States of America in the traffic in dangerous drugs. While the League of Nations has been preoccupied with the consideration of what may be regarded as the “legitimate” use of opium and the other scheduled drugs, the House of Representatives has been inquiring and reporting to the President in favour of very drastic international action. Last January Mr. Stephen G. Porter introduced a resolution to the House of Representatives urging the President of the United States to seek “effective control of these drugs by limiting the production thereof to the quantity required for strictly medicinal and scientific purposes, thus eradicating the source or root of the present conditions, which are solely due to production many times greater than necessary for such purposes.” To this end the President was requested “to urge upon the Governments of Great Britain, Persia, and Turkey the immediate necessity of limiting the growth of the poppy and the production of opium and its derivatives exclusively to the amount actually required for strictly medicinal and scientific purposes,” and also to urge upon the Governments of Peru, Bolivia, and the Netherlands (in respect of Java) the like necessity to restrict the production of coca leaves in a similar fashion. In February the Committee on Foreign Affairs took evidence from medical officers of health, prison governors, and social workers which indicated an amazing growth of the abuse of drugs of addiction in the United States in recent years. There were reported to be more than a million addicts in the States; heroin was said to be largely employed by the vicious and criminal underworld, and it was asserted that even young persons were being introduced to indulgence in and abuse of these perilous narcotics. The Secretary of State for Foreign Affairs, Mr. Charles E. Hughes, has written to Mr. Porter saying that “the restriction of the commercial cultivation

of the opium poppy and the coca leaf to quantities exclusively required for strictly medicinal and scientific purposes is one with which I am in entire accord.” The President is requested to report the results of such action as he may take, on the lines suggested, by December next. From a recent bulletin issued by the League of Nations it would appear that some forty States have now brought the International Opium Convention of 1912 into force; nine others have signed but not ratified the convention (Argentina, Colombia, Costa Rica, Estonia, Latvia, Lithuania, Paraguay, Persia, and Switzerland). Four Powers had not, in March of this year, adhered in any way to the convention (Turkey, Afghanistan, Abyssinia, and Lichtenstein). On the other hand the United States, Germany, and the Free City of Dantzic, though outside the League of Nations, are nevertheless parties to the convention; and it is to be hoped that the Council and Assembly of the League may, before the close of this year, secure the more general and effective enforcement of the Opium Convention, now more than ten years old. Meanwhile, seizures of dangerous drugs in the course of illicit or fraudulent transit are reported from various sources. The Canadian Government seized 442 lb. of morphine cubes, 117 lb. of heroin, and 65 lb. of cocaine, falsely consigned as “cocoa powder” from Switzerland. Again, the smuggling of morphine into China through the French and British Post Offices is reported, and a Danish firm was found to have been exporting morphine and opium to Amoy at the rate of 300 kilograms a year, some of which appears to have been of British origin. It will be remembered the Home Secretary, in connexion with the recent conviction of H. M. F. Humphrey, has cancelled the licence of Messrs. Whiffen and Sons of Battersea (also trading under the name of J. A. Wink and Co.), and they will accordingly not in future be allowed to buy, manufacture, sell, or have any dealings in the preparations to which the Dangerous Drugs Act (1920) applies. There is evident need for keeping constant watch over the international traffic in these drugs, so long as the production continues vastly to exceed medicinal requirements and thus encourages illicit commerce. That the opium trade is not without its financial aspects is disclosed by the recent announcement in the House of Commons that the Straits Settlements, the Malay States, Brunei, and North Borneo respectively derive 37, 16.7, 16, and 12.3 per cent. of their revenues from opium. There is a good deal yet to be done before we can claim imperially that our withers are unwrung. As we learn that Mr. Stephen G. Porter is representing the United States at the meeting of the Opium Committee now in session, some interesting and, we trust, fruitful discussions are doubtless proceeding.

#### LEAGUE OF NATIONS HEALTH COMMITTEE.

THE sixth session of the League of Nations Health Committee began in Paris on May 26th, and the discussions which have taken place there show that co-operation in public health matters among the various Governments has greatly developed in the two years since the League Health Organization was founded. In the field of epidemiological intelligence and public health statistics considerable progress has been made in organizing a regular and rapid collection and distribution of information, and it is hoped by the League Health Organization that in time it will become a central clearing house for all such matters. Reports on the progress of the three committees of inquiry working under the auspices of the Health Organization were discussed. The first is a small committee of experts set up to investigate the prevalence of sleeping sickness and tuberculosis in tropical Africa since the war. The second is the joint subcommittee of the League of Nations Opium and Health Committees which deals with the present position of the subject as set out

above. The third is a joint subcommittee of the Health and Transit Committees, which is collecting information to serve as the technical basis for a conference between the various European States which have navigable inland waterways, for the purpose of co-ordinating and tightening up sanitary control and anti-epidemic measures without interfering with the normal working of these arteries of trade. Further reports which were discussed concerned the progress of the applied research work, which aims at international agreement as to the methods of establishing serological tests in order to facilitate international co-operation in improving the whole technique of immunization by serum injections. It is proposed by the Health Organization that a similar programme of research work, conducted in many countries on a common plan, should be instituted in regard to certain biological products used as drugs, such as digitalis, pituitary extract, and insulin. The question of further perfecting and developing the system of visits of international groups of public health officers to study the sanitary systems of one or two countries was also considered. The first of these study visits, so-called "interchanges," took place in Belgium and Italy, the second in Great Britain and Austria; a third (for specialists in the campaign against malaria) is at present taking place in Italy, and another visit is being arranged to the United States.

#### THE NATURE OF RICKETTSIA BODIES.

BODIES which have been regarded either as definite species of "Rickettsia" and named accordingly, or placed in this group as being of similar type, are now known to be of widespread occurrence among ectoparasitic arthropods, and fresh species are being discovered continually. Dr. H. M. Woodcock holds a different view from that of many authorities as to the nature of rickettsias, and in a recent paper<sup>1</sup> he describes the way in which structures morphologically indistinguishable from rickettsia bodies appear as granular end-products of the digestion or lysis of cellular elements. Although the rickettsias are usually classed with the bacteria rather than the protozoa, they differ from well known bacteria in two respects: they stain best with Giemsa's stain, but appear bright red to lilac instead of intense purple, and they can be cultivated only with the greatest difficulty, and usually in association with other organisms, such as flagellates, from the disintegration of which similar granules are produced. On morphological grounds it is impossible to distinguish the granular end-products of the digestion of cells from the rickettsia granules, nor does cultivation enable us to distinguish the true from the false. The rickettsia-like granules all appear to be of the same fundamental character; the morphological variations which occur may possibly be explained by the action of slightly differing enzymes in the case of different types of cell, or even in the same cell type on different occasions, and upon the different kinds of organic matter on which these enzymes act, such as haemoglobin, nuclear material, and parasites. The epithelial cells of the louse take in and absorb haemoglobin, which they metabolize in such a manner that no pigment is produced; and the intracellular rickettsias, in Dr. Woodcock's opinion, should be regarded as having been produced as the result mainly of an altered abnormal form of metabolism of the blood upon which the louse feeds. Diseases such as typhus, in which rickettsias have been demonstrated, are, he considers, due to pathogenic enzymes, and the granular elements are the inevitable witnesses of the digestion of the cells. For him the virus is the invisible pathogenic enzyme, attached or adsorbed to and carried by the protein particles or bodies of various kinds which are constantly found in such diseases. The virus of typhus in the blood is, he holds, intimately

associated with the platelets, and lice can be experimentally infected by inoculation with platelets, success being evidenced by the subsequent production of rickettsia bodies. Dr. Woodcock's argument is supported by a number of excellent photomicrographs showing the types of granules which result from cell digestion or lysis, and which he considers have often been mistaken for rickettsia bodies.

#### PASTEUR CELEBRATIONS IN FRANCE.

THE official French celebration of the centenary of Pasteur began in Paris on May 24th, when the many delegates from universities and institutions throughout the world attended a reception given by the President of the French Republic. On the following morning the delegates were welcomed by Dr. Roux at the Pasteur Institute; a bust of Pasteur erected in the gardens of the Institute was unveiled and wreaths laid at its foot by foreign delegates, who afterwards visited the museum and the crypt, where is the tomb of Pasteur. Later in the day there was a great meeting in the amphitheatre of the Sorbonne, presided over by the President of the Republic, who was accompanied by the Ministers, by members of the diplomatic corps, by members of the five academies of the Institut de France and the Académie de Médecine, and by foreign delegates, to the number, it is said, of some seven hundred. The proceedings began with the unveiling by M. Paul Appell, Rector of the University of Paris, of a marble tablet placed by the university in the Salle des Autorités, bearing an inscription stating that it has been erected on the spot where "le grand Français et le grand Anglais Lister se sont embrassés" to commemorate "cette étreinte fraternelle, symbole de l'amitié de deux peuples." Afterwards the Marquess of Crewe, British Ambassador in Paris, expressed the deep appreciation of this homage to Lister paid in the heart of the intellect of France. The popular celebration took place on Sunday, which was a flag day in Paris and the chief towns of France, and badges were sold for the benefit of the laboratories of France. In the afternoon the delegates attended a reception given by the City of Paris at the Hôtel de Ville. On Monday a visit was paid to Versailles, when a bust of Pasteur given by his daughter and son-in-law, Mme and M. Vallery-Radot, was unveiled in the Galerie de Glaces. The President of the Republic at the end of last week started on a tour, during the course of which he is taking part in celebrations at Arbois and Strasbourg.

Among the names in the short list of honours bestowed on the occasion of Mr. Bonar Law's retirement are those of Sir Thomas Horder, who receives a baronetcy, and Dr. Chichester Gould May, who is created a knight. They have shared the anxiety which the state of Mr. Bonar Law's health has caused during the last few months.

We regret to record the death on May 29th of Professor John Chiene, C.B., Emeritus Professor of Surgery in the University of Edinburgh. Professor Chiene, who was in his 81st year, resigned his chair in 1909. We hope to publish an obituary notice in an early issue.

SIR CLIFFORD ALBUTT will attend the annual dinner of the West London Medico-Chirurgical Society at the Café Monaco on June 19th to receive the triennial gold medal presented by the society to a distinguished member of the profession.

THERE is no better check on extravagant administration in public institutions than comparison with those of a similar character. This is only possible, however, if there is a standard system of accountancy so that the figures are really made comparable. With a view to securing such a standard method of book-keeping in tuberculosis institutions the Ministry of Health has issued a skeleton form of accounts (Form T.90) the adoption of which will make it possible to ascertain the average weekly cost of a patient not only for the whole of the services rendered but also under various subheads such as salaries, provisions, drugs, lighting and fuel, laundry, etc.

<sup>1</sup>Journ. R.A.M.C., February-April, 1923.

## CANCER RESEARCH.

We have received for publication the following appeal, which has been issued to the press this week by the provisional executive committee of a newly constituted body, the British Empire Cancer Campaign. The full list of the committee, with particulars of the institutions already engaged in cancer research which are willing to be associated with the new organization, will, we understand, be published at an early date. The appeal is made under the auspices of the British Red Cross Society, which will receive subscriptions.

## BRITISH EMPIRE CANCER CAMPAIGN.

30th May, 1923.

Sir,

Cancer, in spite of the advances which have been made, both in diagnosis and treatment, is still the most common single cause of death in persons over 30 years of age, and is becoming so in an increasing degree. During 1920, in England and Wales, nearly 43,000 persons over 30 and upwards died of cancer. In 1921, the last year for which the Registrar-General's figures are available, the corresponding number was 45,323. During that year one in every seven deaths from the age of 30 onwards was caused by cancer.

We are still ignorant both of the causation and cure of cancer. Many other diseases have yielded their secrets to patient investigation, and there is no reason to suppose that the problem of cancer will not eventually be solved. Yet thousands of suffering men and women, and those who suffer with them, are asking how long they must wait, and if there is nothing that can be done to hasten a discovery which will bring relief to those whose outlook is to-day so hopeless.

The answer to this question is clear. The first step towards finding the cure of cancer is to discover its cause. To find that cause no effort must be spared. Every possible line of research must be diligently explored. More men must be set free to devote themselves wholly to research, and their work must not be hampered or prevented by want of money.

Much research work is being carried on and considerable advances have been made in the technique of operations designed to remove the disease in its early stages or retard its progress in more advanced cases. All honour is due to those who have done and are doing the work, but a vast amount still remains to be done. Impressed by the need for immediate action, we have joined together to found a movement which will co-ordinate and support research on cancer throughout the British Empire.

This new concerted movement will be called the British Empire Cancer Campaign. It will be governed and directed by an Executive Council, the members of which will act as chairmen of small working committees, each dealing with a separate aspect of the cancer problem.

Medicine, surgery, human pathology, chemistry, physics, radiology, animal and plant pathology, hygiene and vital statistics, will all be represented by committees whose work will be co-ordinated by the Executive Council acting, in fact, as a central clearing house. The Council is anxious to make it clear from the outset that it has no wish to interfere with the work already being carried out. Individuals and institutions now working on the cancer problem will be helped and encouraged, and, where practicable, financially assisted.

In this way investigation can be carried out simultaneously along many lines, and the results of these inquiries will be brought into the common stock of knowledge. A discovery in any one branch will be made known to all, and may lead to discoveries in other branches. It is in this co-ordination of effort that our most confident hopes are placed.

No one can say with certainty that we shall succeed in our quest to find the cause of cancer, but a movement so broad must inevitably advance the knowledge which we have of this disease, and every step forward brings us nearer to our goal.

The British Red Cross Society has placed its organization and machinery at the disposal of the Council of the Campaign, and a generous donor has already given a sum sufficient to cover the preliminary expenses of this appeal. All future contributions will therefore be expended in encouraging, assisting, organizing and administering systematic research and treatment on a scale that has hitherto been impossible.

To do this a large sum of money will be needed, and we appeal with confidence to the British public in the United Kingdom and in the Dominions and Colonies overseas. During the war we had ample evidence of the capacity of this Empire for united and intensive effort, and in no field was it more effectively shown than in the relief of suffering and the prevention of disease. Is it too much to hope that the same spirit will animate our people when they are called upon to wage war

against an enemy that is in their very midst? We plead with all earnestness that we may be given the means wherewithal to carry through the task which we have set ourselves to accomplish, and thus to bring relief and hope to those whose lives are now darkened by suffering and despair.

The Fund will be administered under the direction of a strong finance committee.

Cheques should be made payable to the British Red Cross Society, crossed "British Empire Cancer Campaign," and sent to the Hon. Sir Arthur Stanley, G.B.E., C.B., 19, Berkeley Street, London, W.1, or to Lloyd's Bank, Ltd., 71, Lombard Street, or to any of their branches or agencies at home or abroad.

We are, Sir, yours faithfully,

ATHLONE.	F. L. HOPWOOD.
J. BLAND-SUTTON.	THOMAS HORDER.
NAPIER BURNETT.	ROBERT KNOX.
DAWSON OF PENN.	G. LOCKER-LAMPSON.
J. B. FARMER.	J. P. LOCKHART-MUMFERY.
F. E. FREMANTLE.	EDWARD MARSHALL-HALL.
RICHARD GARTON.	J. BEAUMONT PEASE.
CHAS. GORDON-WATSON.	BERNARD SPILSBURY.
R. A. GIBBONS.	ARTHUR STANLEY.
ALFRED GREENWOOD.	WILLIAM WILCOX.

Communications should be addressed to the Honorary Secretary, Godfrey Locker-Lampson, Esq., M.P., at 19, Berkeley Street, W.1.

The British Empire Cancer Campaign has been registered as a company limited by guarantee.

## CANCER RESEARCH NOW IN PROGRESS.

The appeal, it will be observed, promises to encourage, and help financially where practicable, individuals and institutions now working on the cancer problem, and distinctly repudiates any wish to interfere with work already being carried on. We have thought, therefore, that it would be interesting to put together from information at present available some particulars of the institutions engaged in such work.

## THE IMPERIAL CANCER RESEARCH FUND.

The Imperial Cancer Research Fund was founded in 1902 by the joint action of the Royal Colleges of Physicians and Surgeons; representatives of the Royal Societies of London and Edinburgh, the Royal Veterinary College, and other scientific bodies, and of several Government departments, were added to the Executive Committee, which is the governing body. From the beginning the main efforts of the Fund were directed to the development and extension of the experimental method to the study of cancer. Statistical investigations on the incidence of the disease in man at home and abroad were undertaken in conjunction with the Registrar-General's Office and through the Colonial and India Offices. An experimental study of the part played by heredity in modifying the incidence of cancer was undertaken and carried on for many years.

Coincidentally with the starting of the Fund, the foundations of the experimental study of cancer in laboratory animals were laid by Jensen and Borrel, and the workers of the Fund took a large part in its development. The detailed analysis of the phenomena of transplantation and the production of resistance to inoculation was carried out. In particular, the significant limitation of the resistant condition to prevention of successful grafting, and the failure of these reactions in animals spontaneously affected by the disease, were worked out and their importance insisted on. During the war, by rigid economy of effort, the Director, Dr. J. A. Murray, found it possible to maintain the essentials of the working organization. In consequence the other institutes at home and abroad which had suspended operations were able to call on the Fund for material enabling them to begin work again without delay.

Since the war, the experimental production of cancer by the application of tar has been energetically studied. The essential characters of cancer cells and the subtle distinctions between them and normal cells have been investigated by the method of tissue culture and by a study of the processes of respiration of surviving tissues. In addition an elaborate investigation of the relation of the growth of cancer to diet has been carried through, defining the effects of vitamin and other specific deficiencies both in normal animals and in those carrying inoculated tumours.

A summary of the published work in each year is given in the annual report, along with an account of the administration and financial position of the Fund by the Executive Committee and treasurer respectively. Full accounts of the investigations are published from time to time in the scientific reports, of which seven have already appeared (Taylor and Francis, Red Lion Court, Fleet Street, E.C.4).

#### CANCER HOSPITAL RESEARCH INSTITUTE, LONDON.

The Cancer Hospital, founded in 1857, possesses a well designed and well equipped Research Institute, built a few years before the war. For the last two years it has been under the directorship of Dr. Archibald Leitch, with whom are associated Dr. E. L. Kennaway as chemical pathologist and Dr. H. J. B. Fry as clinical pathologist. Working in close connexion with the surgical and radiological departments of the hospital they have unrivalled opportunities of being familiar with all sides of the cancer problem. The chemical and biochemical investigation of tumours and of serum from cancerous patients, histological examinations of tumours of all kinds, the study of cell and tissue changes under treatment by x rays and radium, and the detailed investigation of operative and *post-mortem* material from the point of view of practical surgical pathology, represent some of the numerous lines of research provided by the association of clinical and pathological departments. From the purely experimental side work has been proceeding on an intensive scale, mainly on inquiries into the causation of cancer. We published in the JOURNAL last December three important papers from the Cancer Hospital Research Institute on the experimental production of cancer, and we hope soon to publish two more. The research staff have been endeavouring to add to the number of substances which are capable of producing tumours, and though they have already contributed three or four such substances, we understand that scores of suspected agents have been tested. Studies of the early changes preceding and accompanying tumour formation, chemotherapeutic essays in experimental cancers, and the investigation of the conditions under which occupational cancers arise, constitute at present the main objectives. The striking feature about the Cancer Hospital is the particularly friendly co-operation between the surgeons, radiologists, and laboratory staff, so that each individual member is conversant with the observations and problems of the others. The governing board appears to be very progressive.

#### THE MIDDLESEX HOSPITAL.

The Middlesex Hospital Cancer Charity was founded in 1791 with the object of alleviating suffering and investigating the disease. Until 1900 its activities in the latter direction consisted chiefly in the compilation of records and publication of papers on cancer from time to time by members of the hospital staff. In 1900, largely owing to the initiative of Sir Alfred Pearce Gould, laboratories were opened for investigation of malignant disease by modern methods, and Mr. A. G. R. Foulerton was appointed director. On his resignation in 1903, Dr. W. S. Lazarus-Barlow was elected to the office, and held it until in 1920 it was merged in a Professorship of Experimental Pathology in the University of London, to which he was appointed. The avowed object of the change was to widen the range of activities available for cancer research and enable it to be taken up in any department of the Medical School that seemed advisable. It coincided with the establishment in the school of University Professorships in Physics, Chemistry, Anatomy, Physiology, and Pathology. Recently a University Reader in Biology has been appointed. From its first inception the charity has grown continuously, but benefactions have been mainly on the clinical side. Specifically for research the cancer laboratories (which were built and equipped by the trustees of the Barnato bequest in 1910) have to rely upon the income of a sum of £20,000 and £1,000 per annum for ten years recently given by Sir W. Veno, and for the remainder of the expenditure on annual voluntary contributions. The amount thus obtained is inadequate to the complexity and difficulty of the subject, and extension in many directions is possible and desirable. The assets for cancer research which the

Middlesex Hospital possesses are 92 beds in the charity dedicated to cancer patients and the resources of the Medical School completely equipped in all branches.

During the twenty-three years the laboratories have been in existence the advantage of their close association with the hospital wards has been shown by the very practical character of the researches carried out and by the names of those who have held assistantships or scholarships. Among those who have held appointments may be mentioned Mr. Sampson Handley, Mr. Gordon-Taylor, Mr. Victor Bonney, Mr. Somerville Hastings, Dr. Henry MacCormac, all of whom are now members of the honorary staff of the hospital; Mr. Cecil Rowntree, surgeon to the Cancer Hospital, Fulham Road; Dr. Archibald Leitch, director of the Cancer Research Laboratory at the Cancer Hospital; and Dr. J. C. Mottram, director of the Pathological Department of the Radium Institute. The practical character of the researches is indicated by the fact that all the records of the hospital have been worked up statistically and a number of monographs on cancer at the principal primary sites have been published; investigations have been conducted into the increase of cancer, and attempts made towards earlier and better diagnosis. Much work has been done in reference to radium and x rays and as to the production of cancer in lower animals by these agents. Research in the therapeutic value of radium or x rays has been instituted, and since 1914—though much interrupted by the war—investigations have been conducted, and are still in progress, with the hope of causing experimental animals to develop an immunity towards cancer. Sufficient success has been obtained in the case of transplanted tumours in rats to apply the principle, with caution, to man, and during the past two years it has been utilized in the treatment of selected patients in the wards. It is too early to speak of the results, but at least it may be said that they are hopeful. At the present time experimental endeavours are being made to facilitate the technique and heighten the degree of induced immunity. In these animal experiments, as always, the underlying thought in the mind of the investigator is that they must be applicable to the human sufferer. The Medical Research Council, in addition to the important allocation of radium mentioned below, has supplied the services of Dr. Helen Chambers for work in Dr. Lazarus-Barlow's department and of a whole-time assistant. In laboratories attached to a general hospital and medical school the practical as contrasted with the academic side of research comes to the fore, and this is the guiding principle of the work at the cancer laboratories of the Middlesex Hospital.

#### MANCHESTER.

Research work on the various aspects of cancer is being carried out in several departments at Manchester. At the Royal Infirmary, the new x-ray department is one of the most completely equipped of its kind in the country. With the advent of the intensive x-ray therapy a research committee was instituted, consisting of physicians, surgeons, radiologist, pathologist, and physicist, to investigate the effects of this form of treatment in cancer. For this purpose a research scholarship in radiotherapy for the intensive treatment of cancer has been instituted, and the first scholar spent six months on the Continent studying the latest technique in x-ray therapy. The new apparatus is all at the Royal Infirmary, where the investigations are in their initial stages, and two separate outfits for the intensive x-ray treatment of cancer are in use. Although it is too early to speak with any confidence, as the work has only been in progress for about twelve months, yet the initial response in carcinoma is considered to have been satisfactory. The late results cannot, of course, yet be stated. In sarcoma the outlook appears more hopeful, and in some cases the primary growth has apparently completely disappeared. Six beds are set apart at the Radium Institute and the Christie Hospital for patients undergoing intensive x-ray treatment for the relief of inoperable carcinoma. So far about 100 cases have been treated. At the Radium Institute thirteen beds are set apart solely for the treatment and investigation of cases of cancer; 668 cases of cancer were treated last year, and the whole work of the Institute is really an investigation into the cause of cancer. A new

research laboratory is shortly to be equipped; all the cases at the Institute are subject to pathological investigation, and careful records are kept which are available for statistical study. Results at the Institute show that 7½ per cent. of all cancer cases (many inoperable) under treatment are alive and well after periods of two to seven years. A special research into the physical chemistry of serum in health and disease has recently been undertaken with the help of the Institute's radium; it has been found that alpha, beta, and gamma rays have a very marked effect on serum. A technique has also been devised for following changes in the colloidal condition of whole blood, whereby only a very small quantity of blood is required for each determination. A natural extension of this work will be to follow the colloidal changes in blood due to the absorption of the products of the destruction of a tumour in a patient who is being treated with radium. In this way help may be obtained in prognosis and in judging the dose a patient will tolerate. The Committee of the Christie Hospital has recently received a gift of £1,000 to be devoted to research work, and it is hoped shortly to start a cancer research fund in Manchester. Investigations are being carried out at the Cancer Research Laboratory at the University on the metabolic functions of patients suffering from cancer and also into the chemistry of tumours. Considerable interest has been aroused in the question of the incidence of scrotal cancer among cotton-spinners in Lancashire. A paper on this subject by Mr. A. H. Southam and Mr. S. R. Wilson was published in our columns last November (page 971). Their attention was called to the matter by cases observed at the Manchester Royal Infirmary. They made some inquiries at a Manchester cotton mill; further investigations are in progress, and experimental work is under consideration with a view to getting this condition scheduled under the Workmen's Compensation Acts, if it should be proved to be due to the occupation. Statistics show that the death rate from cancer is steadily on the increase in Manchester, the annual increase being nearly 4 per cent. In a period of thirty years the death rate from this cause has doubled, and deaths are occurring at an earlier age. It is held that the hope of the future lies in research. Men and the brains can, we are assured, be found at Manchester to proceed with this work if more money is forthcoming.

#### LIVERPOOL.

There has been in existence in Liverpool for some time a committee for cancer research consisting of business men and scientists working in close association with the University. It has secured the services of the best men in all departments—chemical, biochemical, pathological, medical, and surgical—either as whole-time or part-time workers, and has the necessary laboratories with accommodation for animals and other equipment, and also the command of clinical beds necessary to enable it to conduct its inquiries. This small but well equipped and self-contained body is prepared to carry on the piece of work it has undertaken. It is entirely due to the initiative of Professor Blair Bell, who recently published a preliminary statement, giving his reasons for believing that lead salts possess an inhibitory action on the growth of malignant cells. He pointed out the practical difficulties and dangers which necessarily accompany the use of these toxic substances in treatment. Lead salts have, however, already been used on many occasions during the present inquiry, and those who have been closely associated with the treatment throughout are impressed with the belief that lead undoubtedly has a destructive action upon cancer cells. A preparation has not yet been found which can be pressed sufficiently to make the treatment specific. Some cases have yielded striking results, though the investigators as yet hesitate to speak of them as cured; many others have responded, but not to the extent of cure, and in some the toxicity of the remedy has been a difficulty. The Liverpool Cancer Committee has scope in Liverpool for a definite and, it is believed, important research, and it has a very enthusiastic body of men prepared to do their utmost to carry it to a successful conclusion, if that be possible. A good income is guaranteed for the next two years.

#### ABERDEEN.

In 1907 Sir Alexander McRobert, Cawnpore, India, established the Georgina McRobert Fellowship at Aberdeen University, for the investigation of the cause, prevention, and treatment of cancer. In 1916 this fellowship, as a result of a further gift from Sir Alexander McRobert, was merged in a larger foundation, the McRobert Lectureship in Pathology, with special reference to malignant diseases. The first appointment to the lectureship was made in 1920. Accommodation for a laboratory and funds for its equipment were provided by the University of Aberdeen, and work has been in progress since 1921. The staff consists of Dr. John Cruickshank, the lecturer, and one assistant, Miss J. L. Lockhart. The annual income from the trust is not large enough to allow work on a large scale to be undertaken. During the last two years the production of cancer in animals by the application of tar and other substances has been investigated. The results of this work have in part been communicated to various societies, and will shortly be published in full. A study of some of the biochemical activities of cancer cells as contrasted with normal cells has also been attempted. In this work Dr. Cruickshank has been in close association with the Imperial Cancer Research Fund. The scope of the laboratory work has been extended by the loan of radium from the Medical Research Council to Aberdeen Royal Infirmary, and to facilitate clinical research work Dr. Cruickshank has been appointed to the honorary staff of Aberdeen Royal Infirmary as Director of Radium Therapy and Research. Dr. D. W. Berry, a part-time worker under the Medical Research Council, is associated with Dr. Cruickshank in the investigation of the clinical effects of radium treatment, and assists in the laboratory work on malignant diseases.

#### GLASGOW ROYAL CANCER HOSPITAL.

The Research Department of the Glasgow Royal Cancer Hospital is directed by a Research Committee of five, consisting of three medical men and two laymen. The medical men are Sir George Beatson, Dr. Robert Muir, professor of pathology, and Dr. Noël Paton, professor of physiology in the University of Glasgow; the lay members are the Chairmen of Directors of the Hospital and of its House Committee. The Research Department was broken up by the war, and, owing to want of money, has only been re-established during the last two years. As soon as funds were available the chemical branch of the work was set in order under Mr. Currie, a biochemist. At present efforts are being concentrated on the biochemical features of cancer; last year Mr. Currie published a paper in the *Journal of Pathology and Bacteriology* on the condition of the fat in cancer patients, especially in the vicinity of the growth, and Sir George Beatson published in the *Lancet* a paper on the possibility of a pigmentary origin of cancer. Mr. Currie is also working at tar cancer in mice and studying the respective frequency of its occurrence under the different pigments of coal tar and the susceptibility of different coloured mice to develop the disease. Dr. Primrose is also working in the department, investigating in particular the internal secretions in relation to carcinoma and the growth of cancer tissue *in vitro*. A proposal has been made to the Committee of the Glasgow Hospital to co-operate with the appeal, but it will not come to a decision until after it has considered the views of its Research Committee.

#### THE MEDICAL RESEARCH COUNCIL.

A great deal of valuable research into the nature and treatment of cancer is being carried on in various centres with the assistance of the Medical Research Council. Grants are made towards the cost of inquiries now in progress at the Middlesex Hospital, London, by Dr. James Young at the Royal Infirmary, Edinburgh, at St. Mark's Hospital, and at the Glasgow Royal Cancer Hospital, as mentioned above. The Government has entrusted to the Council for medical research purposes nearly 5 grams of radium bromide recovered from military uses; the whole amount was lent in the first instance to workers at the Middlesex Hospital to carry out a series of initial experiments and therapeutic trials, and the results were published in one of the Council's Special Reports. Later on the whole supply was divided

and fractions allotted to a number of hospitals in England, Wales, and Scotland. Research committees have been established at the different centres, and the Council has appointed a central radiological committee, of which Sir Cuthbert Wallace is chairman, and Professor Sidney Russ, D.Sc., of the Middlesex Hospital, secretary. An important fraction of the radium is in use at the Middlesex Hospital, where it is being used both clinically and for pathological and physical investigations. At University College Hospital, London, the radium has been employed chiefly in the treatment of malignant disease of the uterus and of menorrhagia. The quatum supplied to St. Bartholomew's Hospital has been employed in the treatment of carcinomata of the uterine cervix, and the treatment of malignant growths of the nasopharynx, larynx, and oesophagus. At King's College Hospital the radium has been used for the treatment of cancer of the uterus and breast, rodent ulcers and naevi, and it has also been made available for experimental work on the effects of radiation on the body tissues, for which purpose the Council makes a grant for a part-time assistant. The fraction in use at the London Hospital is being applied to the treatment of diseases of the skin and of malignant diseases of the uterus. Other fractions have been allotted to the King Edward VII Hospital, Cardiff, and to the General Hospital, Birmingham, where observations are now being made. In all instances the observations on the effect and treatment are carefully controlled, and recorded with scientific precision. Reference is made above to the radium lent to the Aberdeen Royal Infirmary. One of the earliest allocations was to the Irish Public Health Council, under whose supervision radium emanation, prepared from a central laboratory in Dublin under the direction of Professor J. Joly, F.R.S., is issued to certain hospitals and private practitioners, and records are kept of the results obtained. A fraction has also been allotted for experimental purposes to the Radium Institute, London, where Dr. J. C. Mottram is studying the effects of radiation upon the testes, the pituitary gland, the thyroid glands, and the blood platelets, and upon fat absorption in the intestine. Dr. William Cramer and Dr. A. H. Drew of the Imperial Cancer Research Fund have been associated with Dr. Mottram in part of this work, and the Council has made a grant to Dr. A. N. Kingsbury of the Middlesex Hospital for co-operation in some bacteriological problems that have incidentally arisen. Finally, a fraction has been allotted to Professor Sir Ernest Rutherford, F.R.S., for experimental work at the Cavendish Laboratory of the University of Cambridge.

An inquiry is being made by the Statistical Department of the Council into the incidence of cancer in different trades. The Registrar-General has for this purpose made available data referring to 46,235 deaths from cancer among males, both occupied and retired, occurring in over 900 trades and professions in England and Wales during a given period. Particulars are thus being obtained for each trade as to the type of cancer, the site of the growth, and the age distribution among occupied and retired males. The analysis is being made by Dr. John Brownlee, director of the department, in collaboration with Professor E. L. Collis.

#### FOREIGN COUNTRIES.

The desire to attack the problems of cancer by intensive research has not been confined to this country. In the United States the most important organization is the Crocker Institute of Cancer Research at New York, which is now a department of Columbia University and produces very valuable work. It was in this Institute, for example, that the experimental production of sarcoma of the liver was accomplished in rats by the transmission of *Taenia crassicolis*. The laboratories are under the direction of Dr. J. C. Wood and Dr. William Woglom. Under their auspices is published the *Journal of Cancer Research*, the only special journal on the subject in the English language. We ought also to mention the Research Institute at Chicago, where the important experiments of Miss Maud Slye and Dr. Gideon Wells on the heredity of mouse cancer have been conducted.

France is badly off for specialist institutions dealing with cancer research; there are a few scattered places, but nothing adequate. The most efficient, perhaps, is the Hospice Paul Brousse, of which the director is Professor G. Roussy, an able and energetic pathologist, whose recent experimental

work has attracted favourable attention. The Association française pour l'étude du Cancer, founded in 1906, is a voluntary organization of pathologists and clinicians interested in cancer; it makes a gallant attempt to stimulate public interest and has a very distinguished list of members, both French and foreign. Its proceedings are recorded monthly in a *Bulletin* which contains the papers read at its meetings and short abstracts of foreign literature. Under the guidance of its secrétaire-général, Professor Roussy, it has become a most important journal and is probably now to be considered the premier organ of cancer research. It is publishing an atlas of beautifully drawn histological preparation of all kinds of tumours, which may possibly be the standard work of reference on the subject. The French Association has arranged to hold a congress in Strasbourg on July 23rd and 24th in connexion with the Pasteur celebrations there. The first subject for discussion—the experimental production of cancer—will be introduced by Professor Borrel of Strasbourg University, and continued by Professor Fibiger of Copenhagen, Professor Ichikawa of Japan, Dr. J. A. Murray, Director of the Imperial Cancer Research Fund, London, Dr. Archibald Leitch, Director of the Cancer Research Institute, London, and Dr. Pentimalli of Naples. The other subjects to be debated are the local and clinical reactions to cancer, and treatment by radium and  $\alpha$  rays of epithelioma of the skin and mouth.

In Germany ambitious plans were made previous to the war, and a special institute of experimental research in cancer was established at Heidelberg under the direction of Professor Czerny; it is an association with a home which receives patients suffering from or suspected to be suffering from cancer, or from tumours of other kinds. It was reported that some well known pathologists originally associated with the project withdrew, believing it probable that fruitful results were little likely to be reached until more was known of the structure and physiology of the healthy cell. Since the war the institute has been placed under the directorship of Professor Sachs, a former assistant of Professor Ehrlich, though Dr. Teutschländer seems to have carried out most of the experimental work on the genesis of cancer. Dr. R. Bierich presides over a small cancer research institute at Hamburg. Owing to the economic conditions prevailing in Germany, research work has suffered, and in no department more than cancer investigations. The Germans publish regularly the *Zeitschrift für Krebsforschung*, a well known though somewhat heavy journal of international repute.

In Holland a young and promising laboratory has been in existence for two or three years, conducted under the auspices of the Netherlands Cancer Investigation Society by Dr. H. T. Deelman. It was here that last October a small band of enthusiasts met round a laboratory table and submitted to each other their recent experimental investigations in malignant disease. They agreed to form a friendly society which, at the suggestion of Dr. Archibald Leitch, was, out of compliment to the Dutch hosts, named the "Leeuwenhoek Vereeniging." We understand that the members are in constant communication and indicate to each other the particular lines of investigation they are pursuing. The Society consists of Drs. Fibiger, Bang, Murray, Leitch, Rotgans, Deelman, Roussy, Peyre, Bierich, Teutschländer, Lipschutz, and Bloch.

THE fifth French Congress of Orthopaedics will be held in Paris on October 12th, when the following subjects will be discussed: (1) *Pes cavus*, introduced by M. Laroyenne of Lyons; (2) bone cysts (exclusion of hydatid cysts), introduced by M. Roederer of Paris; (3) congenital elevation of the shoulder, introduced by M. Delchef of Brussels.

A PUBLIC appeal is being made for funds to extend the National Library for the Blind in Westminster. The library began on a small scale in 1882, and has grown (including the Northern Branch at Manchester) to a collection of some 92,000 volumes in Braille and Moon types. The bulk of the volumes (14 in. high, 11 in. broad, 2 in. thick, and 5 lb. in weight), in addition to their cost, precludes the blind reader from possessing an adequate private library, and the National Library dispatches daily over a ton of literature to readers at home and abroad. Donations should be addressed to Captain Lachlan Maclean, National Library for the Blind, Tufnell Street, Westminster, S.W.1.

## UNIVERSITY OF DURHAM COLLEGE OF MEDICINE, NEWCASTLE-ON-TYNE.

### OPENING OF NEW BACTERIOLOGICAL DEPARTMENT.

The new building recently erected by the College of Medicine for the Department of Bacteriology was opened by Sir Frederick Andrewes, M.D., F.R.S., on the afternoon of May 25th. The ceremony was attended by a large number of people, including many members of the medical and dental professions, the members of the councils of Armstrong College and the College of Medicine, the Principal and heads of departments of Armstrong College, and the President, staff, and undergraduates of the College of Medicine, as well as by many men prominent in the public affairs of the district. The guests were received by Sir David Drummond, M.D., D.C.L., LL.D., President of the College of Medicine, in the King's Hall of Armstrong College, and, after being entertained at tea, adjourned to the Physics Theatre, where an address was delivered by Sir Frederick Andrewes.

Sir DAVID DRUMMOND offered a hearty welcome to Sir Frederick Andrewes and the visitors who had assembled to take part in the function. He explained why a new building was found to be necessary, and why it had been erected upon a site in connexion with Armstrong College rather than upon the site at present occupied by the College of Medicine. The accommodation in the latter had fallen short of the requirements, especially in so far as the more technical and practical sections of the curriculum were concerned, and the pressure had been felt most acutely in the department of bacteriology. The Council of the College in 1918 appointed a committee to consider the best method of meeting the requirements, and various proposals were made, amongst them to build upon the present College of Medicine site, but this was found to be impracticable on account of want of space. The Council of their sister college, Armstrong College, then made the magnanimous offer of a site adjacent to the agricultural department, and further offered to advance the capital necessary for the erection of the building, stipulating only that they—Armstrong College—should be consulted as to the design and structure of the building, so that it might readily be converted to their needs when the College of Medicine found themselves able to erect the new college upon the site recently acquired by the two colleges in Queen Victoria Road, next to Armstrong College and opposite the Royal Victoria Infirmary; the College of Medicine to rent the building and so to pay the interest upon the capital. This most generous offer was accepted by the Council of the College of Medicine with thankfulness, and he, as President, took the present opportunity to announce publicly the great debt of gratitude they owed the Council and their colleagues of their sister College, by whose liberality and generous outlook they—the College of Medicine—had been relieved of much of the inconvenience from which they were suffering from overcrowding. The University of Durham and the city of Newcastle-upon-Tyne had thus acquired a most important educational development in the shape of what, he ventured to hope, Sir Frederick Andrewes would find to be one of the best bacteriological departments in the country.

### SIR FREDERICK ANDREWES'S ADDRESS.

Sir FREDERICK ANDREWES, in outlining the place of bacteriology in the arts and sciences of the present day, said that to make the position of bacteriology clear, it was needful first to consider a little of the history and development of that science. Probably the first human eye which distinctly saw the organisms now known as bacteria was that of the great Dutchman, Leeuwenhoek, often spoken of as the "father of microscopy." This was nearly 250 years ago, and to Leeuwenhoek, and indeed to his successors for more than 150 years, they were merely objects of interest and wonder. They were regarded as animals, and with improvements in the microscope it was found that they varied in size and shape, so that Ehrenberg in 1828 was able to distinguish four different types. It was not until after the middle of the nineteenth century that their vegetable

nature was established. During the nineteenth century the foundations of bacteriology were laid. Two great discoveries opened men's eyes to the fact that these insignificant specks of living vegetable matter were after all of serious importance to man. It was found that they were the causes of various fermentations, and that they might be the causes of infectious disease. It was not until the rise of chemistry that the nature of fermentation could be understood, and then the microscope revealed that the mysterious substance which, when added to the fermentable material, initiated the chemical changes, owed its power to the presence of micro-organisms. An even more important impulse was given by the discovery of the relation of micro-organisms to infective disease. As early as 1825 a silkworm disease known as "muscardine" was found by Bassi to be due to a fungus, and in the following decade the parasites of favus and ringworm were discovered. The first bacterial disease to be identified was anthrax: the infecting agent was seen in the blood of infected animals by Pollender in 1849 and by Davaine in 1850. Of all the great names which stood out in the nineteenth century that of Pasteur must take the first place in connexion with bacteriology. For his chief claim to immortality was not that he was a great chemist—as he was—but that he founded a new science. Pasteur transformed bacteriology into an experimental science. He was the first to cultivate bacteria artificially and to bring them into the domain of the laboratory. The second great name in bacteriological science was that of Robert Koch. The principles of most of our modern methods were owed to the technical genius of Koch, who devised the means of culture on solid media and enabled the bacteriologist to make certain of the purity of his growths. No difficulties seemed too great for this man to overcome, as was well shown by his discovery of the cause of tubercle.

It was on the medical side that bacteriology first developed. As the new methods of study began to be applied, the actual causal organisms of the various infectious diseases which scourged mankind had been one after the other unveiled. The earliest discovered causes of infectious disease were fungi of a higher group than the bacteria, and for the causes of many diseases which in the most modern times received their explanation it had been needful to go still further afield. The first new light came from workers on tropical diseases. As early as 1880 Laveran had found the malarial parasite, which was shown to be a member of the animal kingdom, while before this a trypanosome had been found in rat's blood. Obermeier, too, had found in relapsing fever the spiral organism now bearing his name, though the exact nature of this and similar microbes was still a matter of some dispute. It soon became clear that some important tropical diseases were due to animal micro-parasites and others to organisms which could with certainty be referred either to the animal or to the vegetable kingdom, and which were grouped by Haeckel under a new kingdom—"Protista." Nor did matters stop there, for in recent years evidence had been brought forward to show that many specific fevers were due to viruses invisible or almost invisible under the microscope, and capable of passing through the pores of a filter so fine as to keep back ordinary bacteria. Bacteriology had to change itself into microbiology. The younger sciences of protozoology and protistology were now beginning to claim their own separate places in the field. Presently came a time when workers turned to the effects of pathogenic bacteria on the human and animal body. In particular they asked why some men and some animals were susceptible to a given infection and others immune. Pasteur himself had opened up this field of inquiry in relation to anthrax and rabies. But the mechanism by which immunity was produced was still obscure. Fortunately, the subject lent itself to the experimental method. First in the field was Metchnikoff, whose brilliant researches on the comparative pathology of inflammation led him to lay great stress on the destruction of invading bacteria by certain cells of the body, notably the leucocytes of the blood. It was now known that Metchnikoff was largely, but not wholly, right in this idea; phagocytosis seemed to be the main defence of the body against certain bacteria, but his doctrines soon suffered eclipse, owing to the discovery of the power of the fluid elements in the blood of an immune animal. It was even

found that the body fluids might become "antitoxic." Yet another science was thus founded—the science of immunology. It could now be affirmed that the body had many different means of defence.

What practical results had emerged? So far as medicine was concerned, any doctor would give an answer. Bacteriology had become an integral part of all that section of pathology—fully a half—which dealt with infective processes. The physician would say that without the knowledge of disease which had accrued from bacteriology, he would be still working by rule of thumb in a large part of his practice. What physician would fail to seek the help of the bacteriologist in a doubtful case of diphtheria, or neglect the use of antitoxin in the treatment of that disease? Ask, again, any surgeon what value he set upon aseptic methods in his art and what judgement he had formed of Lister's work in this respect. The name of Lister was honoured throughout the whole world. And what was true of surgery was true of obstetrics. It was all the outcome of bacteriology. While a multitude of diseases were not bacterial, it would scarcely be disputed that, directly or indirectly, bacteriology had saved more lives than all the other sciences combined. In the prevention of disease bacteriology performed two different services: it was able to trace the ways in which infectious diseases spread and to introduce measures by which human beings could be immunized. Once the infecting agent in any disease had been ascertained its distribution in nature could be searched out and the channels found by which it reached man. Consider the change in outlook when it was shown that malaria was exclusively transmitted by the mosquito, typhus by the louse, and plague habitually, though not invariably, by the rat flea. Certain diseases were known to be sometimes water borne, some were spread by milk, others by shellfish and other foodstuffs; in all such cases the services of the bacteriologist were invaluable. But the greatest service the bacteriologist had rendered was the attention he focused on the human carrier of infection. It was now known that many human beings might become so far immune that they were capable of harbouring and, what was worse, of disseminating the infecting agents of certain diseases in a fully virulent condition: the bacteriologist alone could detect these dangerous people.

Sir Frederick Andrewes then spoke of the service which immunology furnished to preventive medicine in devising means for rendering a population immune to certain diseases—at least for a time. The experience of the war was conclusive as to the vast reduction in the incidence and mortality of typhoid as the result of preventive vaccines and as to the marvellous diminution of tetanus which followed the serum treatment of the wounded. Yet, notwithstanding the attention which their importance had attracted, probably not one in a hundred of the existing species of bacteria bore any relation to disease. Take the process loosely described as fermentation: sometimes it was of importance to prevent such chemical changes, as in the preservation of food; in other industries it had proved possible to utilize the chemical powers of bacteria. Nature worked more economically than art, and the chemistry of these minute organisms was more subtle than that which the laboratory could accomplish. But it was in agriculture and allied industries that some of the most important applications of bacteriology were to be found. In the front rank stood the discoveries of the nitrogen-fixing powers of certain bacteria, especially well seen in the root nodules of leguminous plants, whereby the importance of these in the rotation of crops received a rational explanation. Again, milk was a particularly favourable medium for the growth of bacteria, so that the whole dairy industry was deeply concerned in questions of bacteriology. Thus bacteriology was a subject of high industrial importance, fully worthy of careful study even if it had no application to medicine. It must be taught in two stages. First must come the academic study of its general principles. For this purpose the situation of the laboratories opened to-day seemed admirably adapted, and the University might congratulate itself on such provision for the teaching of the subject. The second stage of teaching could only be carried out effectively in relation to the special arts and sciences to which bacteriology might be applied. It would be a mis-

fortune if the establishment of the central teaching of bacteriology in that institution led to any divorce from medicine, and he trusted it might have the contrary effect. The medical aspects of bacteriology could only be studied to advantage in close relation with medicine itself.

On the conclusion of the address Sir DAVID DRUMMOND moved a vote of thanks, which was very heartily received, and presented to Sir Frederick Andrewes a key with which he asked him to open the new building.

#### THE NEW BUILDING.

The building recently erected by the College of Medicine for the department of bacteriology is situated on the north-east side of Armstrong College and next to the building housing the department of agriculture, which was erected largely through the generosity of the late Dr. Clement Stephenson, F.R.C.V.S., in 1912. The building of these laboratories is, as a matter of fact, the first item in a much larger programme which comprehends nothing less than the removal of the College of Medicine from its present situation in Northumberland Road to a site which has been acquired in conjunction with Armstrong College at the junction of Queen Victoria Road and St. Thomas's Street. When this scheme for an entirely new College of Medicine is completed, the University Colleges of the City and the General Hospital will all adjoin each other, with very considerable mutual advantages to everyone concerned.

The building, which has been very skilfully and artistically designed by Messrs. Knowles, Oliver, and Leeson of Newcastle, is of fireproof construction and was built by Messrs. Pringle of Gateshead. It is built of red brick and stone in the style of the late Renaissance, and harmonizes with, though it does not repeat, the design of the buildings about it. The main laboratories are situated on the ground and first floors. Below there is a basement and in the roof accommodation is provided for experimental animals. There is a large and lofty entrance hall into which open a large laboratory to accommodate fifty students or more, a chemical laboratory, three small laboratories for special work, a dark room, and a room fitted as a writing room and office. Access is given by a staircase behind the door to the basement below. The main staircase, which is very well lighted by a large lead-glazed window occupying the whole width of the staircase, leads to the first floor, upon which are situated a large laboratory partly lighted from the roof and fitted for purposes of sterilization and the preparation of culture media, and four other spacious laboratories intended chiefly to accommodate the staff of the department. A small staircase leads from the landing to the animal houses above.

In going through the building the visitor is greatly struck by the amount of light in all the various rooms; yet this has been provided without in any way sacrificing the architectural amenities of the building. Moreover, the laboratories give a sense of loftiness and space. So far as the structure itself is concerned, it appears to be extraordinarily well adapted for the purpose for which it has been built. Considerable attention, too, has been devoted to the finishing of the building. The concrete floors are overlaid with wood blocks; the corners both of walls and floors are rounded, and the walls of the laboratories are tiled with white glazed tiles below and enamelled white above—this latter, of course, contributing materially to the lighting, which is so conspicuous a feature throughout. The benches are, as in the present laboratories, made of pitch pine covered with linoleum; incubators, water-baths, etc., stand on tables covered with asbestos sheets. The cupboards and bookcases are similarly constructed of pitch pine, stained and varnished, and have sliding doors. The animal cages on the top floor are raised some two feet above the floor and consist of reinforced concrete with stout galvanized iron wire tops and fronts. This method of construction was introduced into the College of Medicine some few years ago, and has been found eminently satisfactory in practice, for it allows of thorough cleaning and limewashing. In the basement are cloak rooms, store rooms, boiler house, etc., and a room for heavy centrifuges. The building is heated by steam on the atmospheric system and artificial ventilation is effected by means of an electrically driven fan placed on the roof, the air inlets being behind the radiators. The fan is capable of

extracting 5,500 cubic feet of air a minute, which is equivalent to changing the air of the laboratories four times an hour.

The standard set in these laboratories is high, and if it be maintained in the future the Newcastle Medical School will possess buildings second to none in the kingdom.

## Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

### The New Government.

MR. BALDWIN'S Ministry was announced as complete, subject to one office, on May 28th. For a time Mr. Baldwin retains, along with the Premiership, the Chancellorship of the Exchequer, but his hope is that Mr. Reginald McKenna, who is convalescent from a serious illness, will be able to take this position (which has been offered to him) in the autumn. One addition has been made to the Government. Lord Robert Cecil has become Lord Privy Seal, an office which of late was linked with another, but which, having comparatively few duties, will enable Lord Robert to undertake service for the Government in connexion with the League of Nations, and also assist in debate in the House of Commons. Sir William Joynson-Hicks, who was Postmaster-General in Mr. Law's administration, has been made Financial Secretary to the Treasury and is thus available to aid Mr. Baldwin in the passage of the Finance Bill through its stages. Sir L. Worthington-Evans, who went out of office when the Coalition ended, succeeds at St. Martin's-le-Grand. One other change is of special interest to our readers. Lord Eustace Percy, who was Parliamentary Secretary to the Board of Education, has been appointed Parliamentary Secretary to the Ministry of Health, so that Mr. Neville Chamberlain may have assistance in the Commons in his arduous work. The Earl of Onslow, who was Secretary to the Ministry of Health and answered for it in the Lords, is now Secretary to the Board of Education.

**Coroners' Law and Death Certification (Amendment) Bill.**—This bill, which is designed "to amend the law relating to coroners' law and the certification and registration of deaths and burials," has now been printed. It was presented by Dr. Molloy, and is backed by Dr. Fremantle and Dr. Watts. Broadly it embodies a scheme of death certification based on the policy adopted by the Annual Representative Meeting of the British Medical Association in 1905; with proposals in the Draft Coroners' Bill approved by the same meeting; and the recommendations on burial regulations adopted by the Association in 1905. It is understood that in the present state of business the bill has no prospect of passage this session; but the publication of the text will tend to elucidate matters.

**Vaccination at St. Lucia.**—In reply to Mr. Rhys Davies, on May 28th, Mr. Ormsby-Gore said that the St. Lucia ordinances relating to public vaccination, which were passed many years ago, did not provide for exemption on grounds of conscientious objection. He had no information as to any legislation or administrative action taken or contemplated by the local Government, but inquiry would be made of the Governor.

## Scotland.

### FARMER'S RESPONSIBILITY FOR HEALTH OF WORKERS.

AT the beginning of this year a rather serious outbreak of typhoid fever occurred at Campbeltown, in Argyllshire; some two hundred persons were affected, and three died. The *Campbeltown Courier* of May 12th gives a full report of an action raised in the sheriff's court against a local farmer, under the Dairies, Cowsheds and Milkshops Order, for allowing a female worker (who was apparently the cause of the epidemic) to milk cows while suffering from an infectious disease. In the course of the epidemic Dr. Harvey Thomson, medical officer of health for Campbeltown, was able to trace the source of infection to a certain farm, and found on investigation that a woman employed there (whose husband was a scavenger) was suffering from typhoid fever. It was not alleged that the farmer knew that the woman was suffering from an infectious disease. Sheriff Macmaster Campbell, in delivering judgement, said that the facts and conditions were of such a description as to exclude the defence of excusable ignorance. A milk producer dealt with a commodity which was peculiarly and highly susceptible to contamination by the communication of infection. The obvious disability of an employer of milkers to detect the presence of infectious disease in any of his workers should induce care to ensure that his workers were in a sound condition of health, and where a

worker was ill reference should be made to a medical man to know whether it was safe or otherwise for the affected worker to proceed with the work of milking. The defendant in the present case should have got from his employee, when she sought to resume work after an illness, a certificate from her medical attendant that she did not suffer from an infectious disease and was otherwise fit to undertake milking. As the defendant was apparently the first person to be prosecuted in Scotland for this offence, the sheriff imposed a modified penalty of £1, with the option of seven days in gaol.

### HOME NURSING WORK IN FIFESHIRE.

Viscountess Novar, presiding at the half-yearly meeting of the Fife County Nursing Association at Dunfermline last week, stated that, as a whole, the progress of the Association had been most satisfactory; fifteen new nurses had begun work in the county and four associations had been resuscitated. At the present time the Association had sixty nurses at work in the county, but it was hoped to increase the number to eighty, as there was still a great deal of scope for organizing this service, particularly in the mining districts. One aim of the Association was to secure co-ordination between private nurses, voluntary nurses, and public health work, so as to prevent waste of effort and expenditure. The meeting was also addressed by the Countess of Elgin, who made an appeal for financial assistance.

### EDINBURGH SICK CHILDREN'S HOSPITAL.

The sixty-fourth annual meeting of contributors to the Royal Edinburgh Hospital for Sick Children was held on May 17th, Sir John R. Findlay, chairman of the directors, presiding. During the year 1922 there were treated in the wards 2,427 cases, as compared with 2,634 in the previous year; the average daily number in hospital was 108 and the average duration of residence 18 days. Of the total number of patients admitted 1,281 were medical and 1,037 surgical. In the out-patient department 2,811 medical cases and 3,121 surgical cases were treated, and 1,853 minor surgical operations performed. The number of further operations on in-patients was 879. The seaside convalescent home had been fully occupied during the year by 165 children, of whom 126 were medical and 39 surgical. In the medical report the staff expressed the opinion that the effects of unemployment and its attendant poverty had been strikingly manifest, both in the class of case and the condition of the patients admitted to the medical wards during the second half of 1922. Just as towards the close of the war there appeared an unusually large number of cases of tuberculosis, so, after twenty-four months of bad trade, the hospital was now experiencing an increased demand for the admission of patients on account of malnutrition and its results. The chairman stated that expenses continued to decrease and were now £2,000 less than they had been two years ago. There was cause for congratulation on the very handsome contribution made to the hospital funds by employees in offices and public works. Such subscriptions ought to be the mainstay of the finances, whereas legacies had to be drawn on to a very much larger extent than was desirable. This year the hospital had an unprecedented revenue from this source (£18,000).

### CARE OF INCURABLES IN THEIR HOMES

The annual meeting of the Royal Society for Home Relief to Incurables was held in the Council Chambers, Edinburgh, on May 18th. In moving adoption of the report for 1922, which was approved, Lord Provost Hutchison, who was in the chair, said that the society had had a long, honourable, and most useful career. Its work was not confined to Edinburgh, for its beneficiaries were situated in nearly every county in Scotland, and possibly its operations in outlying country districts were even of greater value than in a town, where people suffering from incurable disease could be received and treated in institutions. The society's work originally had been upon a small scale, but every year had seen an increase in its usefulness, till now there were nearly 500 annuitants on the roll. The yearly grant of £10 to each beneficiary was of assistance in securing better attendance and greater comfort. The amount of subscriptions received during the year was £2,176 12s.

## Ireland.

## SCHOOL MEDICAL SERVICE.

In the course of an article, specially contributed to the *Freeman's Journal*, a correspondent, "M. B. W.," states in connexion with the medical inspection of school children in Ireland, that even to the casual observer a vast amount of child suffering is apparent; and those who have to do with juveniles, either in or out of school years, know how long is the average standard of fitness. Defective vision and hearing, decayed teeth, adenoids, enlarged tonsils and other forms of throat and nose troubles, minor skin ailments—all these are apparent, and he who runs may read. There are the more serious ailments, such as heart or chest trouble, spinal complaints, and—most serious of all—the various forms and stages of tuberculosis which are operating amongst the children of school age, unchecked because unsuspected, and unsuspected because the machinery for their detection does not exist.

How many parents (the writer asks), even among those of education and experience, can detect with certainty the first signs of incipient disease? How much less able are those already overburdened mothers whose lives are little else save a ceaseless struggle against poverty and bad housing, and who are, at best, ill equipped for the struggle? The day has gone by when we could afford to believe that every woman was, by virtue of her womanhood, a suitable mother; and by virtue of her motherhood, a capable mother. We know now that the rearing of healthy children is the result, not of unaided instincts, but of knowledge, often painfully, always with difficulty, acquired. Where that knowledge is lacking, the result is suffering in one form or another; and it is the innocent victims who pay the price; but the community at large foots the bill ultimately in the shape of hospitals, sanatoria, lunatic asylums and prisons.

The case, therefore, for the medical inspection and treatment of school children rests primarily upon the needs of the children themselves. In the words of Sir James Craig, "A large proportion of the children attending the national schools are suffering from preventable and remediable disease; and an important fact to comprehend . . . is that many defects are unrecognized either by teachers or parents." It is in this fact, that the diseases are preventable and remediable in the main, that the chief strength of the children's case lies. Not every defect is curable; but at least the chance should be given to every child that if there is a defect it should be discovered in time. One at least of the tragedies of after-life can be removed—the tragedy of finding out that ill-health could have been prevented had the trouble been discovered and treated in childhood.

## WEXFORD LOCAL MEDICAL COMMITTEE.

A meeting of the medical practitioners of County Wexford was held recently at Enniscorthy. The question of the inadequacy of the salaries paid to medical officials in County Wexford was considered, and, after being fully discussed, it was proposed and passed that the following resolution in the form of an application be sent to the County Board of Health:

"That the salaries of the dispensary medical officers of the dispensary districts in County Wexford, and the salary of the physician to the County Home in Enniscorthy, are inadequate, and we ask that the salaries of the dispensary medical officers be fixed at £300 per annum, rising by £5 yearly to £400, and that the salary of the physician to the County Home be fixed also at £300, rising by £5 yearly to £400—both scales to be retrospectively applied."

A letter was read from Dr. Hennessy drawing attention to the complaints which are being made by the approved societies regarding the irregular and unsatisfactory manner in which certificates for sickness benefit are occasionally issued. The following resolution was passed unanimously:

"That the medical practitioners of County Wexford urge that medical certifiers should comply with the regulations issued by the Irish Insurance Commission with regard to the issue of medical certificates, and where it is not possible to do so, that an explanation to this effect should be recorded in the space in the certificate for 'remarks.'"

REPORT OF INTERNATIONAL RED CROSS ON IRISH  
INTERMENT CAMPS.

The International Red Cross Committee at Geneva has communicated the following note to the press:

"Thanks to the courtesy of the Government of the Irish Free State a delegation of the International Red Cross has been able to visit the Free State internment camps, in which about 12,000 prisoners are concentrated. The report which the delegation has presented to the International Red Cross Committee proves that so far as the healthy prisoners, as well as the sick and wounded, are concerned, the sanitary conditions of the camps, the nourishment and lodging, are, in general, very satisfactory."

It is understood that the investigation which led to the report took place during the first two weeks of the present month, and was carried out by a distinguished Continental medical authority, who has visited internment camps in various parts of Europe and has the widest experience of this work. It is considered probable that the reports made as a result of these investigations will be published in detail at an early date.

## Correspondence.

## THE COUNTRY PRACTITIONER.

SIR,—As is truly said in your leading article of May 26th (p. 904), dealing with the under-payment of rural practitioners with small panel lists, it is easier to demonstrate the evil than point out the cure. It may be well, therefore, before seeking for specific remedies, to consider the case on broad principles—principles which should be applied to the whole question of remuneration and not to that of rural practices only.

It will probably be conceded that the best professional work will be done by a man whose income is sufficient to place him above the anxieties and worries of a constant struggle for existence.

What, then, should be the standard of remuneration for general practitioners at large which will attract the right stamp of man in competition with other professions? And within our own profession what yearly income will render life in country practice as attractive as that in the navy or army, or overseas, or in the towns?

Let us take a man of five-and-twenty who has qualified fairly early, spent three or four years learning the practice of his profession under the varying conditions of human existence, broadening his views and learning his world, and who is prepared to marry and settle down to forty years of strenuous, responsible work both of mind and body. During those years I submit he ought to earn an average net income, after paying his taxes, large enough to ensure for himself, his wife, and an average family of four children the following benefits:

- (a) Rent and maintain a suitable establishment.
- (b) Feed and clothe himself, wife, and four children.
- (c) Educate four children.
- (d) Insure himself against sickness and disablement during his working life.
- (e) Provide a retiring annuity of £600 a year for himself at the age of 65, and for his wife if she survives him.
- (f) Provide an annuity of, say, £100 a year for one child after his death—this on the assumption that on an average one child out of the four will require assistance.
- (g) Provide the expenses of a holiday of six weeks a year.
- (h) Provide for some personal expenses.

Now let us try to put a value on these charges for a man living in a completely rural district—I will not do so in detail, as the calculation, though interesting, is too long and complicated for a letter—but spreading education expenses over the whole forty years, providing for d, c, and f by insurance premiums similarly spread, allowing for a locumtenent during his holiday, and £100 a year for his personal expenses, such a man will require about £1,350 a year after paying all wholly professional and travelling expenses and income tax.

Generally speaking all over the rural districts the insured population is about one-third of the whole, and assuming, what is not quite the case, that the mileage allowance and the 2s. for drugs meet the expenses under these heads, we may take the capitation fee as a net figure. To provide its share of the requirements of the rural practitioner the Insurance Fund should pay about £450 a year; to this must be added at least £50 to cover income tax, so that about £500 should be the share that ought to be borne by the National Health Insurance Fund if a rural practitioner is to be put on anything like an equality with other men of his own professional standard. This means at the present rate of 11s. (less 1s. 6d. deducted for patriotic purposes) a panel list of some 1,100, which is, of course, far above the available insured population of a really rural district.

I must not be taken to mean that if the insurance authorities do shoulder their proper burden the lot of the

country practitioner will be made equal to that of his town colleagues. The remaining two-thirds necessary to give him a proper income will still have to be made up out of a rural population engaged in a depressed industry—people who are and seem likely to remain, so far as money is concerned, in a state of chronic destitution. For this two-thirds he must wait for: better times, better organization of rural contract practice, and perhaps better pay for Poor Law work; but because the proper figure is unattainable I see no reason why it should not be stated fully, and why the Government should not be called upon to do its share towards solving the problem.—I am, etc.,

Weyhill, Andover, May 26th.

J. P. WILLIAMS-FREEMAN.

#### THE EDUCATION OF MYOPES.

SIR,—I have read Mr. Harrison Butler's excellent lecture on refraction with much interest, and with the greater part of it I am in entire agreement, but I am a little puzzled by one sentence about the treatment of myopia in children. Mr. Butler says: "In my private practice I allow myopes to continue their education, but I forbid music and novel reading." Why this ban on music? I am a myope myself to the extent of  $4\frac{1}{2}$  dioptres, and I may, perhaps, claim to have some practical acquaintance with music (piano and organ), but I cannot say that I have ever found that reading music was more trying to the eyes than reading a book—rather, perhaps, if anything, the reverse. If a short-sighted child has a real talent for music it would be positively cruel, and in my judgement quite unnecessary, to interfere in any way—not even excluding "examination training"—with the pursuit of what is and always will be to that child probably the greatest delight of its life. In the very rare cases where such interference or prohibition might be considered desirable it would surely be necessary also to stop entirely all reading and writing for a time. I am glad to see, however, that Mr. Butler says: "The objections to the theory that myopia is due to close work *per se* are to my mind conclusive."

Incidentally I would remark that, in my opinion, a moderate degree of myopia is a positive asset to an ophthalmic surgeon, as, when about to operate on the eye, he takes off his glasses because he sees better without them, and that is why I think he has the advantage over a hypermetropic, astigmatic, or presbyopic surgeon, who may be obliged to wear glasses in his operative work.

With regard to the wearing of glasses for reading in cases of a moderate degree of myopia—say up to about 3 or 4 dioptres—I have always left it to the patient to do as he or she likes. In my own case I have sometimes found it a relief to read with glasses, but much more frequently I have found myself, all my life, reading without them.

I think that the majority of medical men, including ophthalmic surgeons, are apt at times to be a little too dogmatic and too rigid in the advice they give to their patients, for we must all remember that, as Mr. Butler truly says, "the object of refraction is to make the patient comfortable, not the solution of a problem in optics."—I am, etc.,

Gloucester, May 21st.

E. DYKES BOWER.

SIR,—I do not propose to open a general discussion upon the relative merits of the many theories which have been advanced to account for progressive myopia; the subject is far too abstruse to be of general interest, and one more suited for treatment at a meeting of ophthalmologists than in the correspondence columns of the JOURNAL. I am in full agreement with Mr. Bishop Harman that rapidly advancing cases of progressive myopia require very special treatment, and that they are unsuited for any employment that calls for constant confinement indoors. At Coventry we try to educate such children in an open-air school, which has many advantages over an indoor school of the ordinary type. On the other hand, we must not forget that many of our most eminent citizens are high myopes, and it is doubtful whether they would have attained the position they hold had their elementary education been restricted. It seems to me that it is a great mistake to lay down an arbitrary standard of refraction as a qualification for holding a scholarship. If a child has been

carefully examined from time to time, and has been found to have a steadily increasing myopia, then it is right and proper for the State to consider him unsuitable to hold a scholarship; but the mere fact that he has 3 dioptres of myopia should not be a disqualification *per se*. In a certain proportion of children myopia becomes stationary, or at most reaches about 5 dioptres, and our universities would be deprived of many of their most learned professors had Mr. Harman's standard of education been applied to them.

As regards music, my lecture has suffered from the condensation necessary for publication, and I may not have made my view quite clear. In my private practice I see many clever children who are being educated at secondary schools, and who are suffering from slowly progressive myopia. The question arises, What is to be done with them? Is education to be given up, and are they to become hewers of wood and drawers of water? My answer is, certainly not. Some may become eminent men and women in spite of their disability. I find that in the case of girls many of them are working for examinations and at the same time practising the piano an hour a day and spending all their spare time reading novels. I advise that all extraneous reading must be given up in term time, and a choice must be made between music and examinations. If the child is likely to become a real musician let her give up examination work and take up music, but I forbid both. Novel reading must be reserved for the vacations. The main consideration is that the myopic child shall be encouraged to spend all spare time in the open air. The average myope is naturally studious, and is not disposed to games. This tendency must be resisted. Above all, a long rest is necessary after any debilitating illness.

As regards "current theories," the mere fact that a theory is "current" leaves it still a theory, and a fit subject for "cock-shies." Even the established and "current" theories of light and gravitation are being "tilted" at, and the German-made theories of myopia are not sacrosanct. In common with many other ophthalmologists I do not believe that close work *per se* is the cause of progressive myopia, but I am quite willing to change my opinion if the weight of evidence, carefully sifted and scientifically tested, conclusively points in this direction.—I am, etc.,

Birmingham, May 25th.

T. HARRISON BUTLER.

#### PERNICIOUS ANAEMIA.

SIR,—May I say at once that I welcome the letter of Dr. Gordon Ward, because I recognize him not only as a clinician of experience but as a skilled haematologist, and his contributions to haematological literature are well known. I would, however, assure him that I have had some clinical experience, and my book *Haematology in General Practice* was largely the outcome of the combined clinical and haematological study of a number of cases of anaemia from various forms of sepsis in hospital practice. I would not, therefore, like to be labelled as taking the exclusively pathological point of view. I have dealt with the whole question in my book, but I may perhaps briefly summarize my conception of the problem as follows:

In almost all forms of grave anaemia the bone marrow is affected by a toxin which is probably, though not certainly, bacterial in origin, the haemolytic streptococcus being, I think, the most usual offender. In some of these the bone marrow is affected beyond repair, in others recovery is possible when the focus has been eliminated and the toxin thereof combated by appropriate methods. The former are commonly classed as "pernicious," and the latter as "septic" anaemia. On clinical grounds alone it is at least very difficult to make the distinction, but if blood films are examined on repeated occasions the lethal type is recognized by the presence and persistence of the following signs: a low total red cell count (below two millions approximately), a colour index above 1, and megaloblasts in fair numbers—approximately 5 per cent. of white cells. In addition, polychromasia and leucopenia with presence of primitive forms of leucocyte are almost invariably present.

I lay stress on the persistence of these signs because I recognize that even in the lethal form periods of remission occur.

I suggest that as between the clinician and the pathologist there should be no question of domination of either, but of co-operation to their mutual benefit. To describe the pathologist as a "specialist in blood films" is an unkindly gibe.—I am, etc.,

A. KNYVETT GORDON, M.B., B.C., B.A. Cantab.  
London, W.C., May 19th.

SIR,—Dr. Knyvett Gordon has favoured me with a copy of his letter published above. May I at once make it clear that the implication that he lacked clinical experience was not intended to be conveyed, and is hereby unreservedly withdrawn. As a matter of fact his clinical experience is longer than my own, so that it would ill become me to question it.

But I am still far from agreeing that "pernicious anaemia" is a disease, clinically or pathologically, in which "the bone marrow is affected beyond repair." We differ fundamentally on the point of whether the bone marrow is or is not primarily affected. He thinks that it is. His book (of which he has also been good enough to send me a copy) contains the following: "The pathologist, however, restricts the term [pernicious anaemia] to a destructive lesion of the bone marrow leading to a fatal termination, though short periods of remission may occur." I, on the contrary, have written in my book (which is out of print or I would reciprocate the compliment), "Why the particular blood picture which we associate especially with this disease should follow intravascular destruction of blood is not yet determined, but as far as we know at the present it depends on the rate at which the destruction takes place, and on the presence in the body of the products of blood destruction, which seem to have a particularly powerful influence on blood regeneration." I admit that the view taken by Dr. Knyvett Gordon is, or has been, widely held. But I cannot find that it is consistent with the facts, especially the following facts:

1. That the erythrocytic marrow (assumed to be poisoned) increases greatly in area and activity.
2. That temporary benefit can often be obtained by splenectomy which, in my view, necessarily diminishes the amount of haemolysis (all this function can be assumed by other structures).
3. That the marrow can return to normal during remissions of several years' duration.
4. That no signs of degeneration are found in the marrow which are in any way comparable to those found in other diseases or which exist in the spinal cord, alimentary canal, etc., in this disease. I refer in particular to necrotic changes followed by fibrosis, and to atrophy.

Dr. Knyvett Gordon takes certain signs as criteria, *if persistent*, of "pernicious" and necessarily fatal anaemia. I agree, for one of these is a 2,000,000 red cell count, and no one can survive this indefinitely. But I would ask him whether he can point to any disease or syndrome in which these signs are *necessarily persistent*. Can he point to any disease, in fact, which is necessarily fatal even in the present state of our knowledge? If he cannot, what precise significance is the clinician to attribute to these criteria? There certainly exists a disease characterized in general by glossitis, intestinal lesions, nervous symptoms, which may be profound, and severe anaemia. His criteria are not, in the experience of a great many people, persistent in this disease, although usually present at some time. They are also present with less frequency in other conditions—for example, sprue, some helminth infections, severe sepsis, and cancer. In none of these do they help us in treatment, diagnosis, or prognosis. All that they tell us we can deduce from other indications. I feel that if we should discover next week a cure for what the clinician calls pernicious anaemia (that is, the Addisonian or glossitic anaemia of Hunter) no more would be heard of the significance of "megaloblastic degeneration."

This is where the clinician joins issue with the pathologist. Neither denies that such and such a blood picture occurs nor that such and such a clinical syndrome occurs. Both desire to employ the term "pernicious"; both have, in fact, employed it. But the conceptions to which they apply it do not coincide. They merely overlap. Hence great confusion has arisen, and it is apparent that one or other should give way. I claim, on grounds of priority for the name, and on the further ground that

pathology is merely a subsidiary study designed to serve the dominant purposes of clinical medicine, that the pathologist should give way. And when it comes to "pathological diagnosis" I am scandalized at the boldness of the daughter science, which ought but to play her part as a handmaid in the great art of clinical diagnosis, but who, with Dr. Knyvett Gordon's approval, is setting up a system of diagnosis of her own and demanding that the clinician study and admire it.—I am, etc.,

Sevenoaks, May 21st.

GORDON WARD.

## Obituary.

VAUGHAN HARLEY, M.D. EDIN., M.R.C.P. LOND.,

Late Professor of Pathological Chemistry, University College, London.

WE regret to announce the death of Dr. Vaughan Harley, which occurred very suddenly on May 21st at his country home, Walton Hall, Bletchley, Bucks.

Vaughan Harley was the son of the late Dr. George Harley, F.R.S., and was born December 28th, 1863. He studied medicine at Edinburgh University (bronze medal in pathology) and graduated M.D. with honours in 1886, being awarded the gold medal for the best thesis. The next two years were spent travelling round the world; during that period he worked for a time under Sir Patrick Manson. The succeeding four years were occupied in scientific study in Paris (under Pasteur and Roux), in Leipzig (under Ludwig), Turin (under Mosso), and in Vienna, Budapest, and Christiania. In 1893 the late Sir Victor Horsley invited him to return to London to organize the first department of pathological chemistry in England, in the pathological department of University College, London, and Harley made it a centre of research for post-graduate students. In 1894 he was appointed Grocers' Research Student and held this for four years. When Sir Victor Horsley retired in 1896 Harley was appointed Professor of Pathological Chemistry in University College, London, an appointment he held until 1919. During this period he published a large number of scientific papers and collected a band of enthusiastic workers in the laboratory. He took a keen interest in the incorporation of University College in the University of London and served on the committee engaged in raising the necessary funds. At the Annual Meeting of the British Medical Association held in London in 1895 he was honorary secretary of the Section of Pharmacology and Therapeutics. He was a Fellow of the Physiological Society and of the Chemical Society. In addition to his work as a physician Vaughan Harley was much interested in farming, especially in short-horns. For the last twenty years he applied scientific methods at his farm at Walton Hall and took a particular interest in forming the herd of shorthorns known as the "Notlaw" herd. He won numerous prizes at all the big shows, the best year being in 1918, when he won the championship, reserve championship, and Maclellan cup at the Birmingham spring show. He was the breeder of numerous prize winners under other names and his animals did very well in the Argentine. His Oxford Downs sheep were also successful in the show yard. In addition, he was a breeder of Shires and large black pigs. In 1911 he was elected a member of the council of the Shorthorn Society and served on it until his death, being vice-president in 1917 and president in 1918. He was also a member of the Shire Horse, Oxford Downs, and Large Black Pig Societies. Dr. Vaughan Harley married in 1905 Mary, eldest daughter of the late Canon Blagden, and leaves two daughters. He was buried at Walton Church, Bucks, on Friday, May 25th.

R. J. EWART, M.D., D.Sc.,

M.O.H. Barking.

WE regret to have to record the death of Dr. Robert John Ewart, M.O.H. for Barking, Essex. He was a distinguished student of University College, Liverpool, where in 1894-96 he held the Holt tutorial scholarship and the Junior Lyon Jones scholarship. He took the B.Sc. of the Victoria University, with honours, in 1896, and the diplomas of L.R.C.P., M.R.C.S. in 1899, graduated M.B., B.Ch. in

1899, M.Sc. in 1903, M.D. in 1904, and D.Sc.Lond. in 1918. He was senior house-surgeon to the Royal Infirmary, Liverpool. After a tenure of the Holt Fellowship of Pathology in the University of Liverpool he turned his attention to public health, and took the diploma of D.P.H. in 1907. He was first appointed Assistant M.O.H. Middlesbrough and later on to the office he held at the time of his death. He was a member of the British Medical Association and a fellow and member of the council of the Society of Medical Officers of Health. He was esteemed one of the ablest medical officers of health in the country, and it is difficult to understand why he had got no further than Barking Town. "It was," a friend writes, "like putting a race-horse in a four-wheel cab. He was a most delightful colleague, modest and unassuming, willing to take any amount of trouble to help those who asked his aid, and apparently quite unaware that he was a more knowledgeable person than anyone else."

We are indebted to Dr. MAJOR GREENWOOD for the following estimate of the high value of Dr. Ewart's contributions to the literature of public health.

By the death of Dr. R. J. Ewart our profession has lost one of its very small band of enthusiastic statisticians. Ewart's principal statistical work is contained in a series of memoirs published in the *Journal of Hygiene* (xiv, 453; xv, 127; xv, 208; xvi, 12; xviii, 95). His idea was that the age of the parents at the time of the birth of a child affected the latter's physiological characters, that the physiological make-up of a later-born child was essentially different from that of a child born earlier in the fertile period. He surmised that changes in the reproductive habits of the people correlated with the declining birth rate were not without influence upon the evolution and prevalence of tuberculosis and the zymotic diseases. Ewart took up this work in spite of grave difficulties. His data were scanty and he had to begin to acquire a knowledge of the difficult technique of modern statistical analysis at an age when few very busy men—and he was a very busy man—care to tackle a new subject. The data available—mainly collected by himself at Middlesbrough and Barking—were meagre and open to criticisms which none urged more strongly than he did himself. It is not therefore surprising that he failed to establish conclusively any important proposition, although in some matters he created a fair presumption that his views were just. But his papers are full of valuable suggestions from which some later investigator with more material will derive advantage. Incidentally, some of Ewart's memoirs contain valuable contributions to the general statistical study of epidemic disease. I would particularly instance the paper printed in the fifteenth volume of the *Journal of Hygiene* (pp. 208-256), which contains one of the best statistical studies of scarlet fever and diphtheria with which I am acquainted.

It would be very easy for a critic having the advantage of wider training and experience in research, above all having had the advantage of time and leisure, to point the blemishes in Ewart's work. Ewart had very little time to devote to pure science and naturally made some mistakes, as every single-handed worker must. I believe he will be remembered as an original-minded investigator, a real student of nature. Of the keenness and skill with which he carried out his administrative duties others can speak more authoritatively than I, but several members of the staff of the Lister Institute will recollect how he contrived to save the lives of some babies in his district in a time of milk shortage by a pretty application of a scientific idea. He did not live long enough to secure wide recognition, but long enough to prove to all who knew him that they have lost a man worthy of the highest traditions of the public health service.

J. G. OGLE, M.D., B.Ch.Oxon.,

Reigate, Surrey.

THE announcement of the death of Dr. John Gilbert Ogle, of Reigate, will be received with deep regret by his numerous friends. He was the son of the Rev. J. A. Ogle, vicar of Sedgeford, Norfolk, and came of a medical stock, his grandfather having been Regius Professor of Medicine

at Oxford, and his uncle, William Ogle, the well known scholar and physician, who was Superintendent of Statistics in the Registrar-General's department. Dr. J. G. Ogle was educated at Haileybury College, Keble College, Oxford, and St. Bartholomew's Hospital, where he held the post of house-physician to Sir Dyce Duckworth. Afterwards he was house-physician at the Royal Chest Hospital, London, and at the Radcliffe Infirmary, Oxford.

He took the diploma of L.R.C.P. and M.R.C.S. in 1888 and graduated M.A. and M.B., B.Ch.Oxon. in 1889; in 1891 he proceeded to the degree of M.D.

He practised in Reigate from 1891 to 1914 as a member of the old established firm of Ogle, Walters and Pegg, the successors of Holman, Walters, Hallows and Berridge. When he retired owing to ill health his loss was deeply felt, not only by his partners and colleagues, but also by his many patients and friends. His skill in his profession was only equalled by his great care and kindness. In fact it may truthfully be said of him that he never failed to seize any opportunity for doing kind and generous acts, and he was greatly beloved by all.

Dr. Ogle was twice married, firstly to Miss E. M. Perfect of Lewes, who died in 1919, and secondly in 1921 to Miss Dorothy Hunter.

## Universities and Colleges.

### UNIVERSITY OF CAMBRIDGE.

APPLICATIONS for the E. G. Fearnside's scholarship for clinical research on the organic diseases of the nervous system must be sent to the University Registry before June 20th. The scholarship is open to graduates in medicine and to graduates in arts who have passed Part II of the Natural Sciences Tripos.

### UNIVERSITY OF LONDON.

A COURSE of four lectures on tropical hygiene will be delivered by Dr. Andrew Balfour, C.B., C.M.G., at St. Bartholomew's Hospital Medical College, E.C., on June 12th, 14th, 19th, and 21st, at 5 p.m. The lectures are addressed to advanced students and to others interested in the subject. Lord Stanmore, treasurer of the hospital, will take the chair at the first lecture.

## Medical News.

THE Duke of Connaught will distribute the prizes at St. Thomas's Hospital Medical School on Wednesday, June 13th, at 3 p.m.

THE annual meeting and dinner of the Cambridge Graduates' Medical Club will be held at Gonville and Caius College, Cambridge, on the evening of Friday, June 22nd, with Sir H. K. Anderson, M.D., F.R.S., Master of Caius, in the chair. The honorary secretary is Mr. R. Davies-Colley, C.M.G., M.Ch. (10, Devonshire Place, W.).

A TWO weeks' refresher course in general medicine and surgery will be given, under the auspices of the Fellowship of Medicine and Post-Graduate Medical Association, at the North-East London Post Graduate College (Prince of Wales's General Hospital), Tottenham, from June 11th to 23rd inclusive. It will include demonstrations in clinical and laboratory methods with special demonstrations each Saturday at the North-Eastern Fever Hospital and the London County Council Mental Hospital respectively. A clinical lecture will be given every day at 4.30 p.m. A course of eight practical lecture demonstrations on gastro-intestinal diseases of children will be given by Sir William Bayliss, Dr. Bernard Myers, and Mr. E. T. C. Milligan at the "Children's Clinic," Western General Dispensary, from June 11th to July 5th. A special course in neurology will be given at the West End Hospital for Nervous Diseases from the middle of June till the end of July, and should a sufficient number of entries be received courses will also be held in ophthalmology and dermatology at the Royal London Ophthalmic Hospital and St. John's Hospital for Diseases of the Skin respectively. Beginning on June 11th, Dr. Gustave Monod, M.R.C.P.Lond., will give a short course of clinical demonstrations (in English) on practical hydrology at the Thermal Hospital in Vichy. The subjects to be dealt with will be hepatitis, gout, diabetes, obesity, etc. Further particulars regarding these courses, copies of the syllabus, and tickets of admission can be obtained from the Secretary to the Fellowship of Medicine, 1, Wimpole Street, W.1.

DR. J. WRIGHT MASON, on the completion of forty years' service as surgeon to the Hull City Police Force, has been presented by the serving and retired members thereof with a silver rose bowl and Mrs. Mason with a gold wristlet watch.

THE next meeting of the North-Western Tuberculosis Society will be held at 3 p.m. on June 7th at the Tuberculosis Offices, Joddrell Street, Hardman Street, Deansgate, Manchester, when Dr. H. de Carle Woodcock (Leeds) will read a paper on the diagnosis and treatment of tuberculous glands. Any medical practitioner interested in the subject is cordially invited to attend.

THE sixth edition of the *Aids to Ophthalmology* by Mr. Bishop Harman has been translated into Polish by Dr. W. H. Melanowski, one of the teachers of the University of Warsaw. The Polish edition makes a book of 300 pages and is printed in good type of rather larger size than the English edition.

THE third and last block of the United Services Hospital at Ascot was declared open by H.R.H. the Duke of Connaught on May 29th, when the whole hospital was thrown open for the inspection of many interested visitors. The funds for this building have been derived from the large profits made by the Army and Navy Canteen Board out of the money expended by naval ratings and army rank and file, and the benefits of this hospital are intended for the children of ex-service men who suffer from surgical tuberculosis. The great experience of the consulting surgeon to the institution, Sir Henry Gauvain, has been freely drawn upon, and the design of the buildings and equipment owes a great deal to the lessons learnt at Alton. The buildings here, however, are of a much more substantial and permanent character than at Alton and at some other "open-air" hospitals, and unlike some of these, the wards can be entirely closed if it is thought desirable to do so. There is accommodation in the three wards for 138 patients, and there are 12 beds in the isolation annexes, making in all 150. The treatment block contains plaster, splint, and x-ray rooms, all of which are admirably adapted for their purposes. Nearly all the beds are already occupied and the appearance of the patients showed the good effects of the open air treatment and of such sunshine as our climate has lately allowed us. The country house Heatherwood, in the grounds of which the hospital has been built, now serves as a charming residence for the nurses. The soil is sandy and dry and the situation elevated. The sewage is treated in a disposal plant consisting of a settling tank and filter bed, and the effluent is distributed over fields at a distance from the buildings. The hospital has its own power station and is thus self-contained.

EXPERIMENTS made three years ago indicated that breathing for five minutes daily of air containing small amounts of chlorine acted as a preventive of influenza. Further tests made at the University of Arkansas recently upon nearly 300 persons are stated to confirm this conclusion.

DR. T. S. HIGGINS, M.O.H. for St. Pancras, who (as recently announced in our columns) has been appointed medical officer of health at Cape Town and lecturer on public health at Cape Town University, was presented on May 28th by the St. Pancras Borough Council with a gold watch.

THE second International Congress of Military Medicine and Pharmacy opened on May 28th at Rome. H.M. the King of Italy and Signor Mussolini, President of the Council, attended the opening ceremony, and General Diaz delivered an inaugural address. The British representatives at the Congress are Lieut.-Colonel D. S. Harvey and Major Dawson.

THE annual general meeting of the Society for Relief of Widows and Orphans of Medical Men was held on May 23rd, with Dr. F. de Havilland Hall, President, in the chair. The annual report which was submitted to the meeting showed that the invested capital of the society now amounts to £146,650, only the income from which may be used for the payment of grants and expenses. £4,407 10s. was distributed in grants during the year, and the expenses were £335. At the present time there are 51 widows and 4 orphans in receipt of relief. Relief is only granted to the widows and orphans of deceased members. Any widow left with an income of £125 or under, and any orphan with an income of £60 or under, is eligible to receive relief. The average relief given is £80 per annum to each widow and £50 per annum to each orphan. Special grants are also made to enable orphans to learn a profession or trade. The society was founded in 1788, and incorporated by Royal Charter in 1864. Membership is open to any registered medical practitioner, who at the time of his election is resident within a twenty-mile radius of Charing Cross. The annual subscription for a member who at time of election is under 40 years of age is £2 2s.; if over 40 but under 50, £3 3s.; and if over 50, £4 4s. There are special terms for life membership. All particulars may be obtained from the Secretary at the offices of the society, 11, Chandos Street, Cavendish Square, W.1. The society is both a provident and beneficent one. Were it not for the income derived from investments the society would not be able to make the grants, as the income from subscriptions about pays the working expenses. These work out at about 6 per cent. of the income.

## Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Aitiology*, Westrand, London; telephone, 2630, Gerrard.

2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate*, Westrand, London; telephone, 2630, Gerrard.

3. MEDICAL SECRETARY, *Mediscera*, Westrand, London; telephone, 2630, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus*, Dublin); telephone, 4737, Dublin, and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: *Associate*, Edinburgh; telephone, 4361, Central).

### QUERIES AND ANSWERS.

#### ACCIDENT OR ILLNESS?

"PASCE" submits the following question: "Does a septic finger following a scratch, wound, or 'hang-nail,' necessitating opening under general anaesthesia three times and on the third occasion avulsion of the nail, constitute an accident or an illness?"

\* \* The form of this question is not very clear, but we are advised that if the scratch, wound, or hang-nail arises out of or in the course of employment and if proper notice is given, in all probability there would be grounds for a claim under the Workmen's Compensation Acts. If the condition arises in a private person and he is insured, everything would depend on the terms of the policy. It would perhaps be advisable to consult a solicitor.

### LETTERS, NOTES, ETC.

#### QUININE SALICYLATE.

DR. NINIAN M. FALKNER (Dublin) writes: Many years ago I was requested by a leading consultant in Dublin to prepare some quinine salicylate; this I readily accomplished in the pharmacy of my dispensary. My friend published a note of the incident in the *Dublin Journal of Medical Science*. Since then the insolubility of this salt has come before me, and when occasion permitted I have made rough experiments; the outcome of these was to find that with tinctura quinae ammon. (B.P.) and sodium salicylate a permanently clear mixture can be obtained.

R. Tr. quinae ammon. (B.P.)	...	...	...	...	℥ ss
Sodii salicyl.	...	...	...	...	gr. x
Glycerini	...	...	...	...	5 ss
Aquam	...	...	...	...	ad 3j

Ft. mist.

I presume, although I have not verified the reaction, that a double salicylate of quinine and sodium is formed, soluble in dilute ammonium hydrate. I hope to investigate this further, but there are analogies in Nessler's reagent and Liebig's test for cyanogen to support this view. I have given this to many of my friends and used it largely during the war in the base hospital to which I was attached, principally in influenza.

#### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 47, 48, 49, 52, and 53 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 50 and 51.

A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 227.

### SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Six lines and under	...	...	0 9 0
Each additional line	...	...	0 1 6
Whole single column (three columns to page)	...	...	7 10 0
Half single column	...	...	3 15 0
Half page	...	...	10 0 0
Whole page	...	...	20 0 0

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, W.C.2, not later than the first post on Tuesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive *poste restante* letters addressed either in initials or numbers.

## The Oliver-Sharpey Lectures

ON

## THE ACTIVITY OF THE CAPILLARY BLOOD VESSELS,

AND ITS RELATION TO CERTAIN FORMS OF TOXAEMIA.

DELIVERED BEFORE

THE ROYAL COLLEGE OF PHYSICIANS OF LONDON

BY

H. H. DALE, M.D., F.R.C.P., F.R.S.,

HEAD OF THE DEPARTMENT OF BIOCHEMISTRY AND PHARMACOLOGY UNDER THE MEDICAL RESEARCH COUNCIL.

## LECTURE I.

It is fitting that the Oliver-Sharpey Lectures should deal with the application to medical problems of some physiological development of current interest. Among fresh developments of recent years has been a rather remarkable awakening of interest in the function of the capillary blood vessels as an active factor in the circulation. But a few years ago discussion of a possible activity of the capillaries was almost limited to the question whether their primary function, of facilitating chemical interchange between the blood and the tissues, involved an active secretion, or could wholly be explained by the physical processes of filtration, osmosis, and diffusion. There were not wanting, indeed, records in detail of appearances seen under the microscope, which were difficult to interpret except by attributing to the capillary walls an independent power of contracting, relaxing, and maintaining a tonus. But the prevailing tendency was to find alternative explanations for these appearances, or, in so far as a contractile function of the capillaries was admitted as a possibility, to regard it as a remnant of an embryonic condition, which, if it persisted in the fully differentiated vascular system of the higher vertebrates, played no real part in the regulation of the blood stream.

As long ago as 1858 Lister,<sup>1</sup> in his classical work on inflammation, described appearances which, I think, we should to-day not hesitate to attribute to active changes in capillary tone; but tradition was strong enough to lead him to interpret them as secondary to changes of pressure, produced by changes in the tone of the arterioles. Stricker,<sup>2</sup> in 1865, was the first observer to claim that changes in the capillary lumen took place independently of the blood pressure, since he was able to see them in the nictitating membrane of the frog, even when excised from the body. The soundness of the observation was challenged by the authority of Cohnheim,<sup>3</sup> and a series of workers—Golubew,<sup>4</sup> Tarchanoff,<sup>5</sup> Severini<sup>6</sup>—who confirmed and extended Stricker's observation, were so far reluctant to attribute the narrowing of the capillary lumen to contraction of the wall in the ordinary sense, that they described it as due to the swelling of the nuclei of certain fusiform elements, which produced a partial or complete blockage.

In contrast to these, and in conformity with the most recent observations, was the description given by Rouget<sup>7</sup> of special flat contractile cells, applied to the outside of the capillary endothelium, and encircling the vessel by delicate protoplasmic processes. Roy and Graham Brown,<sup>8</sup> whose elaborate investigation was published in an early volume of the *Journal of Physiology* (1879), produced convincing evidence of the independent tone and contractility of the capillaries, but, apparently in ignorance of Rouget's work, were content to ascribe the function to the capillary wall as a whole. Rouget's work, indeed, was practically forgotten until Mayer,<sup>9</sup> nearly thirty years later, repeated and confirmed his observations, describing not only the special form of contractile cell seen on the true capillaries, but all intermediate forms between this and the true plain muscle fibres of the arterioles and venules respectively. Steinach and Kahn<sup>10</sup> then renewed observation of the living capillaries, and demonstrated contraction in response to stimulation, the contraction being in accord with the descriptions given by Rouget and by Mayer, in that the endothelial wall was seen to become folded and creased by an external con-

stricting force. They added the important point that the capillaries, like the arterioles, have a motor nerve supply from the sympathetic system.

This body of direct evidence, produced up to the year 1903, seems to have had little effect on physiological teaching. Attention being naturally concentrated on the picture of the capillaries, as that part of the vascular system in which the blood performs its respiratory, nutritive, and cleansing functions, it was apparently assumed that their walls had become so differentiated to facilitate filtration, diffusion, and osmosis, as to have lost the primitive contractile function, so that their state of patency or collapse was held to be determined entirely by the pressure in the arteries or the veins. For the next fourteen years this conception was only disturbed by observations which did not seriously influence the general trend of opinion. The observations of Heubner<sup>11</sup> on the type of circulatory collapse, produced by certain metallic and bacterial poisons which injured the capillary wall, were apparently not regarded as having a bearing on normal conditions. Langley's<sup>12</sup> suggestion that the intense local ischaemia produced by adrenaline seemed to involve an active participation of the capillaries in the vasoconstriction, and<sup>13</sup> that this intrinsic capillary tone might be of importance under conditions of very low arterial pressure, seemed to lie rather aside from the main current of interest in the physiology of the circulation. From the point of view of the normal regulation of the blood flow, the rôle of the capillaries was regarded as one of passive obedience to external forces; and to emphasize the contrast between this view and that to which the work of recent years had led us I entitled these lectures "The activity of the capillary blood vessels."

A feeling of dissatisfaction with the accepted teaching seems to have been in the scientific atmosphere in the early years of the war; for about the year 1917 evidence pointing in another direction began to appear from at least four different and independent sources. Early in that year Cotton, Slade, and Lewis<sup>14</sup> published a very important communication on the reaction of the capillaries in the skin of man, as exhibited in the phenomena long known as "dermatographism"—the local vasomotor response following non-traumatic pressure. They showed that both the red and the white tache, representing reactions to different degrees of pressure, or different degrees of sensitiveness, and often appearing alongside one another in the same individual, must be attributed to intrinsic relaxation and contraction of the capillary walls, since they were produced, often with little or no impairment, in a limb with the circulation completely arrested by closure of the arteries. Only the diffuse flush, surrounding the tache, was obliterated by arterial obstruction, and, like the flush developing round a painful, punctiform stimulus, which it closely resembled, must be attributed to reflex relaxation of the arterioles. They found, further, that, in a limb in which the circulation had been brought to a standstill, a small injection of a dilute solution of adrenaline still produced an area of characteristic pallor. Mere constriction of arterioles or venules containing stationary blood could not thus empty the capillaries, so that Langley's suggestion that these also contracted actively in response to adrenaline was definitely established, and, by inference, the motor sympathetic innervation of their walls, described by Steinach and Kahn, was confirmed.

Later in the same year Ebbecke<sup>15</sup> published, in *Pflüger's Archiv*, a paper which, owing to conditions then existing, only later became available in other countries. It covered much of the same ground and led him to conclusions, concerning the local vasomotor reactions of the skin vessels, very similar to those of Cotton, Slade, and Lewis. He added the important point that a closely similar reaction of the capillaries, by dilatation, to stroking pressure, could be observed on the surface of viscera, such as the liver and the kidney. Both these sets of quite independent observers noticed that a pronounced local dilatation of capillaries, thus produced, might result in a local oedema, with formation of a raised wheal. This increase of permeability, accompanying full relaxation of the capillary wall, is, as we shall see, a point of very general importance. In his long and suggestive paper Ebbecke also reviewed a wide range of phenomena in which the varying tone of the capillaries might participate,

mentioning, in this connexion, the action of poisons like peptone and histamine, and some of the features of the anaphylactic reaction.

It was this last aspect of capillary function—the connexion of changes in capillary tone with the action of certain poisonous protein derivatives—which at this same period had forced itself on the notice of my co-workers and myself. But it will be convenient if I depart a little from strict chronology, to mention another group of investigations which was also, at this same time, proceeding independently—namely, the beautiful series of observations by Krogh, which, though by accident their publication began a little later, were already in active progress, and which, with the help of his fellow workers in Copenhagen, have continued to the present day. Fortunately Professor Krogh, by the recent publication of his Silliman lectures,<sup>19</sup> has made it unnecessary that I should give more than a general review of his work. We may note that he had been led to this question by yet another entirely different route, his original problem being that of the oxygen supply to the voluntary muscle fibre. He was impressed by the difficulty of accounting for the adjustment of the blood supply to the widely varying needs of the active and the resting muscle for oxygen, unless the capillary vessels were actively contractile, so that, with a large proportion closed and impervious to blood in the resting muscle, there would be a large reserve of potential channels, the opening of which would meet the need for a relatively enormous increase of blood in close relation to the muscle fibres, during and after contraction.

By an ingenious method of intravital injection with Indian ink Krogh was able to give a clear demonstration of this adjustment. He counted and measured the capillaries open to the blood flow in the resting and the working muscles of frogs and small mammals, and his figures show an impressive contrast. One actual count of the open capillaries in a guinea-pig's muscle at rest showed only 85 per square millimetre, while in the muscle at work no less than 2,500 were counted in the same area—a ratio of 1 to 30. Still more impressive was the disparity between the volumes of blood in the muscle capillaries under the two conditions, calculated from measurements of the sectional areas and lengths of the capillaries open to the circulation. The blood volume, given as a percentage of the muscle volume, varied from 0.02 per cent. in the resting muscle, to 5.5 per cent. in the active muscle, and 15 per cent. in the muscle with all the capillaries fully dilated. In other words, the volume held by the capillaries open for transmission of blood in a normal, resting muscle, may be as little as one 750th part of the total capacity of the whole capillary network in the muscle, if all were fully dilated. We may note the obvious inference. If we suppose that, under normal conditions of rest, the capillary vessels in the voluntary muscles hold at any moment no more than 1/750 of the blood in circulation, if all, for any reason, were simultaneously relaxed to the fullest extent they would accommodate the whole of the blood in the body.

Having become convinced of the importance of this variable intrinsic tone of the capillaries in regulating the flow of blood, Krogh and his fellow workers proceeded to investigate its finer mechanism, by physiological studies carried out under the microscope, with the aid of the facilities for illumination now available. They have confirmed, on all points, the description given by earlier workers, such as Steinach and Kahn, of the response of the capillaries to minutely localized stimuli by variations of their proper tonus. They have demonstrated the possibility of making an individual capillary relax by gentle local stimulation. They have confirmed, as also has Hooker<sup>20</sup> of Baltimore, the presence of a motor supply to the capillaries in the sympathetic nerves, and have added the highly significant observation that stimulation of true sensory nerve fibres, arising in the dorsal root ganglia, not only causes dilatation of arterioles, as Nicker<sup>21</sup> had first shown, and Bayliss<sup>22</sup> much more convincingly, but independent relaxation of the capillary walls as well. The dilator effect on capillaries of stimulating sensory roots was first described by Doi,<sup>23</sup> working in Starling's laboratory. Krogh and his colleagues have related this sensory supply to the spread of the capillary dilator reaction from a punctiform stimulus, which disappears when the nerves are degenerated. Krogh<sup>19</sup> suggests the existence of a peripheral nervous network, formed by

anastomosis of these branches from sensory fibres. There are here many points of detail still needing elucidation.

Of at least equal interest is the fact that Vimtrup,<sup>24</sup> at Krogh's suggestion, has reinvestigated the minute histology of the capillary motor mechanism, and has fully confirmed and extended the descriptions of contractile cells given by Rouget and by Mayer. It seems no longer possible to question the presence of these flat, branching contractile cells; applied externally to the endothelial wall of the capillary, and girdling it with fine processes. Equally certain seems the continuity of this contractile coat of the capillaries with the plain muscle coats of arterioles, on the one hand, and venules on the other, all intermediate forms between the fully differentiated plain muscle fibre and the flat, branching Rouget cell being found at the transition in either direction. There are vessels, indeed, in the subcapillary plexuses of the skin, which from their size would be counted veins, but from their structure must rank as giant capillaries (Krogh<sup>19</sup>).

Such evidence is making it inevitable that we should abandon the conception of contractile function, active regulation of the blood flow, as ceasing abruptly where an arteriole opens into the capillary network. We cannot longer, I think, regard the capillaries as passive, membranous tubules, opening or collapsing merely in response to rise or fall of pressure, whether internal pressure of the blood, as has generally been assumed, or external pressure due to swelling or deturgescence of the surrounding tissues, as in the view put forward by Leonard Hill<sup>25</sup> in a highly suggestive lecture. I think we must accept it as established that the capillaries have their own contractile coat, continuous with the plain muscle coats of the arterioles and venules—more delicate and less fully differentiated than these, indeed, but similarly supplied with motor and inhibitor nerve fibres.

This contractility of the capillaries being accepted as proven, we have to inquire into its function and its significance for the control of the circulation. It can hardly be doubted that its normal function is a fine adjustment of the circulation, supplementing the relatively coarse adjustment effected by the varying tone of the arteries. We have seen that, under normal conditions, only a small proportion of the capillaries in any tissue must be regarded as simultaneously open for the transmission of blood; and we must suppose that, as the metabolic demand shifts from one cell or tissue unit to another, some capillary paths close down, while others open. The fact, demonstrated by Krogh, that the capillary tone is not only under nervous control, but finely responsive to chemical stimuli, obviously fits it for that purpose.

These results of direct observation of the individual capillaries correspond in a very striking manner with conclusions to which my fellow workers and I had found ourselves driven by evidence of a very different kind, and which, indeed, we had already put forward a few months before the publication of Krogh's investigations began. Dr. Laidlaw and I<sup>26</sup> had been interested and puzzled for some years by the action of the intensely active base histamine, which reproduced a type of action exhibited by a large group of poisonous protein derivatives—a complex of symptoms which, at the outset of our work, had recently come into renewed prominence in the guise of the so-called "anaphylactic shock." The occurrence of a kind of toxæmic collapse in a proportion of severely wounded soldiers<sup>27</sup> had given, in the early years of the war, a new keenness to our desire to clear up outstanding difficulties in the action of histamine, which was capable of producing a condition in many ways so similar.

The main difficulty was briefly this. It was a powerful and general stimulant of plain muscle, of that of the arteries, so far as direct evidence could show, as well as of other organs. When added to blood or a saline solution perfused through the vessels of any excised organ it produced, in accordance with expectation, a simple retardation of the flow and diminution of the organ volume, by increasing the arterial resistance. Yet, when injected in a small dose into the vein or artery of an anaesthetized animal of the same species, it caused a simple fall of arterial pressure, having all the features of a pure vaso-dilator effect—that is, an action due to diminution of the peripheral resistance to the circulation.

There have been several attempts, some of them quite recent, to explain this paradox by representing this depressor

action of histamine as due, not to vaso-dilatation, but to constriction at some point on the venous side of the circulation, retarding the return of blood to the left side of the heart. These various constrictor actions—on the hepatic veins (Mautner and Pick<sup>28</sup>), on the pulmonary arterioles (MacDowall<sup>29</sup>), and on the mesenteric venules (Inchley<sup>30</sup>)—do doubtless occur. Indeed, their occurrence was explicitly recognized by Laidlaw and myself as playing a minor part in effects seen at different stages of the action of large, shock-producing doses of histamine. But we satisfied ourselves that they were not seriously concerned in the evanescent effects produced by small doses. These in every respect—in the increase of the heart's output, the accentuated volume-pulse in a limb, the bright red flush which can be seen by simple inspection of the exposed intestine—resembled those of substances causing arterial dilatation.

A somewhat complex investigation, in which I had the great advantage of co-operating with Professor A. N. Richards<sup>31</sup> of Philadelphia, drove us, in the face of the accepted physiological teaching, to the conclusion that this depressor action of histamine was due to a vaso-dilator action, not on arterioles, like the long familiar effect of nitrites and the more recently studied effect of acetylcholine, but on the capillaries. The failure hitherto to demonstrate this action of histamine on the artificially perfused organ was attributable to the fact that, under the conditions of such an experiment, the capillaries had not retained any of their normal tone, so that further relaxation was impossible, and only the constrictor effect on arteries appeared. By finding the conditions necessary for the artificial maintenance of the capillary tone—namely, the presence in the perfusion fluid of red corpuscles, to maintain a free supply of oxygen to the tissues, and a small proportion of adrenaline—we were able, in the perfused organ, to demonstrate the vaso-dilator action of histamine as in the whole animal. The perfusion pressure fell, the volume of the organ increased, and the venous outflow was accelerated. Venous constriction would not produce such an effect, since it would impede the outflow and raise the perfusion pressure. Arterial dilatation might do so, but it could be shown that this did not occur; a preparation consisting only of the arteries, down to the finest branches which could be separated from the tissues, perfused under identical conditions responded to histamine with simple constriction, while nitrites and acetylcholine caused prompt and wide relaxation.

There remained only, as the site of this demonstrated vaso-dilatation, the capillaries and possibly the microscopic arterioles immediately preceding them. Between these our methods could not distinguish; and, indeed, the evidence now to hand as to the structure and behaviour of the capillaries makes it doubtful whether the distinction would be a logical one. No sharp line, apparently, in relation either to structure or function, can be drawn between the ultimate arterioles and capillaries. At some point in the vascular system the response to histamine changes from the constriction, seen in the finest separable arteries, to dilatation; and whether we think of this change as occurring where vessels are still anatomically called arterioles, or at the level where arterioles are branching into capillaries is of comparatively little moment. That the capillaries share in the dilatation seems to be beyond doubt (Doi<sup>32</sup>).

The evidence I am putting before you is nearly five years old, and I have forborne to trouble you with details. My immediate object is to point out to you that it involved somewhat new assumptions, concerning the nature of the capillary circulation, which the more recent, direct evidence has fully upheld. We were accustomed to the diagram in which the gradient of the blood pressure fell ever more steeply as the blood passed into finer and finer arteries, to become suddenly flattened and almost horizontal where the arterioles branched out into the relatively enormous capillary network. This conception, and the corollary that change in the tone of the capillaries, if it occurred, would have little effect on the peripheral resistance, and hence on the arterial pressure, would be inevitable on the view that a large proportion of the capillaries were regularly open for the passage of blood. Our conception of the capillaries as the site of an important part of the peripheral resistance, so that the steep

portion of the pressure gradient was shifted to cover the arterial side of the capillary zone, necessarily involved the assumption that only a very small proportion of the available capillaries are simultaneously open under normal conditions, so that no great and abrupt increase, of the total sectional area of the path open to the blood, occurs in passing from arterioles to capillaries. This assumption, which was vital to our argument, was unfamiliar at the time, and, I believe, made it difficult for many to accept our conclusions. Krogh's work has provided its much needed justification by direct evidence.

There was a further inference, of much greater significance, to which this conception of the capillary circulation necessarily led us. In dealing with the simple vaso-dilator action of small doses of histamine we had supposed that the small proportion of capillaries which, at the moment, were actually transmitting blood, underwent a dilator relaxation, with an effect resembling an arterial dilatation in all but quantitative details. If such a reaction should spread beyond the immediate path of the blood and involve the whole of the capillary network, so that all the capillaries in the body became simultaneously relaxed, the mere capacity thus developed should, we argued, be sufficient to accommodate practically the whole of the blood at the periphery, where a large part of it would lie stagnant, removed from effective circulation. I have already shown you how Krogh's actual measurements, subsequently published, have given a quantitative reality to this conception of the capacity of the generally dilated capillaries. The condition so produced would correspond exactly with that which Laidlaw and I had for some time been studying, and which followed the injection into an anaesthetized cat or dog of a large dose of histamine.<sup>32</sup> The circulation failed, in this instance, not because the peripheral resistance was low, but because the output from the heart gradually fell to minimal proportions. The muscular action of the heart, and the tone of the arteries remained good; the output, and with it the blood pressure, failed because the blood was accumulating at the periphery in dilated capillaries and venules, while the larger arteries and veins were alike collapsed and empty. The shortage of the blood available for circulation was accentuated by a phenomenon which, again, the more recent work of Krogh has brought into the scheme of the general physiology of the capillaries. We found that the capillaries became not merely relaxed in tone but abnormally permeable. We were inclined, not realizing the importance of the contractile cells as responsible for capillary tone, to regard the relaxation and the morbid permeability as due alike to poisoning of the capillary endothelium, as Heubner also had assumed in describing a very similar condition. It would appear from Krogh's observations that not only the diameter of the capillaries, but the power of the endothelial wall to retain the constituents of the blood is conditioned by the maintenance of an adequate tone by the Rouget cells. Loss of capillary tone, however produced, seems to result in oedema in the area of relaxation. To what extent the abnormal permeability, which we observed, is the result of the loss of the supporting tonus of the Rouget cells, directly modifying the porosity of the endothelial filter, and to what extent, on the other hand, it is due to a poisonous action on the endothelium, or to secondary nutritional changes, caused by the inefficient circulation, is a matter on which evidence is incomplete and difficult to procure. That increase of permeability due to relaxation of tone is an important factor, is strongly suggested by the rapidity with which the loss of plasma through the capillary walls appears; within a few minutes of the injection of histamine as much as one-half of the plasma may have passed from the blood vessels, probably leaving many of the capillaries clogged with a viscid corpuscular cream.

This picture of the histamine shock, which I believe to be the picture of a condition having a wide pathological and clinical importance, was drawn by us chiefly from data obtained by macroscopic methods—measurements of blood pressure, of blood volumes both general and local, of changes in corpuscular content. It has been closely confirmed by the microscopic observations of Hooker<sup>30</sup> and of Rich<sup>32</sup> in America. Inchley<sup>30</sup> has quite recently raised the question of constriction of the venules as the essential factor in pro-

## LIMITATION OF EFFORT IN HEART DISEASE.

[THE BRITISH  
MEDICAL JOURNAL]

landing; then out of doors—walking, or in chair or vehicle, but sleeping on the ground floor, or carried upstairs, though walking down; then walking up a short flight of stairs once a day, then twice, but always walking upstairs first and then down, before walking down and then up—and one begins with not more than half a dozen steps, perhaps at first taken walking backwards. The same rule applies out of doors on gentle inclines and later on steepish hills—always up first and down back, and always turning back as soon as distress begins. The plan, of course, is obvious and is used by every practitioner, but such patients need "rules" more perhaps than any other class of case. They often feel so well (within their limit) that not only are they prone to give up taking their digitalis, with disastrous results, but are apt to think that they can do anything, and that restrictions are needless. And restrictions are *always* needed. The doctor's aim should be to lead them as far as is safe in the path of freedom, and then to tell them to keep within this limit, possibly with the hope of further liberty later on.

I have found it convenient to divide the extremes of human effort into seven degrees: (1) Complete rest in bed. (2) Movement on the level. (3) Quiet ordinary life. (4) Mild gardening, gentle golf, and slow hill-climbing, or easy manual labour allowed. (5) Any effort short of extreme exertion. (6) Full liberty of full health. (7) Exceptional effort only possible for athletes in training.

With regard to cardiac cases, the first four come into fairly consideration, and occasionally the fifth. But it must be supposed that one jumps from one stage to the next; progress must always be gradual, and in the early phases of convalescence from heart failure the greatest caution is needed, each step being taken tentatively, with the knowledge that one may have to go backwards and forwards before giving liberty on the next platform. Further, such patients have their good days and their bad days, and must be cautioned when off colour, or on a very hot day, or a very cold day, or after a bad night, or after some unsought strain, either physical or emotional, to go easy for a day or two, and not push on with the idea that it is "giving in" to do less to-day than they did yesterday. Again, women must regard the menstrual periods, and should take a day or two gently at these times, and perhaps take a midday breakfast in bed as a rule, and never to undertake exertion; and some require to take a rest day once a week, while all must be cautioned not to undertake exertion immediately after meals, and never to hurry. All must be careful also to feed simply, to take mild aperients if needed, and to avoid, as far as possible, catching colds and the like. Subject, however, to these limitations, and to such as may be indicated by individual susceptibilities, requirements, and inclinations, many cases of marked heart failure—with or without fibrillation—who may have to be kept in bed perhaps for several weeks, may be given the hope that they will eventually be able to live a life of usefulness and of enjoyment.

I have a patient, aged 55, who has had fibrillation for at least ten years, who has a somewhat enlarged heart with definite valvular and myocardial disease, and who has had an attack of paraplegia with aphasia (embolic). Yet he has married in the interval and has two children. He drives his own motor (self-starter), goes out for a quiet day's shooting on fairly level ground, and lives a very satisfying life. It is comforting to know that second attacks of cerebral embolism are extremely rare, and this assurance has been of the greatest benefit to this patient, who at one time suffered much from continual apprehension that another "stroke" was inevitable.

## THE HEART'S ENERGY AND RESERVES.

The amount of blood in an average human adult body is about 8 pints and weighs about 10 lb., and the whole of it is driven through the entire circulation, at the normal pulse rate, once in every 40 seconds, in an individual at rest (Haldane). This means that twelve pints of blood (six by each ventricle) are propelled by the heart every minute, or over two thousand gallons, weighing about ten tons, per diem—a truly prodigious display of energy. And yet this is but a minimum, which is increased several fold as muscular work is undertaken; for, given sound muscle wall and healthy coronaries, the reserve capacity of the heart is very large. Of course, as age creeps on there is some loss of elasticity, and the margin is reduced, while in a damaged heart this is further encroached on. Yet such is the reserve that many seriously damaged hearts, even in advanced age, possess margin sufficient for the calls of a quiet life.

Another way of appreciating the amount of work performed by the heart is to compare it with the hand, which can, with a Higginson syringe, only pump a pint and a half of water a minute, and which, even when working a Junker's inhaler at 60 or 70 contractions a minute, tires after two or three minutes, so that one is glad to change the hand. Of course, the comparison is not a fair one, for the hand is a marvellous mechanism, and is capable of playing five or six hundred separate notes on the piano in a minute, while, on another score, it is seldom recalled that the "tireless heart" rests for about twelve hours out of the twenty-four. Between each beat it pauses, and whether it beats fast or slow, it rests for about half the time, though at high rates it is diastole which is chiefly encroached on. The value of securing, if possible, a pulse of moderate rate in a weakened heart is obvious, and is further appreciated if one considers the number of systoles that can be saved in a day; for while a normal pulse rate means about a hundred thousand systoles per diem, a pulse of 100 is roughly half as much again. In relation to cardiac muscular exertion this would mean one and a half times as much work; and though the rapid pulse of fever and debilitating illness probably obeys other laws, there can be no doubt that high frequency in a resting patient means waste of cardiac effort. Rapid action reduces reserve capacity, but unfortunately, apart from fibrillation, our means for dealing with this state are singularly meagre, and often ineffectual.

## INDIVIDUAL SYMPTOMS AND LESIONS.

Before passing to some brief remarks on individual conditions, I would pause to observe that it is chiefly or general lines that the possibilities of effort limit in individual cases are best judged. Prior to the advent of gross evidence, such as swollen legs, albuminuria, enlarged liver, and obvious cyanosis, heart failure is generally ushered in by breathlessness or pain. In either case, no matter what the lesion, reduced effort as an initial step is essential; and, whatever the lesion, the amount of restriction must depend on the urgency of the symptoms, which, if severe, point to a preliminary period of rest in bed for a few days or for a few weeks, and seldom, in recoverable cases, for longer; while in many instances the initial limitation need not be so extreme. Each case must be judged on its own indications. There are, however, a few special conditions which require a special word.

The two varieties of arrhythmia which give direct guidance on effort limitation having been already discussed, a very few words will suffice for the remainder.

*Extra-systoles*, easy of recognition, and the commonest cause of irregular pulse in adults, occur in hearts both healthy and diseased, but in an otherwise healthy heart they do not call for restriction of effort. *Heart-block* of marked degree generally imposes its own limits, but the minor phases, if detected, indicate caution. *Paroxysmal tachycardia* is generally disabling during the attacks, which always start and end with absolute suddenness. Between the paroxysms the patient may do what he can manage comfortably, and may be trusted to do nothing which his experience proves to be unwise.

Much the same may be said of the *anginas*, though, in progressive cases, a period of five or six weeks of complete rest in bed often brings a respite, and delays advance. Attacks of true cardiac asthma commonly occur at night; and these patients are seldom pulled up by immediate distress, as are the sufferers from angina. But the symptom always means serious myocardial disease, and indicates continuous limitation of effort. For congenital heart defects no rules can be laid down; they range from the negligible to the rapidly fatal. But loud murmurs of congenital origin may be heard in hearts which are physiologically quite efficient for ordinary occupations. *Pulsus alternans* is seldom recognized, but is of grave import, and demands the utmost caution.

In acute fevers of all kinds the more completely the patient is kept at rest the better, and the heart should be watched for the intrinsic complications so common in rheumatic fever, but not uncommon in influenza, diphtheria, scarlet fever, and other microbial infections. In convalescence there may be difficulty in deciding whether we

are dealing only with toxæmia, or whether the heart is more seriously affected. If there has been pericarditis or endocarditis, or if the intermissions of minor heart-block are detected, one can hardly be too cautious in the guidance of convalescence; but, with the "poisoned heart," so common after influenza and other acute infections, even though there may be a systolic murmur and perhaps some dilatation, it is a mistake to keep the case in bed after the temperature has been normal for a day or two. In such states the heart recovers its tone much more quickly if the patient is got up and got out pretty soon, and encouraged to take such exercise as brings with it a sense of well-being.

The *rare lesions* give us certain indications, the chief being that while those causing systolic murmurs may be treated on general lines, and the murmur often ignored, the diastolic murmurs always carry a special warning, because the lesions giving rise to them (mitral stenosis and aortic regurgitation) are apt to be progressive, and also because, apart from any previous myocardial change, both lesions interfere with the efficient nutrition of the heart through its coronaries. Such patients may feel very well and equal to anything, but, while they may be allowed to undertake ordinary efforts according to their inclinations, they should be warned against excessive strain, and precluded from occupations involving sudden or severe effort.

In *infective endocarditis*, whether acute or subacute, the patients are generally so ill that the question of allowing effort hardly comes in. But if it should arise, the sufferer may safely be allowed to be in or out of bed—indoors or out of doors—as he prefers. Up to now no cure has been discovered, and as these diseases are invariably fatal the sufferer should be allowed to live the life that brings him most comfort and contentment.

I have left to the last the terrible thing called "blood pressure." I have used the instrument since long before it was a fashionable adjunct to the consulting-room, and occasionally I get useful information from it; though, if one makes a guess at the systolic pressure before taking it, it is easy to be fairly right nine times out of ten. Sometimes one finds the pressure lower than was anticipated; but "blood pressure" means to all patients "high pressure," and it obsesses many doctors, and needlessly alarms many patients. One sees people die of cerebral hæmorrhage with a pressure of 150, while many people with a pressure of 180 to 220, or even more, live for years in excellent health, until "the fear of death" is put into them by some member of our profession, who tells them they have passed the "danger level," and they live ever after with the feeling of the rope around the neck. And "well set-up" people come to us and in reply to the inquiry as to what ails them, simply say "blood pressure." I am looking at a note reading thus: "Mrs. H—, March, 1915, æt. 80—B.P. 220—Sep. 1918, B.P. 180." She took no precautions and few drugs, and she ate and drank what she liked, moved about as she liked, and died in 1921 of bronchitis and patchy pneumonia. I could cite many similar cases, and such people may only feel at their best when their pressure is highest, which is reasonable, as it is then that their coronaries fill best and that pressure is sufficient to force the damaged glomeruli, for the kidneys are seldom unaffected. By all means let early arteriosclerosis be recognized and reasonably treated and dieted; but do not let us put the fear of death into such people, or unduly limit their activities. All tissues retain their elasticity and life longer if they are kept in active use; and my belief is that these cases live longer and in better health if they are allowed to take such exercise as they find agreeable.

#### CONCLUSION.

In conclusion I turn to one or two more generalities, and the first is that every one of us is sure to make mistakes; for, apart from those which we ought to avoid, there are two sources of error which may be unavoidable. People sometimes die suddenly of heart disease who have never had a symptom, and some such cases have been examined within a few months or weeks of their death by the ordinary methods without any abnormal sign being discovered, or anything to suggest that an examination by electro-cardiograph (which might have shown something) was indicated. I have seen many sudden deaths from heart disease, but only two of this kind in which a necropsy was made. In one there was a ruptured aneurysm of the left ventricle, while the other showed degenerated heart wall, especially on the right side.

The second source of error is of happier augury, for we

all occasionally see patients who we think will not survive for many weeks, but who live for years.

I have to-day seen a lady of about 70, who ten years ago was at death's door. During all these years she has had fibrillation, extreme cyanosis, and dyspnoea, and grossly oedematous legs, which often ooze; yet she is marvellously cheerful, and goes up and down stairs on the sly, when she can cheat her guardians. Of course she has been taking digitalis all the time. Had I lost sight of her I should certainly have supposed that she had been dead for many years.

Though mistakes will be made, I believe, however, that it is possible, by a careful all-round survey, to be right in nine cases out of ten; and I think that in framing a prognosis, and with it general rules for effort guidance, the general practitioner who has kept abreast of the times, and who has formed the habit of making short notes, has somewhat of an advantage over the specialist who only sees cases in hospital and in consultation. For we can follow up our cases for ten or twenty years, and watch the slow and often surprising sequence of events—an invaluable experience which is, in the majority of their cases, automatically closed to the specialists, who, I believe, often conclude that the patients of whom they hear nothing are dead. But I am very familiar with the great difficulty of following up cases seen in consultation. The doctor in charge always says he will let one hear how the case goes on, and he means to do so. I fear we are all offenders in this matter.

I began with a warning on an old subject (enlargement) and I end with a warning, which time will prove to be right or wrong, upon a new subject. When the stethoscope had revealed the various heart sounds, and their meaning became gradually elucidated, conclusions based on the integrity of the valves dominated cardiology for many decades and led to views many of which are to-day discredited.

With the advent of the polygraph and the electro-cardiograph, the myocardium has come to its own, and it now dominates. This is, in my view, as it should be; and yet I would venture to predict that some of the anomalies of myocardial activity revealed by the electro-cardiograph, and on which discouraging conclusions are now based, will be proved by time to be either of a temporary nature or else of comparatively minor importance, and well within the great reserves which the heart possesses. As an example of the kind of harm that may be done, let me cite a final case.

A lady, aged 36, suffered from palpitation and irregular pulse, and her doctor, unable to differentiate the rhythm, sent her to a specialist, who examined her very thoroughly. I have seen his very excellent report. The irregularity proved to be of a very unusual kind in a person of her age, being a mixture of sinus arrhythmia and extra-systoles. These, he said, might be safely disregarded, and a skiagram showed a heart of normal size. So far no harm had been done; but the blood pressure was high for her age (155) and the electro-cardiograph showed left-sided preponderance, and from these data he concluded that the myocardium was permanently damaged, and enjoined that "for the rest of her life she must keep this fact in mind and live well inside her limited capacity for effort." She has always lived on these lines, for she has no taste for sport, and has no temptation to undertake excessive toil. But she received a shock, and now suffers from "heart upon the brain." She is becoming neurasthenic, and, finding herself easily tired by efforts which two months ago were not only tolerated but enjoyed, is convinced that her decline of vitality is due to heart disease, that her days are numbered, and that she can never live a normal life again.

The baneful and far-reaching effects of fear should ever be before us, as should be also the tonic effects of hope and reassurance, and the possibilities of improvement which come to all muscles, the heart included, when allowed free activity within the range of pleasurable reaction.

Each case must be looked at all round: no single sign should be given undue weight; but if there is any one point which may be allowed to override the others it is the one to which least attention is often paid—and that is the physiological capacity of the heart, as proved, not so much by set tests, as by careful inquiries and cautious experiment as to the individual patient's capacity for effort in the ordinary calls of life.

THE INFLUENCE OF THE THYROID GLAND ON  
THE RESPONSE TO ADRENALINE.

BY

D. MURRAY LYON, M.D.

(From the Department of Therapeutics, University of Edinburgh.)

At the present time a series of satisfactory tests for functional efficiency is amongst the most urgent needs of the practical physician. Unfortunately most of the tests introduced are so elaborate and require so much apparatus that they can only be performed in well equipped hospital laboratories, and are consequently lost to the general practitioner and his patients. One of the best examples of this need is in the so-called border-line cases where the diagnosis lies between a minor degree of thyroid overactivity and a neurosis. The estimation of the basal metabolic rate gives a measure of the thyroid activity, but this method of examination is confined at present to hospital practice.<sup>1</sup> A close relation between the state of the thyroid gland and the action of adrenaline has long been known to exist, and Goetsch has made this the basis of his test for hyperthyroidism.

In animal experiments it has been shown that removal of the thyroid gland lessens the response of the subject to a subsequent injection of adrenaline, and conversely that the administration of thyroid<sup>2,3,4,5</sup> enhances the adrenaline reaction. Stimulation of the cervical sympathetic, by causing active secretion from the thyroid, produces a similar effect.<sup>6</sup> In these cases the thyroid hormone is believed to sensitize the sympathetic nerve endings to the action of adrenaline. Eppinger and Hess,<sup>7</sup> Barker and Sladen,<sup>8</sup> and Lehmann<sup>9</sup> have shown that these results hold good for man also. Goetsch<sup>10</sup> gives as a standard a dose of 0.5 c.cm. of 1 in 1,000 adrenaline chloride subcutaneously, and notes in the patient the changes produced in the blood pressure and pulse rate. The typical positive reaction is "a rise of about 10 points in pulse or in systolic pressure or in both, together with certain clear-cut subjective and objective symptoms" (palpitation, tremor, apprehension, etc.). The merits of this reaction have been widely discussed and much adverse criticism has appeared.

Plummer<sup>11</sup> believes that thyroxin quantitatively controls the rate of cellular metabolism, but he has pointed out that the supposed relation between thyroid and adrenals can be explained on grounds involving the rate of blood flow, entirely apart from any other action. A similar position is taken up by Kendall<sup>12</sup> when he states that, "if viewed purely from a consideration of the physics involved, the injection of adrenaline into a subject with a normal basal metabolic rate will be necessarily different from injection of the same quantity into a subject with a metabolic rate 30 per cent. above normal." Aub<sup>13</sup> also rejects the theory of specific sensitization and decides that the thyroid is not an essential factor in the action of epinephrin and that the effects of thyroxin and epinephrin are distinct and not interdependent. It is interesting to note that Marine and Lenhart<sup>14</sup> continued to get an increase in metabolic rate after administration of adrenaline to rabbits previously deprived of the thyroid gland. Sandiford,<sup>15</sup> who reports 46 observations in 39 patients, found no relation between the intensity of the adrenaline reaction and the condition of the thyroid; and she doubts if there is any sound physiological foundation for the belief. Other observers have found that positive reactions are frequently obtained in non-goitrous subjects. A number of physically fit, ~~unselected~~ students examined by van Wagenen<sup>16</sup> showed ~~an increase of 10 per cent.~~ in 20 per cent., and Tomkins, Sturgis, and Wearn<sup>17</sup> found 65 per cent. of positives in cases of irritable heart (in which condition the basal metabolic rate is normal<sup>18</sup>). Herring, reviewing the subject, sums up the position thus: "The specific action of the thyroid in sensitizing tissues amenable to adrenaline, though not improbable, is not yet proved."<sup>18</sup>

The present position<sup>19</sup> of the adrenaline test appears to be that a negative finding is valuable in definitely excluding hyperthyroidism, whereas a positive result is of less significance, since it is frequently got in cases where no evidence of an overacting thyroid exists.

*Details of Investigation.*

The question has recently been investigated in a number of patients in the medical wards of the Edinburgh Royal Infirmary. The cases examined include four hypothyroid

patients, seven with exophthalmic goitre, three asthmatics, five diabetics, and several others who showed no obvious sign of endocrine disturbance (some fifty examinations in all). The subjects, having fasted overnight, were allowed to rest quietly with the mask adjusted for thirty to sixty minutes before the records were started. When the pulse rate and blood pressure readings had fallen to a steady level a sample of expired air was taken for the estimation of the basal metabolic rate. A subcutaneous injection of 0.5 c.cm. of a 1 in 1,000 solution of adrenaline chloride (P. D. and Co.) was then given, and thereafter the pulse and blood pressure were estimated at two-minute intervals, and the expired air was collected over successive ten-minute periods for an hour.

TABLE I.

Metabolic Rate.*		Blood Pressure.			Pulse.			Diagnosis.
Bas.	Max.	Bas.	Max.	Inc.	Bas.	Max.	Inc.	
122	143	140	160	20	104	137	33	Exophthalmic.
120	150	148	183	35	105	152	47	Exophthalmic.
120	150	142	186	44	102	148	46	Exophthalmic.
120	152	135	157	22	106	131	25	Treated myxoedema.
119	154	125	150	25	71	86	15	Neurasthenia.
118	153	135	145	11	100	132	32	Asthma.
63	72	115	120	5	78	94	16	Untreated hypothyroids.
64	123	119	132	13	57	78	21	
64	73	110	139	29	69	111	42	

Bas. = Basal; Max. = Maximum; Inc. = Increase.

\* In order to facilitate comparison the Du Bois normal is taken as 100 and the figures found are given as 122 and 63 instead of the more usual + 22 and - 37.

The influence of the state of the thyroid on the character of the response to adrenaline has been investigated in two ways: (a) by comparing the reactions in different subjects, and (b) by examining the same individuals on more than one occasion.

(a) *Reactions in Different Individuals.*—When viewed as a whole, these show little relation to the activity of the thyroid as determined by the basal metabolic rate. A large cardiovascular response may be present in a patient with a low metabolism and vice versa. The majority of the subjects gave a positive response as estimated by Goetsch's criteria, and only four showed an increase of less than ten points in the blood pressure. The lack of uniformity can best be shown by a comparison of patients with approximately similar basal metabolic rates. Two such groups are recorded in Table I. It will be noticed that even in the cases of untreated hypothyroidism all the reactions save one are greater than ten points.

(b) *Reactions in the Same Subject.*—If it be true that thyroxin sensitizes the body to the action of adrenaline the effect should be evident when the amount of the thyroid hormone in the patient is varied. Table II gives the results of the examination of four subjects before and after the administration of thyroid extract. Two of the patients (1 and 2) were cases of myxoedema with very low metabolic rates; the other two suffered from asthma. Of the latter, No. 4 showed rather high basal figures, while No. 3 was

normal. The effect of the thyroid in raising the general activity of the body is evident in the increase of basal metabolic rate, basal pulse rate, and basal systolic pressure readings, while in those observations made after the giving of thyroid extract its sensitizing effect is shown in the great increase in the pulse and pressure seen in all instances except one.

Confirmation would be expected in cases of exophthalmic goitre examined at different phases of the disease. The results shown in Table III at first sight seem contradictory. The cases were first examined shortly after admission to hospital and were re-examined when the clinical condition had improved. On the subsequent occasions the basal metabolic rates had fallen greatly and the slowing of the pulse was even more marked, the reduction in the case of the basal systolic blood pressure being less evident. In case No. 5 the reactions to adrenaline agreed very closely on two occasions when the basal metabolic rate stood at 120. On the third examination, though the basal levels were much reduced, the post-adrenaline increases in metabolic rate and in pulse rate were practically the same as before treatment. Cases 6 and 7 showed a definite reduction in metabolic response, but in both patients the post-adrenaline blood pressure rise was greater and the pulse acceleration was little affected. Such results would suggest that the thyroid controls only the basal levels, while the reaction to adrenaline depends on some other independent mechanism.

Experimental proof of the interrelationship of the thyroid and the suprarenal seems to be complete. Adrenaline stimulates the thyroid to activity, and the thyroid hormone controls the rate of activity of the body tissues, including the adrenal glands. It is also believed that the thyroid sensitizes the sympathetic nerve endings on which adrenaline acts, so that an increase in thyroid activity should lead to an increased reaction to adrenaline. The existence of such a relation is more difficult to prove in the case of man. Table I has shown that the movements of pulse and blood pressure in no way parallel the activity of the thyroid from case to case, and even when allowance is made for size, body weight, age, and sex (as is done in computing the basal metabolic rate) no better results are obtained.

The effect of an injection of a drug must depend to a great extent on the rate of its absorption, and a good deal of the difference between individual cases may be explainable on this ground. In some persons the maximum rise is produced within six minutes after injection, while in others twenty or thirty minutes elapse before the highest point is reached. This can only be explained on the basis of a wide difference in the rate at which the adrenaline reaches the tissues on which it acts. The rate of absorption is closely related to the circulation rate, being most rapid in the hyperthyroid cases (where the venous blood often looks pink and arterialized) and slowest in those with deficient thyroids. The rate of absorption, then, has an extremely important influence on the result, for where the maximum occurs early it reaches a very high level, since a great deal of the adrenaline is in action at once. On the other hand, where absorption is slow only a limited quantity of adrenaline can be reaching the tissues at one time and its stimulating effect must be much less.

It is said that adrenaline acts quantitatively and that the injection of a series of similar doses produces uniform responses without fatigue. Hunt<sup>20</sup> showed that as increasing doses were given the response elicited was always a little less than was expected. This question has been reinvestigated<sup>21</sup> with regard to the blood pressure, and it has been found that the relation between the quantity of adrenaline and the effect

produced is logarithmic. It has also been found that when uniform doses are given the magnitude of the response depends upon the level of the blood pressure from which the reaction started—for example, a dose of 0.2 c.c.m. adrenaline given when the pressure stood at 136 gave a rise of 63, but a similar dose given at 246 produced only an increase of 18 mm. It will thus be seen that a rise of ten points in the blood pressure does not represent a uniform quantity of adrenaline under all circumstances—for example, to produce an increase of pressure from 190 to 200 requires a great deal more of the drug than to raise the level from 110 to 120. When applied to Table II this principle will have the effect of magnifying the increases actually obtained after the administration of thyroid; and in the case of Table III the apparent anomaly will diminish if not disappear, since the relatively large responses from a lower basal level are of less value than if from the original higher basal levels. Even when this allowance has been made, the differences in Table III fall far short of those in Table II, suggesting that the adrenaline sensitive mechanism still remains hypersensitive when the thyroid activity diminishes. (This might lend support to the view that the thyroid changes in exophthalmic goitre are merely secondary to a hypertonus of the sympathetic system.) If the two mechanisms are entirely independent, as Aub believes, an increase in thyroid activity would merely raise the basal levels and the adrenaline effect superimposed on these would have the same value whatever level the reaction started from. This does not fit the facts. The thyroid certainly does control the resting levels of pulse rate, metabolic rate, and systolic pressure, but it also sensitizes the tissues to the action of adrenaline.

Some of the points discussed may help to explain the comparative failure of Goetsch's reaction as a clinical test. The responses obtained from the injection of adrenaline reflect principally the tonus of the sympathetic system, which may or may not depend on the state of the thyroid. It would seem too that the criteria accepted are too low, since so many apparently normal persons give positive reactions.

#### Summary.

In a comparison of the metabolic and cardio-vascular responses to the injection of adrenaline in patients having similar basal metabolic rates no relationship between the reactions is obvious.

If individuals are examined on different occasions when their metabolic rates have altered, a change in the degree of response to adrenaline is noticed.

Administration of thyroid to a patient leads to an exaggeration of the reaction to adrenaline.

In cases of exophthalmic goitre a fall in basal metabolic rate is not accompanied by a very great reduction in the sensitiveness to adrenaline, and it is suggested that this depends on a persisting hypertonus of the sympathetic system.

THE French Association for the Advancement of Science will meet at Bordeaux from July 30th to August 4th, with Professor Sabrazès as president of the Section of Medicine and Surgery, and Professor Auché as president of the Section of Public Health. Further information can be obtained from the Secretariat of the Association, 23, Rue Serpente, Paris.

AN international leprosy conference will be held at Strasbourg from July 28th to 31st, when the following subjects will be discussed: (1) new statistical data, (2) etiology, (3) pathology, (4) treatment, and (5) social and individual prophylaxis. Communications should be sent before June 10th to the General Secretary, Professor Marchoux, 95, Rue Falguère, Paris.

RECTAL PAPILLOMATA IN SCHISTOSOMA  
HAEMATOBIIUM INFESTATIONS.

BY

H. C. SINDERSON, M.B., CH.B., M.R.C.P. EDIN.,  
D.T.M. AND H. LOND.,IRAQ HEALTH SERVICE; PHYSICIAN, NEW GENERAL HOSPITAL, BAGHDAD;  
ANDE. A. MILLS, M.B., CH.B. EDIN., D.T.M. AND H. LOND.,  
IRAQ HEALTH SERVICE; CHIEF PATHOLOGIST, CENTRAL LABORATORY,  
BAGHDAD.

## INTRODUCTION.

In his chapter on schistosomiasis in the latest edition of Manson's *Tropical Diseases* (1921) Manson-Bahr makes the following observation in relation to urinary schistosomiasis: "In a large proportion of cases, much more frequently than was formerly thought to be the case, the characteristic ova of *S. haematobium* may be found in the faeces (Fairley), though it has not yet been proved that they are capable of forming the intestinal papillomata so characteristic of *S. mansoni* infestations."

Our experience in Iraq is fully in support of the observation that ova of *S. haematobium* are commonly to be found in the

FIG. 1.—Longitudinal section from the hypertrophic adenomatous portion of the growth, showing the papillomatous prolongations and numerous deeply stained ova in the tissues. Fixed in formol saline and stained with Ehrlich's acid haematoxylin and orange "G." (x 44.)

faeces, but we hope in this note to demonstrate that it both can and does occasionally form intestinal papillomata. Our experience suggests, moreover, that the condition is not by any means a rarity. In the areas of Iraq infected with schistosomiasis rectal papillomata have been occasionally reported, but not until quite recently have we been able to obtain specimens for section.

Three of these growths have been sectioned; in addition to the case about to be described Dr. Braham and Dr. Perry have both sent specimens of rectal papillomata to the Central Laboratory, Baghdad, for examination, and in each case the ova of *S. haematobium* were found on section.

The present case mainly differs from the other two in that the signs and symptoms presented left little doubt as to the causation of the new growth prior to its removal, and that, as will be seen later, adult worms in addition to ova have been found in the papilloma removed.

The patient, Hassan ibn Bairam, aged 26, a Kurdish coolie from Erbil, was admitted to the New General Hospital, Baghdad, on January 24th, 1923, with a diagnosis of "anaemia"; he complained of increasing shortness of breath on exertion for three months. He stated that he left Erbil for the first time six months previously, and had since been engaged in coolie work on the new cantonment in the course of construction at Hinaidi just south of Baghdad. He was insistent that he had been free from any symptoms whatever pointing to a urinary or rectal lesion until three months previously, when he first noticed a burning pain on micturition, and a month later a few drops of blood at the end of micturition. A week later he noticed the passage of blood and mucus by the rectum, a symptom which steadily increased in frequency up to the time of his admission to hospital. There was a history of occasional attacks of fever in Kurdistan, probably malarial.

## Clinical Examination and Course of Illness.

The patient was a well built man with a pale "bisquit colour" complexion, and was obviously very ill on admission. The spleen was just palpable on deep inspiration; haemic bruits were to be heard on auscultation of the heart, and a few râles at both pulmonary bases. The temperature was 100° F., and the pulse 96. The result of a total and differential blood count was as follows: Haemoglobin 60 per cent., red blood corpuscles 3,235,000 per cubic millimetre, giving a colour index of just under 1. There was a moderate degree of leucocytosis (13,800); the percentage of the respective white elements present being—

Polymorphonuclear leucocytes	...	...	55.4 per cent.
Lymphocytes	...	...	26.6 "
Large mononuclear leucocytes	...	...	5.2 "
Eosinophil leucocytes	...	...	12.8 "

The patient at the time of admission was passing from six to ten motions daily. Naked-eye examination of the stools showed the presence of both blood and mucus, the former dark in colour, free, and greatly in excess of the latter. Microscopically the presence of an enormous number of the typical ova of *S. haematobium* containing active miracidia was noted.

Examination of a centrifuged deposit of urine showed many pus and red blood cells and a large number of live terminally spined ova. Digital examination revealed a papillomatous growth in the rectum just within range of the finger, and the presence of the tumour was confirmed by sigmoidoscopic examination. The growth was removed by Dr. Woodman on February 7th, and under intravenous administration of sodium antimony tartrate the patient is making very satisfactory progress.

FIG. 2.—Transverse section of the adenomatous portion of the growth. Tissue fixed and stained as in Fig. 1. (x 44.)

It is of interest in this case to note that though the infestation was heavy it was apparently of quite recent origin. Erbil is a town in Kurdistan, and as far as is known schistosomiasis does not exist in that country. The presence of an enlarged spleen in a Kurd is quite usual; so rife is malaria in Kurdistan that a Kurd with a non-palpable spleen is quite a rarity.

As to the exact origin of the infestation there is little to help in the history, but everything points to it having occurred either in the neighbourhood of Baghdad, where a focus of this disease undoubtedly exists, or en route from Erbil, though the chances of infestation north of Baghdad would appear to be remote. The degree of eosinophilia is higher than our average in urinary cases of infestation by *S. haematobium* in Iraq, but is possibly to be accounted for by the heaviness of the infection present in this case.

It might here be noted that, as far as our investigations have gone, *S. mansoni* does not occur in either Iraq or Kurdistan.

## PATHOLOGY.

A specimen of faeces and the polypoid growth removed at operation were submitted to the Central Laboratory for examination.

## A. Examination of Faeces.

Examination of the specimen of faeces revealed the presence of the typical terminal-spined ova of *S. haematobium* in large numbers, many containing miracidia showing considerable activity; pus cells and red blood corpuscles were present in moderate numbers.

## B. Examination of the Polypoid Growth.

Microscopically the mass approximated in size to that of a small walnut; it was greyish-white, of firm consistence,

and presented a somewhat nodular surface showing considerable congestion, and in places what appeared to be small areas of superficial ulceration. No marked resistance was offered to the knife. On section the tissue showed a solid core with a marked peripheral radiating structure which on microscopical examination was found to correspond to the hypertrophic adenomatous portion of the growth.

#### Microscopic Examination.

1. *The Peripheral Portion of the Growth.*—Sections taken from the periphery of the polypoid growth show an advanced hypertrophic condition of the rectal glandular tissue, with the formation in places of long papillomatous prolongations of the mucosa. The supporting structure is loose, and consists of delicate strands of fibrous tissue, between which are to be seen numerous cells of the mononuclear type. Young thin-walled blood vessels are plentiful and in a condition of marked engorgement. In several places small collections of ova with deep-staining miracidia are to be seen in the interglandular tissue, and it is of interest to note that in the neighbourhood of such collections the cellular content of the tissue changes, the majority of cells in these situations consisting of polymorphonuclear leucocytes of the eosinophil type. In the transitional area between the adenomatous and the more centrally placed portion of the tissue are collections of ova

FIG. 3.—Section showing collection of embedded ova, one of which shows the terminal spine mentioned in the text. Fixed in formal saline and stained with Heidenhain's iron haematoxylin and orange "G." ( $\times 205$ .)

which, from the failure of the miracidia to take the nuclear stain, would appear to be of less recent date. In such areas we find that the particular stimulus determining the calling forth of the eosinophil polymorphonuclear elements has ceased, the cells found in these particular areas being chiefly of the mononuclear type. Here also stimulation of the fibroblastic elements has taken place, with marked increased production of fibrous tissue and resulting attempts at encapsulation. Sections taken from certain superficial portions of the growth fail to show the adenomatous structure above described; it is replaced by a tissue presenting the appearance of granulation tissue in which numerous ova are present; blood vessels are numerous, and ulceration of the surface is apparently occurring. It is from areas such as these that ova would appear to be liberated into the lumen of the bowel.

2. *The Central Portion of the Growth.*—In this area the glandular structure above described is entirely absent. On the other hand, the fibrous tissue elements show considerable increase, forming a well marked stroma in which numerous ova of various ages are embedded. Here again variation in the cellular content of the tissue is to be noted; in the proximity of ova containing miracidia which stain well the infiltrating cellular type is that of the eosinophil polymorphonuclear leucocyte. In the neighbourhood of ova showing degeneration of the miracidia, evidenced by the absence of nuclear staining, the predominant cell is that of the mononuclear type. In some of the sections ova are present in very large numbers; in one particular area as many as sixty were visible in the field given by an objective Leitz No. 3 with ocular No. 2.

Apart from the fact that numerous terminal-spined ova

were found in the stool it was considered necessary to search sections in the endeavour to find an embedded ovum cut longitudinally through the middle line showing beyond any doubt the presence of the terminal spine. In due course a fine specimen was found (Fig. 3). The complete contained miracidium is unfortunately not shown, but the specimen demonstrates the terminal spine very clearly. No evidence whatever has been obtained after prolonged search of any ova showing the slightest suggestion of a lateral spine.

Certain structures were seen lying within the blood vessels which lead us to think that they were the transverse sections of the terminal portion of a trematode worm. Further search in other sections from the same tissue finally led to the discovery of typical transverse sections of the helminths themselves lying within the blood vessels and presenting the characteristic arrangement of the male and female worms. A portion taken from one of these sections is illustrated in Fig. 4.

From the histo-pathological examination the polypoid growth would appear to be of the nature of a papillo-adenoma, the stimulus producing this hypertrophic condition of the rectal mucosa being the presence in the tissues of numerous ova of *S. haematobium*, and also possibly certain toxic substances secreted by the adult worms themselves whilst lying in the terminal ramifications of the haemorrhoidal vessels.

FIG. 4.—Transverse section showing the helminth lying within the blood vessels; numerous ova can be seen in the surrounding tissue. Fixed in formal saline and stained with Ehrlich's acid haematoxylin and eosin. ( $\times 44$ .)

#### CONCLUSION.

The case under consideration would appear to prove the ability of *S. haematobium* to produce rectal papillomata.

The fact that after very careful search no trematode ova other than those of *S. haematobium* have been found in the urine, faeces, and tissues is, we think, fairly conclusive evidence of a further and previously unproved manifestation of infection with *S. haematobium*.

The accompanying illustrations were kindly drawn from the actual specimens by Mrs. Sinderson, and depict the main points of pathological interest mentioned in the text.

## A TWO-LOOP BUTTON SUTURE.

BY

W. G. SPENCER, M.S., F.R.C.S.,  
SURGEON, WESTMINSTER HOSPITAL.

BEFORE I adopted the suture to be described I had had to experience the unforeseen bursting open of abdominal wounds. This happened after both suturing in stages and the insertion of deep through-and-through sutures. After gastro-jejunostomy or a similar aseptic operation, in weakly patients, somewhere about the tenth day the abdominal incision opened and bowel prolapsed. A cough, vomit, strain at stool, tympanites, merely sitting up in bed, were the immediate causes of the accident, but it could then be noted that there had been an absence of repair. In septic cases, entailing the insertion of a drainage tube, and an undermining of the abdominal wall by suppuration, the

sutures simply cut out; this was followed by the death of the patient.

The suture has prevented such accidents, and there appears to be less tendency to late ventral hernia. I had tried various methods to be found in books before lighting on this one, of which I have not been able to find a similar description. By it the layers of the abdominal wall can be brought into apposition, each to each, and so held during healing, without tension or necrosis, or on the other hand of yielding. The patient can get up, and the sutures need not be taken out for five weeks. In the case of suppuration fomentations can be put on whilst the sutures continue to hold. The method has been applied also secondarily, after an abdominal incision otherwise sutured has burst open, and sound healing has followed. My description applies in particular to the closure of a median abdominal incision, but with modifications I have used the procedure for the closing of other incisions, including cases of ventral hernia and sliding scrotal hernia. The sutures can be inserted even although the abdominal wall is only partly relaxed by the anaesthetic.

#### The Method.

The soft parts under the skin are held a little everted by Lane's tissue forceps, the skin being retracted as required by a blunt hook. A strand of strong fishing gut has one end threaded through the eye of a semi-circular needle and held by a slip-knot; upon the other end clamp forceps are put on to serve as a stop. The needle is entered (Diagram 1, A) one-third of an inch (1 cm.) from the right margin, through the skin and out through the subcutaneous tissue, the suture being drawn through up to the stop. The needle being then carried across to the left side is made to penetrate the anterior sheath, the left rectus muscle, its

posterior sheath, and the parietal peritoneum, not more than two-thirds of an inch (2 cm.) from the cut edge. The needle is next passed (Diagram 1, B) on the right side through the parietal peritoneum, outwards through the right rectus and its anterior sheath. A second loop is now inserted about half an inch (1.5 cm.) distant lengthwise from the first loop, the object being to include about one inch of the incision by each suture. The needle is passed (Diagram 1, C) on the left side from the anterior sheath

to the parietal peritoneum. Finally the needle is pushed from the parietal peritoneum on the right side outwards (Diagram 1, C, D) to emerge through the skin about a third of an inch (1 cm.) horizontally outside the point of entry.

The two ends of the suture are drawn upon until, as tested by the thumb and finger, the margins are brought into apposition without constriction or puckering (Diagram 2, E). Then (Diagram 2, F, G, H) the suture ends are knotted over "buttons"; I have used short lengths of well boiled catapult elastic, but rolls of gauze and other things will serve. The skin is thus approximated, and is further held together by a fine continuous suture which can be removed after a few days. At the time or at subsequent dressing a single layer

of gauze may be slipped under the "buttons" to protect the skin. The sutures should not be taken out until about three (better five) weeks, the patient meanwhile getting about. When doing so the knot is drawn upon sideways, and one end snipped through flush with the skin, into which it withdraws. Later on—whether the same, the next, or the third day—after loosening by the patient's breathing and movement, the suture can be readily withdrawn without liability of breaking or of leaving buried a portion of the fishing gut.

Diagram 2.

## HERPES ZOSTER WITH LOCALIZED MUSCULAR PARALYSIS.

BY

CECIL WORSTER-DROUGHT, M.A., M.D.CANTAB.,  
M.R.C.P.,

LECTURER IN NEUROLOGY, BETHLEM ROYAL HOSPITAL; ASSISTANT  
PHYSICIAN, WEST END HOSPITAL FOR NERVOUS DISEASES.

MUSCULAR paralyses in the affected zone accompanying or following an attack of herpes zoster are very rare; especially is this the case in herpes of the trunk. As the essential lesion in herpes zoster is situated in the posterior root ganglion of the spinal nerve supplying the affected area (Von Bärensprung, 1861<sup>1</sup>) and consists in an inflammation of the ganglion sheath with round-celled infiltration and extravasation of blood into the ganglion itself (Head and Campbell, 1900<sup>2</sup>), it is somewhat surprising—when one considers that it is at the posterior root ganglion that the tubular meningeal sheaths of the anterior and posterior roots blend—that the inflammatory process does not spread more frequently to the neighbouring anterior root and result in localized paralysis. That paralysis of muscles in the affected zone is more often met with in herpes of the upper limb than in herpes of the trunk is probably accounted for by the fact that the anterior and posterior roots in the lower cervical region have an even closer relation to each other than have those in the thoracic region. In this connexion, however, it is to be noted that D. W. Montgomery<sup>3</sup> advances a different explanation. He believes that herpes zoster is caused by a specific virus—probably streptococcal, as was originally suggested by Rosenow and Oftdale—which reaches

the posterior root ganglion from the skin by way of the perineural lymphatics. The fact that the lymphatics of the sensory nerves are more accessible from the surface than are those of the motor nerves accounts for the rarity of an associated paralysis; in the case of the limb and ocular muscles, however, the motor nerves are more superficial, a distribution which is considered by Montgomery to explain the relatively more frequent occurrence of motor complications in these situations. In herpes ophthalmicus, ocular palsies as a complication are said to occur in 7 per cent. of cases.

In an extensive search of available literature I have been able to find very few recorded cases of paralysis accompanying or following herpes zoster of the trunk. Gowers<sup>4</sup> mentions the occurrence of motor complications in herpes zoster, and points out that it is necessary to distinguish between immobility from hyperaesthesia and true paralysis. Ebstein<sup>5</sup> in 1895 collected 20 cases of paralysis complicating herpes zoster, but this series includes no case of herpes of the trunk in which the paralysis followed and was confined to the muscles of the affected zone. The 20 cases consist of 6 of paralysis of certain muscles of the upper limb, 1 of the lower limb, 9 of facial paralysis, 3 of facial paralysis together with other cranial nerve palsies, and 1 of ascending myelitis following herpes of the trunk. Hewlett<sup>6</sup> in 1906 pointed out that although 75 per cent. of cases of herpes zoster affected the trunk, he had found only one case in which muscular paralysis occurred. F. Taylor<sup>7</sup> (1895) recorded a case of herpes on the right side affecting the region of the tenth, eleventh, and twelfth ribs posteriorly and extending to the umbilical region anteriorly, which was followed, about four weeks after the appearance of the eruption, by paralysis of

the abdominal muscles on the same side. Söderbergh<sup>6</sup> (1919) described a case of herpes involving the fifth and sixth thoracic segments with slight paralysis of the external oblique on the same side. Several cases of ocular palsies following herpes ophthalmicus and of facial paralysis complicating facial herpes have also been recorded.

In the following case a typical attack of herpes zoster affecting the area of the twelfth thoracic nerve was followed twelve days after the appearance of the herpetic eruption by paralysis of the muscles in the lower part of the abdominal wall of the same side.

A man, aged 61, in December, 1921, while in Australia, had an attack of pain originating in the precordium and radiating down the inner side of the left arm. About a week later he suddenly developed right-sided hemiplegia and aphasia. Both the paresis and loss of speech, however, rapidly improved, and by the time he left Australia in February, 1922, his speech was practically normal and he complained of no weakness in either the arm or leg.

When first seen (May 19th) the only signs indicating that the patient had had hemiparesis was that the right ankle-jerk was considerably brisker than the left, and the right plantar reflex was less definitely flexor than the left. The cranial nerves, arm and knee jerks, and abdominal reflexes were all normal. He had a certain degree of chronic middle-ear deafness, bone conduction being greater than air conduction, and the tympanic membranes opaque and somewhat indrawn.

The cardiac apex beat was not felt; the area of cardiac dullness extended half an inch external to the nipple line; the first sound was normal, the second accentuated in the aortic area. Pulse 80, regular, right equal in volume to the left; palpable arteries not unduly thickened; blood pressure, systolic 130 mm. and diastolic 80 mm. Hg. X-ray examination showed a slight uniform dilatation of the aortic arch. The patient complained of no particular symptoms.

When seen again (August 5th) he had a typical left-sided herpetic eruption extending from the spine in the lumbar region across the crest of the ilium to the upper gluteal region and round to the groin, just reaching the anterior aspect of the thigh—the area corresponding to the total distribution of the twelfth thoracic nerve. The history was that eight days earlier (July 28th) the boat on which he was leaving England to return to Australia collided with another in mid-channel during the night. He received no injury, but being awakened put his overcoat over his night attire and went on deck to ascertain what had happened. The collision necessitated his return to England. Two days later he began to experience severe pain of a neuralgic character in the left loin which radiated towards the groin; the eruption appeared on the fourth day of pain. The patient was not taking arsenic.

Ten days later (August 15th) he stated that a "rupture" had developed in the affected region, and that for the last few days the side had felt somewhat numb. There was a marked "bulge" in the lateral abdominal wall, immediately above the iliac crest. The local musculature was flaccid and failed to contract either on voluntary effort or on coughing; either act resulted in the umbilicus being drawn over towards the right side. To faradism there was no response in the affected muscles. The patient now complained of pain radiating from the loin to the hypogastrium, but said that the region of the hip and groin felt numb. On testing a narrow area of cutaneous hyperaesthesia was found just above and almost parallel with the groin, while below this area and extending backwards to within two inches of the spine was a zone—now fading eruption—of anaesthesia to and pin-prick, the area of loss to pain and enclosing that of loss to light touch (anaesthesia of root type over a portion of the cutaneous area supplied by the twelfth thoracic nerve).

Other physical signs—nervous and circulatory systems—showed no change from those previously described, with the exception that the systolic blood pressure was now 120 mm. The Wassermann reaction (blood-serum) was negative.

THE International Congress of Medical Hydrology and Climatology will be held at Brussels from October 20th to 22nd.

ACCORDING to the official report recently published, during the first six months of 1922 29,264 cases of cholera occurred in the three Soviet republics of Russian Europe, 4,953 in Caucasus, 1,864 in Asiatic Russia, 2,139 on the railways, 45 on the rivers and canals, and 840 in the Red army.

THE triennial prize of 1,800 francs instituted by Mme d'Ault du Mesnil in honour of her husband for the best unpublished work on prehistoric anthropology will be awarded for the first time in 1924. Candidates are required to send three typewritten copies of their manuscript to the Secretary, École d'Anthropologie, 15, Rue de l'École de Médecine, Paris, before December 31st, 1923.

## HAY FEVER TREATED BY SINUSOIDAL CURRENT TO THE SPINE.

THE following record, which applies to a case treated last summer, may be of interest at a time when this distressing malady is prone to attack its victims.

On June 2nd, 1922, a man aged 33 came to me in a typical attack of hay fever. In previous summers he had tried all the usual remedies, and had been examined and treated by competent nose and throat specialists, but in spite of treatment the trouble was wont to run its course without abatement. He knew exactly the week in which the complaint would commence every year, and it was severe enough to keep him from business while it lasted.

An indifferent pad 4 by 6 inches was applied over the sacrum, and an active electrode, 1 inch in diameter, held over the seventh cervical spine. The sinusoidal current was gradually turned on until he took as much as he could stand without discomfort. Within three minutes there was an improvement. He commenced to take deep inspirations, the general distress lessened, the tickling in the throat and the inflammation and irritation in the eyes subsided. In an incredibly short time, certainly not more than five minutes, he pronounced himself quite normal. The current was turned off, then reapplied twice at intervals of five minutes.

There was no unpleasantness from the current, but he noticed a peculiar metallic taste in the mouth. At subsequent sittings he stated that the relief seemed to come as soon as he felt this metallic taste. We discovered later that the metallic taste could be produced by applying the active electrode to various areas in the cervical region, but the relief only came when the pad was held over the seventh cervical spine.

On the day following his first treatment he motor-cycled to business and back without goggles, and felt perfectly well till on his way home, when the symptoms returned, but in a mild degree. Similar treatment was employed, with the same beneficial result. He remained free from trouble till June 9th, and was treated on June 10th. Subsequently he received treatment on June 13th, 14th, 17th, 26th, 29th, and again on July 10th—altogether nine treatments. During this time the discomfort was much less, he slept well and went to business daily.

The result is probably produced by some action on the sympathetic system. Whether one may hope to produce a permanent cure is problematical, but the method seems worthy of extended trial.

THOMAS MARLIN, M.D.,  
Medical Officer in charge Electro-therapeutic  
Department, University College Hospital.

## TWO CASES OF ACUTE INTUSSUSCEPTION IN CHILDREN: RESECTION: RECOVERY.

ON March 7th, 1923, at the Royal Liverpool Children's Hospital I operated on a boy, aged 2 years, who had suffered from periodic attacks of pain in the umbilical region and vomiting which had become persistent. The symptoms had lasted for seventy-two hours. He showed signs of abdominal distension, had visible peristalsis, and a tumour palpable in the subumbilical region. At the operation I found an ileo-ileal intussusception which was irreducible and gangrenous. I resected 18 inches of ileum and performed a lateral ileo-ileal anastomosis. He made a complete recovery.

On March 22nd, at the same hospital, I operated on a boy, aged 10 years, who for thirty-six hours previously had suffered from periodic attacks of severe abdominal colic accompanied by vomiting which had become persistent. In this case there was a large visible tumour extending from below the umbilicus to the right iliac fossa. This intussusception was also quite irreducible and gangrenous. On attempts being made to effect a reduction, the outer coat commenced to split in several places. I removed the whole mass (which consisted of 3½ feet of ileum), infolded the ends, and as the distal infolded end was close up to the ileo-caecal valve I performed lateral ileo-colic anastomosis. This boy has also made a complete recovery.

In a paper I read before the Liverpool Medical Institution in November, 1922, I stated that 66 per cent. of such cases began as ileo-ileal intussusception. These are examples of cases that remain ileo-ileal. An interesting feature of these two cases is that neither patient passed any blood per rectum.

The importance of the periodicity of the colic in intussusception cannot be exaggerated. It is invariably present in the early stages of the attack.

Liverpool.

## Reports of Societies.

## THE MORTALITY OF COAL AND METALLIFEROUS MINERS.

At a meeting of the Section of Epidemiology and State Medicine of the Royal Society of Medicine on May 25th, the President of the Section, Dr. R. J. REECE, in the chair, Professor E. L. COLLIS read a paper entitled "An inquiry into the mortality of coal and metalliferous miners in England and Wales."

Professor Collis remarked that the mining community consisted for the most part of a compact body of men who did not change their occupation, were employed underground in dimly illuminated and artificially ventilated workings, had to put forth considerable muscular energy, and were exposed to the dust of the materials worked. Notwithstanding a general similarity of working conditions, the rates of mortality of different groups of miners differed widely. In coal mining, pneumonia, bronchitis, and accidents were responsible for rates of mortality considerably above the standard of all occupied males; diseases attributed to alcoholism and phthisis were, on the other hand, less deadly amongst coal miners than in the Lancashire field. When the separate coal fields were considered it appeared that the rate of mortality in the Lancashire field much exceeded that in any other, and was nearly double the rate of Nottinghamshire coal miners. The conclusion seemed forced that although local conditions must be held to contribute something to the differences, inquiry within the industry was needed to ascertain why they were so accentuated, particularly, perhaps, in the instance of phthisis. The age distribution of phthisis amongst coal miners brought it into line with the type affecting workers exposed to silica dust, but the unusually low absolute prevalence of the disease needed explanation. Possibly Mavrogordato's work provided the clue; he exposed one group of guinea-pigs to silica dust alone, a second to silica dust followed by coal, and that "once silica is fixed in the lung tissues, coal exerts no eliminative effect. If anything the influence is in an opposite direction, but that a prior or even simultaneous exposure to coal dust appears to set up a condition in the lung which is inimical to the fixation of silica." With regard to mortality attributable to alcoholism, the order of the fields did not correspond to their order in respect of other causes of death. The miner was a "convivial" rather than an "industrial" drinker, usually taking no alcohol until the day's work was over. There appeared to be a relation between the depth of working and the mortality from alcohol. Bearing in mind the strenuous nature of the task and the heat of the workings, it might be that the provision of drinking water underground would appreciably lessen consumption amongst coal miners. Cancer was not an exceptionally important cause of mortality amongst coal miners; cancer of the stomach and liver was the only form which showed a rate appreciably above that of the standard. Passing to the three forms of metalliferous mining, tin, lead, and ironstone mining, it was remarked that the two former stood out because not only was the general rate of mortality in each excessive, but in each the same groups of disease were prominent—phthisis, respiratory diseases, and occurred exclusively in Cornwall, not only contained quartz dust lay in a rock largely made up of quartz, so that much age distribution of phthisis was in accord with what was recognized to occur amongst men exposed to the dust of silica. Recent work by Gye, Purdy, and Kettle on the toxicity of colloidal silica lent interest to the somewhat high rates for Bright's disease. The conclusion suggested was that silica dust was gradually converted into soluble silica in the lungs and caused the well known fibrotic changes, but some escaped into the blood to be excreted by the kidneys, which were consequently similarly affected. The phthisis mortality was excessive at Greenside, where the veins of lead ore occurred in granite, but not at Keswick, where the ore

was in a limestone rock. Phthisis among haematite miners appeared statistically to resemble in a modified way fibroid phthisis and might be due to oxide of iron. Other workers, such as boiler makers, exposed to iron oxide exhibited a similar statistical type. This distribution was not found in iron carbonate miners. Alumina dust, judging from the mortality data for slate quarriers, resembled iron oxide and silica in its effect on the lungs. A point mentioned in the incidence of phthisis upon coal miners received some support from the facts of the ganister industry. Ganister is a quartzite rock found underlying coal and overlying fire clay. Best ganister, which contains over 95 per cent. of other material used for lining steel furnaces. The dust to which the workers were exposed was nearly pure silica, and which contained veins of fire clay was made into second grade refractory materials used for coke ovens. The dust had no excessive mortality from phthisis. The theory had been put forward that the influence of coal was due to some organic substance and that this substance might be washed down from the coal into the underlying fire clay, where it was retained, this accounting for the protective action of the fire clay; it might be that the substance was of a nature to prevent silica becoming colloidal. An interesting point in connexion with tuberculous silicosis, first noted amongst metalliferous miners, was its low power of infecting contacts not themselves exposed to silica dust, such as the wives and children of the miners.

The paper was discussed by the PRESIDENT, who remarked that one factor of the low mortality from phthisis of coal miners might be their comparatively high standard of diet. Dr. R. J. Ewart—whose untimely death they all deplored—had called attention to the correspondence between the rising curve of food consumption and the decline of phthisis. It would be of interest to learn whether the Lancashire field, where, from the tables shown, it seemed that the phthisis rate had varied little of recent years, differed in the matter of food consumption from the other fields. Sir KENNETH GOADBY spoke of the high sickness rate experienced by the miners. Dr. BROWNLEE fully concurred with the reader of the paper in emphasizing the chemical as opposed to the crudely physical theory of the mode of action of silica. Dr. GREENWOOD wished to associate himself with the President in calling attention to the loss epidemiological science had sustained by the death of Dr. Ewart, a most brilliant and original-minded investigator. Dr. McKAIL referred to the difficulty of interpreting accidents statistics, and Dr. McVAIL urged the importance of making fuller use of the morbidity data in process of collection under the National Health Insurance rules.

Professor COLLIS, in his reply, paid a tribute to the work of Dr. Ewart, the news of whose death had saddened a pleasant evening.

PSYCHIATRY IN CANADA.  
*The Maudsley Lecture.*

The quarterly meeting of the Medico-Psychological Association of Great Britain and Ireland was held at the rooms of the Medical Society of London on May 24th, under the presidency of Professor GEORGE M. ROBERTSON of Edinburgh. After transacting Association business—during which it was announced that the new President will be Dr. Nolan of Downpatrick Asylum—an adjournment was made to the Barnes Hall of the Royal Society of Medicine, to hear the Maudsley Lecture by Dr. C. K. Clarke, Professor of Psychiatry in the University of Toronto.

Dr. CLARKE said that in a developing country, where population was sparse and territories enormous, the cost of building and maintaining institutions for the care of the mentally ill was a heavy burden, and it was a wonder that anything of the kind was done. And among immigrants from the Old World there was an undue proportion of defectives and mentally diseased who looked to the Terra Nova for a solution of their troubles. There was no reason why a

young country should burden itself with the weaklings of other nations, and he agreed with a close scrutiny of immigrants. The activities of the National Committee for Mental Hygiene enabled the mental state of the country to be accurately assessed. The population of Canada had not progressed rapidly, because it had been bled white by the emigration of their best youth, and those who had been induced to take their place had not always even come up to the average. However, the migration north into Canada of the men of the Nordic type was doing much to redress this. Especially did child immigration need watching, as it contained an undue proportion of mental weaklings. Of 5,800 children referred for examination to the national mental hygiene psychiatrists—they were special cases—1,386 were mentally subnormal to such a degree that they could not acquire the ordinary school education. Only 25 per cent. of these were Canadian, 33 per cent. foreign-born, the remainder being children of recently arrived immigrants. Nearly all the girls were persistently immoral, and the mothers mostly unmarried; a great burden on a young country. In his country the relations between general medicine and psychiatry had been anything but intimate, and superintendents of Canadian asylums had too often been politicians who received their reward not because of their psychiatric knowledge, but on account of their influence with the Government in power. And medical education ignored psychiatry to a great extent, providing but little instruction in it to the student. He spoke highly of the good effects of occupation for patients with mental conditions. In Toronto there was established a psychiatric outdoor clinic at the General Hospital, and in a short time most of the agencies in that city were working for it. Psychology there could now be said to be coming into its own. Psychiatry had a good many sins to answer for, and it could not be said to have kept pace with the progress in medicine. In Canada there were outbursts of enthusiasm in certain circles over psycho-analysis, Freudian theories and sex problems, but it was when the war broke out that the neo-psychiatrists, the neuro-psychiatrists, the psycho-neurologists, and psychological healers of all kinds found themselves, shell-shock being their particular fad. Many of the mentally diseased could become useful hewers of wood and drawers of water, and by a careful study of industrial misfits more could be done than had been thought possible. The staffs of asylums, as a rule, were so small that research and study could not be carried on in the best way possible. The work of national mental hygiene in a large clinic had shown that the road to complete success was in the early prevention of mental disease. He congratulated his colleagues in this country on the establishment of a mental hygiene association in Great Britain; psychiatry had never before had such an opportunity to prove its worth, to show the people how to lead better and saner lives. Psychiatrists must no longer be mere custodians of people overtaken with dire calamity, but aggressive leaders who were ready to show their mettle in a great cause. In Canada more good had been done by the mental hygiene movement in five years in improving the care of the insane, the study of defectives, and educating the public to the importance of these problems than in the preceding six decades. The victims of psychosis could nearly always be detected at an early age, and it was most important to learn how to steer the subjects of it clear of the tragedy ordinarily awaiting them. Eugenics as taught by some ultra-modern teachers would prove not only difficult, but impossible. The psychiatry of the past had proved sadly disappointing, and he asked whether the ratio of actual recoveries had increased in the last fifteen years. And the relations between law and medicine in psychiatric matters in Canada were most unsatisfactory, hence the well advised psychiatrist hesitated before appearing in court to give evidence in criminal cases, chiefly because the law had not yet recognized that mental disease was, ordinarily, a distinct entity; and in murder trials the *McNaghten* decision "still works overtime." It was necessary for psychiatrists of the new school to force the issue, and already the thin end of the wedge had been inserted. Here the mental hygiene movement stepped in and taught the community what was their duty in such matters. If Maudsley's *Responsibility in Mental Disease* could be made a legal textbook, a much saner policy would be developed in dealing

with mental disease and defect; the law must be advised to meet the psychiatrist more than half-way.

Speaking of the future, Dr. Clarke maintained that the time had come to revise the methods of teaching psychiatrists. The University of Toronto had developed an optional course of five years in psychology and psychiatry. The young graduate had been ill equipped in these subjects, and the specialty had very few prizes to offer, hence it was not regarded as attractive. Asylums had too long been closed corporations, and a great awakening factor was the war. For the young psychiatrist, the best early training in the specialty was to be obtained in outdoor clinics and psychopathic hospitals, rather than in institutions, for in the latter the herding of "chronics" often interfered with the research and study of the individual. A course of options for the University of Toronto had been outlined, providing for sixty hours a year in special training extending over five years; the fifth and sixth years of the course being largely clinical. Men taking this course would not fall easy victims to the many fads extant, and the adoption of the caravan system of educating the public would prove invaluable. They also intended to follow the lead of this country in the matter of post-graduate courses. And the realm of research must be invaded as never before; there must be co-operation between School Boards and Public Health Departments; in Toronto that was already the case. With their experience in intelligence tests, he claimed they were in a position to estimate their value, as well as appreciate their inadequacy; but their apparent simplicity had stimulated the ambition of many amateurs, whose activities were very likely to be harmful. Group tests had proved to be of little value. At the present time in psychological and pedagogical circles there was a warm discussion on the supernormal child, a term which was unfortunate and unscientific. Some of the very brilliant children were found to be on the verge of a mental and physical collapse. The psychiatrist of to-morrow must be educated along different lines from those hitherto followed; even the institutional physician must be trained to grapple with the problems presented by social misfits; he must be in a position to advise regarding the mental hygiene of the community. Voluntary clinics had robbed the institutions of much of the stigma formerly associated with them, and the admissions to them were on the increase. The importance of prevention must never be forgotten. To do all that was here pointed out as desirable, it was obvious that psychiatrists must be emancipated from much of the administrative work which was now their portion.

In conclusion Dr. Clarke declared that psychiatry must show the public its just reasons for existence, its readiness to adjust itself to the new order of things, and to do something more than care for those who fell by the wayside.

Dr. SOUTAR, in proposing a vote of thanks to the lecturer for his address, said it was recognized that it contained a message of the highest importance and value, and was not only helpful, but hopeful. While Dr. Clarke's enthusiasm had driven him, it had never stamped him. Notwithstanding the distance of Canada from us, the same problems confronted both countries, and in the dominion they were faced under more favourable conditions, for while tradition might be an excellent thing in itself, it was apt to exert a "strangle hold" on progress, and the Canadians were freer than we were from preconceptions, behind which we were apt to find ourselves entrenched. The lecturer rightly took the view that psychiatry was not a subject concerning only a small section of the community; its importance was so great that there was need for those who had been trained in it to go out amongst the public and instruct them in matters which would tend to the maintenance of their sanity; that the function of the psychiatrist to-day was not only that of mind mender, but that of mind tender.

Dr. HELEN BOYLE (Brighton) seconded the proposition and spoke of the kindly hospitality she received when visiting Canada. Dr. Clarke was a member of the International Committee of Mental Hygiene, of which branches were now established not only in this country, but also in France, Belgium, and China.

The vote, having been supported in a few words by the PRESIDENT, was carried by acclamation.

## Reviews.

## SIR RONALD ROSS'S MEMOIRS.

THE volume entitled *Memoirs, with a Full Account of the Great Malaria Problem and its Solution*,<sup>1</sup> by Sir Ronald Ross, is in substance an autobiography. It is as recently become popular to write an autobiography instead of waiting for someone else to write a biography. Which is the better method of the two is open to doubt. Some men—though this is rare—have even forbidden the publication of any detailed account of their life and work altogether. Sir James Bower was a notable example; in his will he expressly stated that no biography of him should be published as a separate book. Sir Ronald Ross's memoirs are voluminous; with its index the book contains over 550 pages. It is divided, like all Gaul, into three parts: Part I, India; Part II, Malaria; Part III, The Fight for life. Appendices deal with honours and awards, and honorary membership of societies, and there is a final section giving references to writings on malaria and mosquitos, to mathematical papers by the author, to literary works by the author, and a variety of other subjects. The first part is interesting in one respect—namely, that it shows what the author's bent was; before he took seriously to medicine and science he seems to have spent most of his time studying mathematics, writing poetry, dramas in verse, and romances. Little is said about medical work as such. The second part, to which readers will turn with special interest, describes the four years of the author's life which were almost entirely devoted to investigations on malaria; it is written clearly and with much dramatic force.

It may truly be stated that the story related in these pages is fascinating, and that it will be of great value to future historians of science. We find first the young man who had dabbled with malaria in India, who had even looked for the new Laveran parasites, but had failed to find or recognize them, who comes to London on leave, sees Professor Kanthack, then pathologist at St. Bartholomew's Hospital, and is sent by him to Dr. Patrick Manson. Here the romance begins. Within a few minutes Manson has shown the inquirer Laveran's "crescents," and a few days later the other forms of the organisms, in a patient in Charing Cross Hospital. All doubts at once fled, and one day soon afterwards, when walking along Oxford Street, Manson made the pregnant remark, "Do you know, I have formed the theory that mosquitos carry malaria just as they carry filariae." The author of the memoirs replied that he had seen the same conjecture in one of Laveran's books. Impressed, however, with Manson's arguments, he determined to test the hypothesis thoroughly on his return to India. From that time the research began, the two men corresponding with each other constantly, thus helping each other with mutual suggestions and advice. From April, 1895, to February, 1899, Ross wrote 110 letters to Manson, containing almost a thousand words each. Manson could not spare the time to reply so voluminously, but nevertheless sent out much useful advice and fought for his disciple in many other ways at home. Many of these letters are given in full, and form the cream of the narrative. In them Ross is constantly giving credit to his preceptor in generous terms. "What a beautiful discovery is this! I can venture to praise it because it belongs to you, not to me" (p. 276). Again, at the end of his report on the cultivation of proteosoma (p. 288): "These observations prove the mosquito theory of malaria as expounded by Dr. Patrick Manson; and in conclusion I should add that I have constantly received the benefit of his advice during the inquiry. His brilliant induction so accurately indicated the true line of research that it has been my part merely to follow its direction." Yet again, "I was and am a hero-worshipper and he [Manson] and Laveran were my heroes. He [Manson] almost alone had helped me in the long fight, and I swore to give him all the credit I

may have acquired in return. So! Let the cup of gratitude spill over rather than be stinted." It is pleasant to record these passages, but it is equally pleasant to be able to say that it was the untiring energy, keenness, indomitable perseverance, and courage under adversity of Ross that carried the research to its final successful conclusion. Many times the want of sympathy and help from his own service would have damped the enthusiasm of even the most virile, but he kept on and did not give way. What fate could have been more cruel than, on the eve of success, to be banished to Kherwara? Yet here again his friend in London was with him, and by judicious representations at home had the sentence quashed. Then comes the final scene, the Calcutta work and fame. Yes! no doubt it is a fine story, an epic of scientific research.

Part III is entitled "The Fight for Life"; it is dull compared with the chapters just described. A tendency to polemics creeps in. The attempts of the Italians to pirate his work were deplorable, but unfortunately such attempts are not unknown in science even in Britain. It is difficult to know how to deal with such people—perhaps better to ignore them altogether than enter into direct argument with them. After all, posterity will judge, and Sir Ronald Ross may rest assured that his own countrymen know well what he has done, and in future generations his name and Manson's will hold the highest niche in scientific research and momentous discovery. Even for the present Sir Ronald has not fared so badly, as is shown by the list of honours and awards (p. 525). Though he has not amassed a fortune he has won fame and honour—and, after all, what is higher than honour, even though adorned with its laurel wreath alone?

DIAGNOSIS AND CONTROL OF TREATMENT IN  
DIABETES.

PROFESSOR HUGH MACLEAN, in his monograph entitled *Modern Methods in the Diagnosis and Treatment of Glycosuria and Diabetes*,<sup>2</sup> aims at giving to the busy general practitioner a short and concise account of the present state of our knowledge of diabetes and glycosuria, with special reference to their clinical aspects.

The most important consideration which the author dwells upon is the necessity for studying the variations in blood-sugar concentration in normal and in diabetic individuals. This undoubtedly is an aspect of diabetes which offers the greatest obstacle to the home treatment of the disease. Whether the average general practitioner has the time to carry out his own blood-sugar analyses is a question that we should not care to answer offhand, but the method Dr. Maclean describes for performing the estimation with 0.2 c.cm. of blood obtained by skin puncture simplifies the technique greatly. Accuracy is, of course, demanded, but with practice there is no reason why reliable analyses should not be obtained by anyone capable of very ordinary chemistry. It is obvious that the modern treatment of diabetes cannot be controlled by estimations of the urine sugar alone; indeed, it is almost the case nowadays that all quantitative analyses must be carried out on the blood sugar, the amount of sugar in the urine being of secondary importance.

Dr. Maclean follows Marcel Labbé in insisting that diabetes is not only a carbohydrate derangement. Defects in fat and protein metabolism may play an equally large part in the malady. He rightly emphasizes the effect of fat in the diet in producing ketonuria, and says that it is easy enough to get rid of glycosuria by giving large amounts of fat with protein instead of carbohydrate, but the resulting acidosis may be much worse than the glycosuria.

His observations on the time when maximum blood-sugar concentration occurs after ingestion of sugar reveal a remarkable difference between the normal individual and the diabetic. In the normal the maximum is reached in from thirty to sixty minutes after the ingestion of glucose; in the diabetic the rise is slower and the fall is slower, so that the maximum may not be reached before

<sup>1</sup> *Memoirs, with a Full Account of the Great Malaria Problem and its Solution*. By Colonel Sir Ronald Ross, K.C.B., F.R.S. London: J. Murray. 1923. (Med. 8vo, pp. x+547; 11 plates. 24s. net.)

<sup>2</sup> *Modern Methods in the Diagnosis and Treatment of Glycosuria and Diabetes*. By Hugh Maclean, M.D., D.Sc., M.R.C.P. London: Constable and Co., Ltd. 1922. (Demy 8vo, pp. xi + 153; 8 figures. 12s. net.)

two and a half hours, and the fall may scarcely have begun after four and a half hours.

Sugar tolerance tests described by Professor Maclean will be found to provide a rapid means of estimating the character and gravity of a given case of glycosuria, a necessary preliminary to embarking on treatment. These tests are also essential to a correct prognosis. It is interesting to find that a positive Gerhardt's reaction with ferric chloride is of more importance than the nitro-prusside reaction of Rothera, as indicative of a serious condition. Professor Maclean suggests that the minimum number of tests necessary for the treatment of grave cases of diabetes might be thus given:

1. Fehling's test for glucose.
2. Diacetic test with ferric chloride.
3. Estimation of ammonia in urine by formalin method.
4. Fridericia's estimation of  $\text{CO}_2$  in alveolar air.
5. Sellard's sodium bicarbonate test.

The chapters on dietetic treatment are clear and concise; the tables of diets and of food values will be found most helpful. On one point the author fails perhaps to be quite definite enough in his instructions. He gives precise figures for the minimal requirements of protein and total calories, but he does not offer a ready method of reckoning the proportion which fat should bear to the carbohydrate and the protein in the diet. Woodyatt's plan of allowing the amount of fat to be equivalent (in grams) to twice the carbohydrate and half the protein would have been worth mentioning.

Brief reference is made to insulin, but this remedy was not obtainable at the time the book was published. Dr. Maclean's suggestions will be found to lose little or none of their value even when the supply of insulin is freely available. In fact, any practitioner who wishes to make trial of insulin will do well to use Maclean's book as his principal guide.

#### SURGICAL GRAFTS.

THE possibilities of surgical grafts in man arouse both both speculative and scientific interest. Professor MACCLAIRE in a volume entitled *Les Greffes Chirurgicales*<sup>1</sup> has attempted to deal with the subject in an encyclopaedic manner. He has not failed to note every type of graft that has ever been essayed in the human body or in animals. It must, however, be confessed that the book as a whole gives rather the impression of a catalogue of monographs than of a critical survey of a complex and interesting subject. The detail of different techniques which have been employed in the carrying out of various implantation operations is only sketched, and little or no attempt is made to appraise the value of different methods. There is no definition of the histological or other evidence which should be required before classifying a graft as a success; this lack is particularly noticeable in relation to the implantations of various glandular organs.

The section on bone grafts is limited to a few pages. In view of the established value of implants of this character and the extensive study of the subject which has been forced upon us by the great war, very scant justice is meted out to it. Various forms of nerve grafts receive full notice, perhaps more than the doubtful success of such procedures warrants.

An extensive bibliography of the subject, covering some fifty pages, is included in the volume and forms a very useful part of the work.

#### APPLIED ANATOMY OF THE ABDOMEN.

DR. RAYMOND GRÉGOIRE has written an attractive book on the medico-surgical anatomy of the abdomen. He divides the abdomen into two arbitrary portions, a thoraco-abdominal region, and a subthoracic region, the dividing line running horizontally at the lowest level of the tenth rib. He admits the heterodoxy of his divisions, but says with some truth that the more usual partitioning into hypochondriac parts, iliac parts, and so forth, is inconvenient

clinically. He includes the pelys in his subthoracic region, in so far as the coils of small intestine and colon are concerned with it, but unfortunately has not described the rectum. Much could be said against Dr. Grégoire's empirical divisions, but there are none the less arguments in their favour, and if the author has given us a good book otherwise we need not question him too closely on these points.

The volume we have received for review is the second,<sup>2</sup> containing an account of the abdominal wall, small and large intestines, and omentum. The excellence of the book lies in the accuracy of its anatomical facts, and in this respect it is well up to the high standard of descriptive anatomy in France. Considerable care is taken with the account of the linea alba, and more than ten pages are devoted to the umbilicus alone, its development, and the reason for the various malformations and hernia which appear there. This section is well thought out. The position of the loops of small intestine is described, and reference made to Mall's experiments on the return of the intestinal coils to their normal positions after they have been disturbed at operation. Amongst the most satisfactory features of M. Grégoire's book is the description of the large intestine. He describes the ascending colon as fixed in the vast majority of cases; indeed he gives the percentage as 90. He is led, therefore, to describe the mobile right colon as abnormal, an opinion on which many would join issue with him, although the decision is admittedly difficult, not alone on questions of fact, but also on points of interpretation, of physiology as well as anatomy. The right colon, according to M. Grégoire, extends to a point on the transverse colon where the second part of the duodenum crosses behind it. The division is made on grounds of peritoneal fixation, instead of on the more common ground of development, vascular supply, and supposed colonic sphincter. We realize, therefore, that M. Grégoire, when he speaks of mobility of the right colon, is talking of a considerable portion of gut.

The description of the arterial supply of the colon is particularly good, and we are glad to see a workmanlike account of the "critical point" of Sudeck or Hartmann. M. Grégoire explains this greatly overemphasized point in surgical anatomy and gives the real reason for its importance, which is this: If the surgeon ligatures the superior haemorrhoidal artery low down he is working near the gut. If he works along the mesosigmoid near the bowel he will cut into and destroy the anastomotic loops which run parallel with the bowel and not far from it, and so greatly endanger the vitality of the bowel. If, on the other hand, he ligatures the superior haemorrhoidal artery high up he is more likely to keep well away from the gut. Should he fail to do so and disturb the vascular loops he will still get sloughing of the bowel, in spite of his first high ligation.

The illustrations are separately printed to face the pages of print and this allows them to be of unusually large size—a great comfort to the reader.

#### PSYCHO-ANALYSIS.

*Studies in Psychoanalysis*<sup>3</sup> is a translation of a book by M. CHARLES BAUDOUIN, whose name is familiar to psychopathologists in this country on account of his work on suggestion and auto-suggestion. The volume is divided into two parts; the first is concerned with theory, and the second with an account of the analytical study of twenty-seven concrete cases. The author does not strictly adhere to Freud's theories; his psychological outlook is based on his own experience and the teaching of other psychologists, such as Jung, Adler, and Flourney, as well as that of Freud. Generally speaking, throughout this book more stress is laid on the normal than on the pathological, and, in the view of its author, analysis is a method of education or re-education rather than a curative method. The outline given of an affective theory of the association of ideas is a useful contribution to normal psychology. The process of "condensation" which Freud has recognized and described in dreams is here exhibited as a general law of the imagination rather

<sup>2</sup> *Studies in Psychoanalysis.* By Charles Baudouin. Translated from the French by Eden and Cedar Paul. London: George Allen and Unwin, Ltd. 1922. (Demy 8vo, pp. 352. 12s. 6d. net.)

<sup>3</sup> *Les Greffes Chirurgicales.* By Dr. Pl. Maclaure. Paris: J. B. Baillière et Fils. 1922. (Roy. 8vo, pp. 312; 102 figures. Fr. 25.)

than as a mechanism peculiar to the thought processes in sleep. In showing that the same laws are operative in dreams and the waking state, M. Baudouin draws an interesting parallel between the conceptions formulated by Freud on the one hand and Ribot on the other, and thereby indicates some useful points of contact between psycho-analysis and conventional psychology.

As regards the practice of psycho-analysis, the author is of opinion that it is inevitable that suggestion should influence the analysis, however careful be the attempt made to exclude it. He himself advocates a combination of auto-suggestion and psycho-analysis, a method of treatment which has been commended by Dr. William Brown in this country. Dr. Eden Paul and Mr. Cedar Paul, the translators of this book, provide a useful introduction.

### NOTES ON BOOKS.

THE aim of *L'Année Médicale pratique*,<sup>6</sup> edited by Dr. CAMILLE LIAN, is to give a concise and readable account of the most important acquisitions in medicine, surgery, and obstetrics in a series of articles written by thirty contributors, with references to current literature appended. French work naturally receives the greatest attention, but foreign literature, especially that of the United States, has also been laid under contribution, though we have found barely ten references to British journals. The volume should prove a useful work of reference to those who wish to gain some acquaintance with recent French medicine.

The fifth revision of the *Pharmacopœia of the Royal Northern Group of Hospitals*<sup>7</sup> is a useful little production, which contains a number of valuable practical hints. It is divided into sections—dermatological, children's, etc.—and is provided with a good index. The *Pharmacopœia of St. Thomas's Hospital*<sup>8</sup> for 1922 is rather more elaborate, and is more than twice the size of the other; it is interleaved with blank pages for additions, and has nearly a hundred pages of notes and memoranda on the *British Pharmacopœia*. A section deals briefly, but to the point, with the treatment of cases of poisoning, and some useful comparative tables of weights and measures (metric, imperial, and apothecaries') are also given.

The second edition of Dr. HEINRICH LEHDORFF'S<sup>9</sup> short textbook of children's diseases includes an account of Pirquet's system of feeding, the doctrine of avitaminoses, and Finkelstein's classification of nutritional disorders.

In the review published last week (p. 931) of Hope's *Industrial Hygiene* the price was erroneously given as 21s.; it should have been 25s.

<sup>6</sup> *L'Année Médicale pratique*. Revue annuelle des acquisitions cliniques et thérapeutiques. Publiée sous la direction du Dr. Camille Lian. 2me année. Paris: A. Maloine et Fils. 1923. (Fcap. 8vo, pp. xviii + 484. Fr. 18.)

<sup>7</sup> *Pharmacopœia of the Royal Northern Group of Hospitals*. Fifth revision. London: Waterlow and Sons, Ltd. 1922. (Cr. 16mo, pp. 64.)

## INQUIRY ON VENEREAL DISEASE.

### REPORT OF LORD TREVETHIN'S COMMITTEE.

A YEAR ago the then Minister of Health appointed a committee to inquire into certain aspects of the problem of venereal disease with a view to an authoritative pronouncement on its medical aspects. The committee was appointed in response to a proposal by Lord Dawson of Penn, who suggested as the subject for inquiry two questions: (1) What, in the present state of knowledge, are the most efficient medical measures for preventing these diseases? and (2) How far is it ethically justifiable to apply such measures? Sir Alfred Mond approved the suggestion, and in January, 1922, Lord Dawson got together a Committee of Selection, which secured the services of a Committee of Inquiry consisting of Lord Trevethin, late Lord Chief Justice of England (chairman), Mr. T. J. Tomlin, K.C. (vice-chairman), Mr. C. J. Bond, F.R.C.S., Surgeon Commander Reginald Bond, R.N., Dr. John Brownlee, Professor Bulloch, M.D., F.R.S., Dr. D. S. Davies, Professor G. Dreyer, M.D., F.R.S., Group Captain Martin W. Flack, Director of Medical Research, R.A.F., Dr. F. E. Fremantle, M.P., Dr. Dorothy Hare, Professor H. R. Kenwood, M.B., Sir William Leishman, F.R.S., Dr. F. N. K. Menzies, Sir Frederick Mott, M.D., F.R.S., Dr. Morna Rawlins, Dr. J. H. Sequeira, Sir Bernard Spilsbury, and Mr. Kenneth Walker, F.R.C.S. On the advice of the Committee of Selection the instruction for the Committee of Inquiry was as follows: "To consider and report upon the best medical measures for preventing venereal disease in the civil community, having regard to administrative practicability, including cost."

The Committee of Inquiry has now presented its report,<sup>1</sup> which is signed by all the members of the Committee except Professor Bulloch, who resigned his membership at an early stage of the proceedings. In the first paragraph it recalls the circumstances of its appointment and its terms of reference; in the second it states that it has had twenty-eight meetings and that there have been in addition seven meetings of subcommittees; and in the third it reports that it has examined a large number of witnesses, has received written statements, and has consulted a large quantity of literature, both British and foreign. The remainder of the report is as follows:

4. It will be observed that under the terms of reference the functions of the Committee are confined to the considera-

tion of medical measures. Having regard, however, to the origin and nature of venereal diseases, the Committee feel that, in relation to the civil community, medical measures alone can never operate as an absolute preventive of disease, but their success must always depend largely upon the attitude towards them of the community and the co-operation of the community in securing their largest effect. This co-operation can only be hoped for if full knowledge of the nature of the problems to be faced becomes common property.

5. Although, therefore, we are confined by the terms of reference to the consideration of medical measures, it may not be out of place to indicate our view that there are other measures which should be employed contemporaneously with medical measures, if such last mentioned measures are to be made a success.

6. For example, the extension of knowledge as to the nature of venereal disease and its consequences is of the first importance; the community should as far as possible be made to appreciate:

(a) That promiscuous intercourse is the main cause of the prevalence of venereal disease;

(b) That there is no absolute preventive except continence, and a single exposure may result in infection;

(c) That a large number of the sufferers from venereal disease are innocent persons, especially women and children;

(d) That syphilis is a disease of great gravity, which, if not treated in its early stages, may have serious results, including affections of the circulatory system and of the nervous system, as, for example, general paralysis of the insane;

(e) That syphilis is transmissible by a mother to her children, and is a frequent cause of miscarriages, stillbirths, and deaths in early infancy, and, in children who survive, of mutilating deformities, deafness, blindness, mental disease, and other defects;

(f) That gonorrhoea is a more serious disease than is commonly believed, and, if not promptly treated, may have serious after-consequences;

(g) That gonorrhoea is a frequent cause of sterility and serious pelvic disease in women and a cause of blindness in children born of women suffering from gonorrhoea;

(h) That the presence of these diseases in the community is a menace to the maintenance and advancement of the physical and intellectual standard of the race.

7. Again, in addition to the spread of knowledge it is necessary that measures should be pursued which will diminish those conditions of life which tend to foster promiscuous intercourse and the spread of disease.

8. Dealing with medical measures strictly, they appear to fall into two categories:

(a) Medical measures for preventing disease in, or minimizing the risk of disease to, persons exposed to infection; and

(b) Medical measures for rendering non-infective and curing diseased persons.

9. With regard to head 8 (a), highly controversial questions are involved. It is established that in the laboratory, under conditions approximating to those which obtain in intercourse, disinfectants will destroy both *Spirochaeta pallida* (the germ of syphilis) and the gonococcus (the germ of gonorrhoea), and we think that a man who after exposure is thoroughly and promptly disinfected by disinfectants of appropriate nature and strength runs little risk of infection. The chance of failure, however, increases rapidly as the interval between exposure and the application of disinfectants lengthens, and the conclusion seems to be that in syphilis such disinfection as mentioned above within an hour would generally be successful, and that in the case of gonorrhoea it has a prospect of success after a longer interval.

10. It seems, however, to be agreed on all hands that it is extremely difficult for a woman to disinfect herself, and that the prospects of success from disinfection by another person, however skilful, are in the case of a woman less than in the case of a man.

11. The question of disinfection falls to be considered under two headings:

Disinfection by the person himself (hereinafter called self-disinfection), and

Disinfection at the hands of a trained person (hereinafter called skilled disinfection).

Obviously the chances in favour of success are greater in the case of skilled disinfection than in the case of self-disinfection, but we see no reason to doubt that an intelligent man, if furnished with reasonable instructions, could in favourable conditions effectively disinfect himself.

12. The foregoing conclusions as to disinfection of the individual do not, however, carry very far in determining the question whether it is advisable for the purpose of preventing venereal disease in the civil community to introduce any system or measures for affording to the general public facilities for disinfection. From the nature of the case there is very little direct evidence to assist a conclusion. The matter is largely one of speculation, influenced in each case by the views which the exponent holds generally in regard to the tendency of human nature and on questions of a moral and social character.

The important evidence available under this head is derived from the experiences which have been obtained from measures taken in the fighting forces of our and other countries. We have had placed before us a large body of evidence of this character relating both to self-disinfection and skilled disinfection.

Where satisfactory results were recorded, a great difficulty arises in determining how far those results were due to the prophylactic methods employed, or were influenced by other factors in the case—such, for example, as regulation of hours of leave of absence, control of or exclusion from dangerous places, liquor control, imposition of penalties upon men becoming infected, the provision of facilities for recreation, and the moral effect in time of war of appeal for restraint on grounds of patriotism.

Further, the prevalence of disease among women has probably varied widely in different areas and it has rarely been measured.

Where, however, satisfactory results were not recorded, discipline appears to have been defective or the control slack or the medical supervision or instruction inadequate or lacking in enthusiasm, and there is much force in the argument that in any large community a condition of control and influence affecting the life and conduct of all its members such as obtains in a military body under efficient command is essential to securing substantial results from any system of disinfection.

13. We think, however, that we are justified upon the evidence in coming to the following conclusion:

That a community where there has been efficient instruction and where there is such a condition as arises from the control and influence mentioned above substantial results may reasonably be expected to follow from prophylactic measures, but that the actual result is often less favourable than has been claimed.

14. It must be remembered that to a large extent exposure to infection takes place in conditions in which prompt disinfection is either impossible or can only be carried out at great disadvantage. Further, the application of disinfection by a man to himself after exposure demands an effort and care which the circumstances do not tend to promote. It is urged by some that any system of disinfection would tend to increase the number of exposures and to raise the disease rate. We have received no evidence of facts in support of this view, and we are inclined to think that those who hold it attach too much weight to the deterrent effect of the fear of disease. But, however this may be, upon the evidence which we have heard we conclude that the success of any general public facilities for self-disinfection is likely in the civil community to be very small. At the same time, in face of the fact that disinfection in the case of an individual user, if properly and promptly applied, will in all probability be successful, we do not think that there is any justification for putting obstacles in the way of individuals who desire to procure the necessary disinfectants. The law does not to-day prevent the sale of sheaths, which afford by mechanical means a measure of protection against venereal disease, and we think that the law should be altered so as to permit properly qualified chemists to sell *ad hoc* disinfectants, provided such disinfectants are sold in a form approved, and with instructions for use approved by some competent authority. We suggest that the Medical Research Council should be invited to undertake this task. We think, how-

ever, that the commercial advertisement of *ad hoc* disinfectants should be prohibited.

15. We may add that from a medical point of view the instruction by medical officers of venereal disease clinics of male persons attending such clinics in the preventive use of disinfectants would afford a useful means of educating the community.

16. In conclusion on this head, our view is that money spent on a general system of providing facilities for self-disinfection would certainly be less profitable than money spent either on treatment of disease or on those measures of education and improvement of social conditions to which we have referred above.

17. With regard to skilled disinfection, its chances of success must necessarily be much limited by reason of the time that will generally elapse between exposure and disinfection. The cost of any general system of skilled disinfection would be large: it is a system which is wholly inappropriate to rural districts or small towns, and we do not recommend its adoption as part of any general system.

18. With regard to head 8 (b), the treatment of disease, we have reached the following conclusions:

(i) That, speaking generally, the general medical practitioner is not yet adequately equipped with the most advanced knowledge of venereal diseases and their treatment to enable him to deal competently with all the cases that come before him, and that an improvement in medical education in regard to venereal disease is necessary; and

(ii) That the work of existing venereal disease clinics is of high value, and that the system is one which ought to be encouraged, extended, and improved.

19. With regard to clinics, one of the difficulties in practice arises from the tendency of patients to cease treatment before they have completed their course. According to the statistical evidence the amount of this defaulting is serious, but a closer investigation carried out in some treatment centres shows that by no means all the patients who have discontinued attendance before completing treatment were infectious. A large number of syphilis cases attending these centres were from the commencement of the treatment past the infectious stage. Further, in gonorrhoea cases the standard of cure suggested by the Ministry of Health is very high, and to comply with it patients must be treated long after all bacteriological evidence of the presence of gonococci has disappeared. Many cases classed as having failed to complete treatment appear to have ceased attendance with negative bacteriological tests for gonococci, and it is reasonable to suppose that a fair proportion of these were not infectious. The conclusion is that from the point of view of the public health the defaulting is not so serious as the statistics make it appear. It remains, nevertheless, an important factor in the spread of venereal disease.

20. The question of defaulting is a topic which necessarily leads to the consideration of the question of compulsory notification of venereal disease. Apart from any statistical value which may result from notification of disease, notification itself is of little assistance unless it is supported by a system of compulsory treatment, and, if necessary, detention. It is a fact that the stigma which venereal disease carries renders many sufferers reluctant to submit themselves to treatment, and sufferers will surely be led into concealment by any measures which threaten publicity. The principle of the present system is, by maintaining secrecy, to encourage sufferers to come to treatment and to continue treatment; and we think that in the present state of public opinion any system of general compulsory notification of venereal disease would tend to concealment and would prove a backward step.

21. It has been suggested by some that in order to secure unbroken attendance of patients at clinics a modified form of notification, supported by appropriate compulsory measures, should be applied to those who have once attended the clinics in order to secure their continued attendance; but in our view such a system would be more likely at the present time to deter than to encourage attendance, and it seems difficult to justify the imposition of a penalty on those who have come for treatment while leaving untouched those who make no effort to seek treatment.

22. There is another grave difficulty in the way of any form of notification reinforced by measures to compel treat-

ment, that in the present state of knowledge there is no standard of non-infectivity or cure generally accepted by the medical profession, and until this has been attained it is difficult to see how any system involving notification and compulsory measures of treatment could be applied.

23. One main objective, in our view, should be the improvement and extension of the present clinic system. There are many respects in which we think improvement might be made: The provision of more suitable accommodation, the extension of hours of sessions, including greater facilities for intermediate treatment of gonorrhoea, more adequate provision of beds for in-patient treatment, the establishment of more hostels for women attending clinics and living under social conditions which render it difficult for them to treat themselves in their homes, and the establishment of more homes or hospital beds for the treatment of children.

24. As it is agreed that it is essential for the prevention of disease that there should be widespread knowledge among the community of the nature and consequences of these diseases, it follows that the importance of giving repeated personal instruction and warning to patients attending the clinics cannot be overstated. We think that this duty must always devolve mainly on the doctors, but that it might well be supplemented by trained social workers, who for this purpose and that of giving general advice and assistance should be attached to the staff of the clinic.

25. It has been shown that if syphilis is detected in the pregnant woman, treatment during pregnancy is remarkably successful in securing healthy offspring, and gonorrhoeal infection of the infant at birth may generally be prevented if the danger is known. Increased facilities for medical supervision of women during pregnancy is desirable, and may in part be obtained by an extension of the system of antenatal clinics, and by the instruction of midwives, who would refer suspicious cases to a doctor. In this connexion we would also call attention to the importance of including instruction on venereal diseases in the general training of midwives and nurses.

26. All improvements must no doubt be limited by the funds available, but it would facilitate the provision of more adequate accommodation if a system of capital grants such as have been made in connexion with the treatment of tuberculosis were available in proper cases.

We are not in a position to make recommendations more specific than the above, and we have therefore confined ourselves to indicating some of the directions in which improvement is possible.

27. There seems to be unanimity amongst those who have given evidence before us as to the desirability of making patients who can afford to do so pay for their treatment at the clinics, but in view of the importance of encouraging attendance for treatment we do not think that any compulsory step can usefully be taken at present to secure this result.

28. We think it would be desirable if a practical scheme could be worked out that, with a view to providing treatment for patients in rural areas or districts where clinics are not easily available, a panel of medical practitioners should be constituted through whom treatment could be provided. This might be done by a development of the present system, under which the free issue of salvarsan substitutes is made to certain approved practitioners. It would have the further advantage of increasing the number of practitioners with experience of the treatment of venereal diseases.

29. Some evidence has been adduced before us in regard to Poor Law infirmaries, and we think it necessary to organize more thoroughly the methods which obtain at the present moment in Poor Law infirmaries for the treatment of venereal disease. It would, of course, be desirable from the medical point of view that those who enter Poor Law infirmaries suffering from venereal disease should be detained for treatment and cure, and indeed a recommendation to this effect was made by the Report of the Royal Commission on Venereal Diseases, but the uncertainty as to the standard of non-infectivity and cure, to which we have already referred, seems to us a difficulty in such a measure. The same observation would apply to any proposal for the detention after the expiration of their sentences of prisoners

found to be suffering from venereal disease. We doubt whether at present any more can be done than through the agency of social organizations, such as the Prisoners' Aid Society and others, to endeavour to influence the sufferers to obtain and continue proper treatment at the clinics.

30. In connexion with the spread of venereal disease we think that the close attention of the authorities concerned should be given to the following points:

- (1) The entry into this country of persons suffering from venereal disease may be a serious source of danger;
- (2) The treatment of seamen suffering from venereal disease is a matter of great importance and requires special organization; and
- (3) There are found to be a considerable number of persons suffering from venereal disease among mental defectives, and the present arrangements for their control and treatment are inadequate.

31. We do not in this Report discuss many proposals which have been made to us with reference to alterations of the existing law with regard to venereal disease—as, for example, that it should be made a statutory offence knowingly to do any act calculated to expose any other person to infection, and the enactment of measures preventing the marriage of persons suffering from venereal disease. Such topics as these do not strictly fall within the terms of reference.

32. We think that properly and promptly applied disinfection in the case of an individual man would almost certainly prove effectual, but that so far as the community at large is concerned no sufficient case has been made to justify the introduction at the public expense of a general system of facilities either for self-disinfection or skilled disinfection, and wherever there is a limited amount of public money available, we have no doubt that money spent on

(a) Treatment of disease;

(b) Continuous education of the community in regard to the nature and dangers of venereal disease and the importance of seeking prompt and skilled treatment; and

(c) The elimination of those conditions of life which tend to foster promiscuous intercourse and the spread of disease

will be money better spent than any money expended on establishing a general system for affording facilities for disinfection.

33. Notwithstanding what we have said above we are of the opinion that it may well be that in certain areas special measures for the prevention of venereal disease would be justifiable—for example, measures for dealing with defaulters, or in a large seaport town public ablution centres for disinfection in the neighbourhood of docks—and we think that local health authorities who are able to make to the Ministry of Health a special case for some such special measure should be allowed, at any rate for some limited period, by way of experiment, to carry out the measures they propose under the present system, by which a contribution towards the expense is made by the State. In this way there may ultimately be built up a body of experience of great value in determining future policy.

34. It is right to add that, so far as conclusions can be drawn from the available figures of attendances at clinics, venereal disease is once more, as it was before the war, substantially declining.

35. In this Report we have directed our attention exclusively to syphilis and gonorrhoea. Soft chancre is a purely local affection and does not exercise any sensible influence on public health.

36. The views and recommendations recorded above have been based on the existing medical knowledge as to the prevention and treatment of venereal diseases, and the Committee realize that certain modifications might be called for in the light of important new knowledge of which there are indications.

37. We desire to record our thanks to the witnesses who have furnished the Committee with evidence and to the Ministry of Health and its officials for their assistance.

We also desire to express our appreciation of the valuable service rendered to us by Mr. H. A. de Montmorency, of the Ministry of Health, who has acted as Secretary to the Committee.

## CANCER RESEARCH.

### THE BRITISH EMPIRE CANCER CAMPAIGN.

#### THE PROBLEM TO BE SOLVED.

It is unquestionable that our knowledge of the etiology of malignant disease is imperfect, so imperfect that no system of prophylaxis has as yet even reached the stage of serious discussion. It can, of course, be said with perfect truth that we do not at present possess an absolutely sure defence against any other of the great killing diseases except small-pox and enteric fever, but no rational person doubts that our defences against, for instance, tuberculosis are far stronger than a generation ago. In the case of tuberculosis, the improvements of our means of resistance have not been the product of any one technical method of research, but have been based upon a combination of clinical, experimental, and epidemiological discoveries. Before the isolation of the bacillus of tuberculosis made possible the employment of an exact experimental technique, much information respecting the general etiology of the disease, its geographical and economic concomitants, the conditions of its spreading, etc., had been accumulated. *Pari passu* with contemporary experimental work, this statistical and epidemiological knowledge has been extended and made more exact, has served both as a control of and stimulant to experimental work. The same remarks apply, with still greater force, to the case of enteric fevers, where our prophylaxis has been so brilliantly successful. In research upon cancer, the liaison between experimental and observational investigation has been far less complete. The laboratory investigations of experimentally induced or naturally occurring cancers in animals other than man have in point of accuracy and sagacity attained a standard unsurpassed in any other branch of medical research.

As was pointed out in commenting on the matter last week, it is not certain that the method of frontal attack is that most likely to lead to the desired result. In the study of the etiology and pathology of cancer it is necessary to take the widest possible view, for the clue may come from biochemistry, cytology, or immunology, or possibly the study of invisible viruses. The notes on cancer research in various places in this country published last week (p. 947 et seq.) show that the need for this is generally understood. It will have been seen also that it is now more freely recognized that laboratory workers should receive greater assistance from the clinician and the vital statistician. Up to very recent times, this lack of support was inevitable, because the materials for an epidemiological or statistical investigation of the malignant diseases were meagre and imperfect. They are still far inferior to what can be had in some other branches of medicine, but it is now certain that differences of rates of mortality from particular forms of malignant disease which characterize several European nations are too great to be explained as mere variations of accuracy of record. That point having been established, and we think it has been established, the questions at once suggest themselves whether national differences of opportunity for resort to early surgical treatment are sufficient explanations or whether etiological significance attaches to differences of national habits of life. Answers to such questions, if unequivocal, would suggest possible lines of experimental investigation. Nature, as Lord Moulton once said, always answers the question the experimenter asks her—not the one he meant to ask, but the one he did ask. Such inquiries as we have indicated cannot solve the problem—or rather problems—of cancer, but are one way in which the experimenter can be helped to ask the right question. Plainly, the realization of these ideas, which, we believe, inspired the appeal published last week (p. 947), involves not only the availability of a large sum of money but also, as we have already pointed out, that of the best scientific advice in its allocation.

The following notes will serve to complete the account we gave last week of the institutions engaged in the investigation of cancer and its treatment.

## THE RADIUM INSTITUTE, LONDON.

The Radium Institute was opened at 16, Riding House Street, W.1, in August, 1911, and is, therefore, just completing its twelfth year of work. It owes its existence to the generosity of Lord Iveagh and the late Sir Ernest Cassel, and is possibly the most lavishly equipped radium institute in existence. It possesses both an out-patient and an in-patient department, operating theatre, chemical, physical, and pathological laboratories, photographic and x-ray departments. Its medical work is concerned chiefly with the treatment of inoperable and advanced cases of malignant disease in which there is no possibility of further surgical intervention. Much pioneer work has been accomplished in radium therapy, and the annual report furnishes a yearly record of the cases treated, the technique adopted, and the results obtained. A comprehensive and effective type of cross-indexing of all patients is used, which permits of immediate reference to any case or group of cases, and information as to the possible benefit to be derived from the radium treatment of any disease is readily given to any medical practitioner. Full records of all cases are taken, supplemented when necessary by photographs and microscopical sections.

During the past twelve months much has been done in the direction of intensive radium therapy. Certain patients suffering from diseases such as lymphatic leucocythaemia, and lymphosarcomata, are being subjected to intensive radiation with quantities of radium ranging from half a gram to two grams or more. The results so far obtained have proved distinctly encouraging, though much care has to be exercised in the selection of cases subjected to this form of treatment.

The Chemico-Physical Laboratory has initiated many modifications and improvements in the preparation and handling of radium emanation, and dispatches are made daily to all parts of the United Kingdom of radium emanation apparatus for the treatment of patients suffering from cancer, who are unable, for any reason, to come to the Radium Institute. A detailed clinical report of each case so treated is, however, submitted to the medical staff of the Institute before any apparatus is supplied, in order that the appropriate dosage, screening, and exposure may be determined. Numerous researches have been carried out in the Pathological Research Laboratory, the most notable being those on the blood changes induced by prolonged radium irradiation, which were largely responsible for the formation of the x-ray and radium workers protective committee.

Further, the pathological research department has been responsible for contributions to the study of the part played by the lymphocyte in the production of cancer immunity, and of the susceptibility of the mucosa of the alimentary canal to radiations, and the production of definite modifications in the power of its resistance to bacterial and other infections.

## EDINBURGH.

A considerable amount of detail work bearing upon the cancer problem has been done in Edinburgh during past years. For example, the work of Stiles some thirty years ago upon the lymphatics of the breast and axillary lymph glands was an important contribution to our knowledge of metastatic growths and greatly influenced surgical procedure in cancer. Work on the breast has been conducted recently by Mr. John Fraser by tracing the histological changes that take place in various physiological and pathological states of this organ with a view to establishing those that approximate most nearly to malignancy. An investigation of the nature of the cancer cell, from the morphological point of view, is being carried on by Dr. J. W. Dawson, histologist to the Royal College of Physicians' Research Laboratory. This research consists essentially in a comparison of the varying character of the morbid cell as found in different parts of a cancerous growth, in which the cells have arrived at various stages of maturity. Lieut.-Colonel A. G. McKendrick, superintendent of this laboratory, has investigated the question of house infection from

a critical standpoint, and his results were published recently in the *Edinburgh Medical Journal* (March, 1923); he has reached the conclusion that the cancer statistics at present available afford no evidence of contact infection, or of infection resident in particular houses. The most systematic research recently published on cancer in Edinburgh is that carried out by Dr. James Young (*Edinburgh Medical Journal*, June, 1922, and September, 1922, and *Journal of Pathology and Bacteriology*, vol. xxv, 1922, p. 151). A special organism has been obtained by this worker from a number of carcinomatous growths of human origin, and cultivated under partial anaerobic conditions in a weakly acid medium. It was used for inoculation of mice and other animals; in two cases carcinomatous tumours developed in the mice and in twelve large lymphomatous growths. A further study of the organism, made on behalf of the Medical Research Council in the Royal College of Physicians' Laboratory, showed that it belonged to the coli-typhoid group.

THE NEW BUILDINGS OF UNIVERSITY COLLEGE  
HOSPITAL AND UNIVERSITY COLLEGE.

## VISIT OF THE KING AND QUEEN.

THE King and Queen on May 31st laid the foundation stones of the new obstetric hospital and the new nurses' home attached to University College Hospital and opened the new Anatomy Building of University College. These extensions, as already fully explained in these pages, are the result of the gift of the Rockefeller Foundation, amounting to £835,000 for the purposes of the Medical School and £370,000 for those of the College.

In preparation for the royal visit a pavilion was erected over a portion of Huntley Street at the side of the medical school, and so skilfully contrived and decorated that it was difficult to imagine that the proceedings were taking place in the middle of a public thoroughfare, and that the stones on either side ready to be lowered into position represented the outer walls of two buildings above opposite pavements. Among those present were: The French and Italian Ambassadors, the Netherlands Minister, the Counsellor of the American Embassy (Mr. Post Wheeler) and the staff of the Embassy, and Dr. G. E. MacLean, director of the American University Union in Europe. The academic robes of the large audience indicated not only London but many other universities. The staffs both of the college and the hospital were in full attendance, the passages were lined by sisters and nurses, and at the entrance a guard of honour was formed by the medical unit of the University of London Officers' Training Corps. The controller of the ceremony, who merited high praise, was Dr. A. M. H. Gray, vice-dean of the medical school.

Their Majesties, who were attended by the Minister of Health (Mr. Neville Chamberlain), were received on arrival by the Duke of Bedford (President of the Hospital), the Princess Mary Louise (Chairman of the Nursing Committee), Sir Ernest Hatch (Chairman of the General Committee), Mr. H. J. Waring (Vice-Chancellor of the University of London), Viscount Chelmsford (Chairman of the University College Committee), and the Mayor of St. Pancras. A bouquet was presented to the Queen by the little daughter of Dr. Sidney Martin, physician to the hospital. The members of the committee and the principal members of the staff of the hospital and medical school were presented by Sir Ernest Hatch, and the Vice-Chancellor presented the Principal of the University (Sir Cooper Perry), the Provost of University College (Sir Gregory Foster), the Dean of the Faculty of Medical Sciences (Professor Elliot Smith), and others.

THE DUKE OF BEDFORD extended a formal welcome to the King and Queen, and Sir Ernest Hatch read an address, in which he recited the circumstances of the Rockefeller gift, whereby, he said, the hospital and medical school were enabled to provide 120 additional beds for the purposes of the medical and surgical units, and 60 beds for the new obstetric unit, with adequate provision for laboratories, including a special laboratory for biochemistry, and to build

and equip a new nurses' home to provide accommodation incidental to these changes. University College also was placed in a position to proceed with a scheme for the erection of new buildings for anatomy and the allied sciences of histology and embryology, and for the extension of facilities for teaching physiology and pharmacology. The medical school and college were deeply sensible of the responsibility which these gifts involved; but he considered their record in the past, both in training medical men and women for the service of the State, and in advancing medical knowledge and practice through scientific method, was sufficient to inspire confidence that the trust they had undertaken would be fulfilled. The increased accommodation would impose an extra financial burden on the hospital, but the service which it would render to the sick, especially in the department of obstetrics, would become so much more effective that the fullest reliance could be placed on those who upheld the voluntary hospital system to furnish the funds annually required.

#### THE KING ON MEDICAL EDUCATION.

THE KING, after expressing his and the Queen's pleasure in the occasion, went on to say that this was no ordinary extension of a hospital or college. The vast scale of the new development would in itself render it remarkable. There could be few instances on record in which any foundation had received £1,200,000 from a single benefactor in a single gift. The magnificent generosity of the Rockefeller trustees was the more impressive since it was bestowed by citizens of the United States upon a college and hospital in London, and thus upon the people of Great Britain and the Empire. The selection of University College, London, to receive this princely endowment was not merely a high and well deserved compliment, and the creation of another tie of sympathy and friendship with the United States, but it was also the evidence and declaration of the conviction of those responsible for the gift that the progress of science and the welfare of mankind were not delimited by national or racial boundaries. It was not only the magnitude of the endowment which lent importance to the occasion. The buildings were designed for new and far-reaching developments in the traditional organization of British medical education. The college and school had been selected by the Rockefeller trustees for their benefaction from among many distinguished institutions, partly because their situation was central and yet afforded room for expansion, and partly because the close connexion of the hospital and medical school with the college provided favourable opportunities for that intercourse between medicine and other branches of learning which was the surest defence against the evils of a narrow specialism. But he understood that the trustees were chiefly influenced by the establishment at the college of what had come to be known as the "unit system" of medical teaching, and, being convinced of the value of this reform, they desired to supply the resources for carrying it out in an English university on a scale worthy of its importance both to education and research. The essence of the unit system, as explained in the memorandum on medical education in England, recently published by the Ministry of Health, lay in effecting the closest possible correspondence between the science and the art of medicine, between research and education, and between theory and practice, and, as a means to this end, in placing the chief branches of medical education each under the direction of a head who was free to devote his whole time to teaching, research, and hospital practice. No appreciation could be too great for the devotion with which eminent physicians and surgeons had given, and were giving, their services to the treatment of hospital patients and the training of students. But the advance of knowledge and the ever-rising standard of medical education had necessitated reorganization, which would give impetus to the more effective training and equipment of the British practitioner, with corresponding benefits to the health, well-being, and happiness of the people. The underlying principle was as old as Ecclesiasticus: "The wisdom of a learned man cometh by opportunity of leisure, and he that hath little business shall become wise." Its specific application to medical teaching and research was new, in this country at all events. In conclusion, his

Majesty referred to the Queen's particular interest in the maternity hospital and the obstetric unit of which it formed a part, and also in the manner in which the claims of the nursing service had been considered in allocating the endowment. He added that the privilege of accepting this munificent gift of the Rockefeller trustees imposed obligations upon the staff to fulfil the ideals which it represented and upon the public to furnish the necessary support entailed. It was inconceivable that Englishmen should decline to welcome this generous challenge from our kinsmen across the Atlantic to a friendly rivalry in medical skill, devotion, and beneficence. He cordially wished god-speed to this great enterprise.

#### The New Obstetric Hospital and Nurses' Home.

Dr. G. F. BLACKER (dean of the medical school) requested the King to lay the foundation stone of the obstetric hospital, and Dr. Herbert Spencer (senior obstetric physician) handed to the King certain articles to be placed within the stone, including the programme of the day, a newspaper and coins, and the current edition of the Hospital Report, and Mr. George Hornblower (architect of the hospital) offered the trowel. The stone was lowered into place, and the King, after carefully using the maul and the level, declared it to be well and truly laid. A similar ceremony for the new building of the nurses' home was then performed by the Queen, Mr. Paul Waterhouse, the architect, offering to the Queen the trowel, which had a detachable handle which could be used as a parasol-holder, and was carved on one side after the coast-line of this country, and on the other after the coast-line of the United States. The inscription on both stones testified to the generosity of the Rockefeller Foundation.

#### The New Anatomy Building.

Mr. H. J. WARING (Vice-Chancellor of the University) then requested the King to open the new Anatomy Building, which he did by pressing a button. Mr. Waring also read a letter from Lord Rosebery (the Chancellor), who wrote that the gift of the Rockefeller trustees was a magnificent donation which, made soon after the conclusion of the great war, could not but emphasize the friendship which existed between ourselves and the United States. "No more substantial or welcome mark of this feeling could have been afforded, which we appreciate all the more in these days of difficulty. The object of the gift is the promotion of medical education and research, and our university is naturally gratified that it should have been chosen for the benefits of this splendid gift. . . . The choice of University College and of University College Hospital Medical School as the direct beneficiaries of the gift is in full accord with the scientific tradition that has obtained both at the college and at the medical school since their foundation in 1827. We shall long cherish the memory of this supreme occasion."

At the conclusion of the main ceremony a procession was formed to the main entrance of the medical school, and in the school library their Majesties recorded their names in the visitors' book. Then they proceeded across Gower Street, under a pavilion borne by students, to the Anatomy Building, the museum of which was first visited, and here certain further presentations were made, including the architect of the building (Professor F. M. Simpson), the contractor (Sir James Carmichael), the vice-dean of the Faculty of Medical Sciences (Professor J. P. Hill), the Jodrell Professor of Physiology (Professor E. H. Starling), and the dean of the Faculty of Science (Professor D. M. S. Watson). After taking tea their Majesties inspected the building, entering the large lecture theatre, the room on the first floor which is to be devoted to the history of medicine under the direction of Dr. Singer, and the periodicals room and library; descending to the basement, they visited the dissecting room, the prosectorium, and the x-ray rooms, where a demonstration was given. Some anatomical preparations by Professor Elliot Smith also engaged their Majesties' attention. The royal visit lasted altogether nearly two hours, and, on leaving, the King and Queen again expressed their delight in the occasion, and referred particularly to the success of the planning and equipment of the Anatomy Building.

# British Medical Journal.

SATURDAY, JUNE 9TH, 1923.

## CANADA AND THE ASSOCIATION.

UNTIL the establishment of the Irish Free State, Canada was not merely the largest both in area and population of the British self-governing Dominions, but geographically the nearest to our own shores. Discovered by John Cabot, sailing from Bristol in 1497, the territory of Canada became a possession of Great Britain 160 years ago, and for more than half a century her various provinces have been united under the title of the Dominion of Canada. This vast country, the eldest of the daughter nations, with an area not much less than that of Europe and a population of nearly nine millions, is connected with us by innumerable ties, and these were strengthened by the war. This is particularly true of Medicine. As is well said in an editorial article in the current issue of the *Canadian Medical Association Journal*, "One of the results of the great war seems to have been a quickening of the more or less latent regard which the Mother Country, and each of the self-governing Dominions, have always entertained for each other in respect of their medical professions. . . . The great war did more perhaps than has been recognized yet to establish between the medical services of the mother land and the outlying Dominions that foundation of acquaintanceship and mutual respect upon which, if once it be laid, there tends to rise automatically a comely superstructure of active fraternity and goodwill. So that we are not surprised to find that within the last year or two the parent society, the British Medical Association, has arranged a greatly extended and more close relationship with the profession in New Zealand, Australia, and South Africa, as well as in the smaller British communities dotted all about the Seven Seas."

The same issue of our contemporary contains a letter from Dr. Alfred Cox, Medical Secretary of the British Medical Association. He expresses the regret felt by the parent body at the gradual loosening of the ties between our brethren in Canada and ourselves, and asks the Canadian Medical Association whether steps cannot be taken which would provide in some way for a continuing bond between us. In this letter Dr. Cox has managed to convey the feeling that underlies the two short paragraphs numbered 76 and 77 in the last Annual Report of Council, which refer to the possibility of devising such a link between the two Associations as, while strong in sentiment and mutual aid, would in no way fetter the autonomy of either body (SUPPLEMENT, April 28th, p. 132).

The desire for a renewal of friendly co-operation between the medical professions of Canada and the mother country is felt keenly by all who remember the Annual Meetings of the parent body held at Montreal in 1897 and at Toronto in 1906—the only occasions in ninety years on which the British Medical Association has met outside the British Isles. The war brought many of our Canadian colleagues and ourselves into very close touch, and we shall always remember their share in the work of the medical services of the Empire. In its efforts to maintain contact with the Dominion Branches the parent Association has never hampered the way in which they choose to conduct their own affairs; freedom in unity has been the working ideal. Bearing all this in

mind we ask, with Dr. Cox, Is it really inevitable that the bond between the Canadian Medical Association and ourselves shall become less close and finally disappear? We profoundly hope not, and we agree with him that, if our desire is reciprocated in Canada, the most practical way of getting something done is to open up communications between representatives of both sides, meeting informally. The qualities needed in representatives would be a willing mind, an accommodating disposition, and a sufficient knowledge of the constitution and internal working of the Association represented.

The attitude of Canadian practitioners may perhaps be gauged by the replies received to a set of questions lately sent out to the profession at large by the Associate Secretary of the Canadian Medical Association. One of the questions asked was whether an invitation should be sent to the British Medical Association to meet again in Canada, perhaps in 1926. Of 1,328 replies received, 28 said no, 1,227 said yes, and 73 left this particular point unanswered. It is expected that the question will come up at the annual meeting of the Canadian Association to be held next week in Montreal.

Rather than comment further upon a matter in which we feel strongly, we prefer to quote again from the sympathetic editorial article in the *Canadian Medical Association Journal*. The reasons for some form of affiliation between the Canadian and British Medical Associations, it says, "lie upon the surface, and like the bonds of Empire may be found to be all the stronger because sentimental. No close and binding arrangement involving much additional financial responsibility or any impairment of local autonomy, could be desired by either body. But an official connexion with the British Association and through it with the professions of the other Dominions has in it a great appeal to the imagination."

## THE UNITS OF A WHOLE.

THE KING, when he laid the foundation stones of the new obstetric building and the new nurses' home of University College Hospital, and opened the new Anatomical Institute of University College, performed, as head of the State, acts which had two aspects. In the one aspect his presence, accompanied by the Queen, was the national summing-up of all the expressions of gratitude the Rockefeller Foundation has received since its magnificent gift to University College, and the Medical School and Hospital associated with it, for the advancement of medical education. In the other aspect it was evidence of the King's interest in hospitals, and his recognition of the fact that one of the functions of a large hospital is to train medical students and to maintain a high standard of medical education, which, in these days, can only be attained by bringing clinical work into close and habitual relation with the departments of biological research upon which medicine relies. University College, the Medical School, and the Hospital, are constitutionally separated in a rather bewildering manner, but looking at them from the outside it may be seen that a very complete school of the preliminary, the intermediate, and the advanced subjects has been brought together, if not within a ring fence, at least in physical contiguity, and that a degree of co-operation is being achieved which will ensure to student and teacher the skilled assistance needed at the many points where the various subjects come into contact. There are already at work in the Medical School and the Hospital two units—medicine and

surgery—and the addition to the hospital of a large obstetric department will make it possible to complete the third element.

The London clinical units were founded in 1919 and 1920, with money provided by the University Grants Committee, on lines suggested by Sir William Osler and others, for two purposes—partly to encourage discovery in medicine, and partly to quicken the apprehension of students by contact with the "growing points" of the science. All universities except London had professors of medicine already, but it is matter of common knowledge that in the past, though they were excellent physicians of the usual hospital stamp, they were not wantonly prolific in discovery.

The Grants Committee prescribed that the directors of the units should be professors in the University, and the University made an innovation by insisting that they should surrender private practice. The same rule has been adopted in one or two other universities here and in one or two in America. It obtains nowhere else. The monastic life has certain obvious advantages, but also certain drawbacks, and it is a good thing that other experiments are being tried. Many men will refuse to make the sacrifice, but there is a race growing up in the units themselves to whom the academic life will make a greater appeal. We cannot yet tell which will be the more satisfactory plan. The question will provide its own answer in time.

These foundations, however, made a considerable stir, and led to a considerable amount of reorganization and improvement even where no formal change was made in the condition of the professoriate. There has been a general tendency, first, to study the old methods of medicine more closely as well as the newer, and secondly to bring the anatomist and physiologist into more active co-operation with the clinical education. The London units have turned out a considerable body of original work in these three years; they have formed centres round which collect all the young graduates, whether home-bred or foreign, who wish to carry on their studies; they have influenced the general body of students by classes and demonstrations; and their clerkships and dresserships have been sought by the best, since they both demand and give facilities for a somewhat higher and more elaborate standard of work. They are thus no doubt breeding the future staff of the hospitals, and are at the same time affording a good training ground for clinical teachers.

There is probably no subject on which men so readily drop into catch phrases as that of education. A year or two ago "to bring physiology into the wards" was the accepted cry, and now the demand is "to teach the beginnings of disease." Both are excellent aims, but whereas the former requires young teachers who have but lately quitted the laboratory, the latter requires ripe experience. It is some comfort to reflect that both have been the object of teachers of medicine ever since medicine has been taught. It may be confidently predicted that they will not be neglected in the future.

### THE VIENNA REPORT ON RICKETS.

*Studies of Rickets in Vienna, 1919-1922*, just published, and of which an abstract appears elsewhere in this issue (p. 987), is a document of more than ordinary interest and importance. It is essentially a clinical study; it touches important points of scientific matters which have recently been the subject of

laboratory experiments; it deals in an authoritative way with the prevention, early diagnosis, and treatment of rickets. It is a report that especially concerns the practitioner and those engaged in child welfare work, and it is worth while considering some of its main conclusions.

The Vienna investigation of rickets may be described as a hospital study of early rickets. A large group of young infants were observed for many months, and under very exactly controlled conditions of diet and environment; these children were free from rickets on admission; in those who developed the disease there was an unusually exact knowledge of the conditions of food and hygiene. The broad results of this study of rickets in hospital wards were that the disease, on the strict test of the radiograph, never developed from May to December; that in the intervening winter months (January to April) seventeen cases of rickets developed in a group of children fed on sweetened cow's milk without cod-liver oil; that in twelve of these cases the radiographic diagnosis was made at or under seven months of age; that in winter a large group of infants fed on dried milk and given cod-liver oil remained free from rickets. These results confirm previous investigations, both clinical and experimental, which have indicated the pre-eminent value of sunshine and of cod-liver oil in the prevention of rickets, even in children whose defective diet predisposed them to the disease. A further series of observations of breast-fed babies, under less satisfactory hygienic conditions, showed that rickets, clinically diagnosed, was common in winter and not rare in summer; and that here cod-liver oil, while of great value, was not a complete prophylactic.

The controversial question of the vitamin theory of rickets is left by the Vienna investigation pretty much as it was. The cow's milk used, both fresh dairy milk and dried milk, in the controlled diets, was poor in the fat-soluble growth vitamin A, as were also the human milks tested. Not much advance is likely to be made until a more satisfactory test of vitamin content than the present biological one is discovered. Meantime the significant fact remains that cod-liver oil is, of all substances, the richest in its content of fat-soluble vitamin A, and that at the same time it is, apart from light, easily the most potent agent for the prevention and cure of rickets.

Of the two agents—light and some unknown element in milk—light would appear the more important prophylactic, and Francis Glisson's old association of rickets with moist and foggy climates now appears as a shrewd guess that hit the very truth. It is interesting to reflect that the winter incidence of rickets in the northern hemisphere, which has now been established both in America and Continental Europe, is less marked in Great Britain and Ireland. That may be ascribed by critics this year to the absence of summer here; but, on the other hand, our milder winter season permits much more life and movement out of doors than in Continental climates. We may also remember Charles II's praise of the English climate as the finest in the world, allowing as it did a man to be in the open air "more hours of the day and more days of the year" than in any other country. If it is true that light is the best protection against rickets, we have certainly, in the mildness of our winter season, a better opportunity of taking full advantage of it than in the rigorous winter of Vienna and New York. Without a sufficient exposure to radiant light it is probable that even good human and cow's milk have a narrow margin of safety, and may permit that disturbance of the delicate machinery of

calcium metabolism which is the essence of rickets. The important practical lesson of this report is that there are two sure weapons in the prophylaxis of rickets—light and cod-liver oil; but that the surer of them is light.

The report contains a good deal about the familiar clinical stigmata of rickets, craniotabes, cranial bossing, the rickety rosary, and enlarged epiphyses at wrists and ankles. As these clinical signs were nearly always verified by radiographs, and sometimes by histological evidence (the really infallible test of bony rickets), and as there was a great opportunity of observing the earliest stages of developing rickets, these observations are of the greatest value and interest to the practitioner. Dr. Dalzell and Dr. Mackay imply that craniotabes was the earliest sign of rickets in Vienna; and it should be remembered that the majority of their cases, on the radiographic standard, occurred at or under the age of seven months. But craniotabes—a softening of the outer ends of the occipito-parietal sutures—was often observed between three and five months. Not only was it an early sign, but its persistence indicated that the disease was progressing. On the other hand, in older infants—nine months and onwards—it might be absent and yet definite rickets might be present elsewhere. The rickety rosary was a less early sign, and seldom seen before the age of five months; and here there was a possibility of confusion with slight normal beading, and with more definite enlargement produced by scurvy; in a series of histological investigations, however, the great majority of the cases of marked rickets were rachitic. Cranial bossing was of small value in diagnosis. Enlargement of the wrists and ankles seldom occurred before the end of the first year, and radiographic diagnosis could be made long before clinical enlargement could be verified. If these characters of rickets in Vienna are true also for this country, we have in them useful guidance for the clinical diagnosis of early rickets. Under six months of age the sign would be craniotabes with or without cranial bossing; after six months there would be added a marked enlargement of the costo-chondral junctions. The period of infancy at which rickets develops is of importance, for at different ages the criteria of diagnosis will change, and rickets will manifest itself in those parts of the bony skeleton which at the time are growing most rapidly. The observations in the report on craniotabes and the rickety rosary are important, and deserve the attention of the profession in this country. They indicate that rickets may frequently affect infants at an earlier period than has hitherto been recognized; and that in this early stage it may be diagnosed clinically in the skull and thorax with reasonable probability, before radiographic evidence can be obtained of rickets in the bones of the limbs.

#### THE GENERAL MEDICAL COUNCIL.

THE first act of the General Medical Council when it assembled last week was, by acclamation, to re-elect Sir Donald MacAlister, K.C.B., Principal and Vice-Chancellor of the University of Glasgow, to be for the fifth term President of the Council. It was a foregone conclusion, for the ability and impartiality with which he has discharged the duties of the high office are known to all. Under his control the work is so thoroughly prepared for the Council by the Executive and other committees that the sessions are shorter than they were, so that we hear no more of what at one time threatened to be a serious financial crisis. The session of the Council lasted five days,

and was mainly occupied with the consideration of disciplinary cases, but it dealt also with the important matter of certain forms of advertising and canvassing by medical men, raised by Dr. Bolam at the November session. The Executive Committee reported that it had considered the matter in consultation with the Council's legal advisers, and submitted a revised form of paragraph 5 of the existing warning notices. Dr. Bolam introduced what we believe to be a new term when he spoke of the practices to which objection was taken as "prepared publicity." Sir Jenner Verrall said that it was important that the Council should be able to deal with slight infringements of this nature, which called for warning rather than penalty, and both agreed that the revised notice met the case. Professor Harvey Littlejohn observed that it would be an advantage if the attention of final year students could be called by teachers to the Council's warning notices; he had himself taken care that students in his charge were fully acquainted with them. The President said that many other teachers already made a practice of applying for copies, and that every practitioner received a copy of the warning notices along with his certificate. Another warning notice, with regard to dangerous drugs, was accepted without discussion; both notices will be found in full in the report of the proceedings of the Council published in the SUPPLEMENT this week. By putting down a motion, which he eventually withdrew, Mr. Turner elicited some interesting information with regard to the exact meaning to be attached to the phrase sometimes used by Government departments that "regulations have been approved by the General Medical Council"; the phrase was used recently in connexion with the Dangerous Drugs Regulations, which were eventually withdrawn and modified. The General Medical Council is constitutionally a committee of the Privy Council, and it is rather surprising to learn that it has not got the right to call for advance copies of any proposed regulations or legislation affecting the medical profession. Apparently the form in which a Government department may request the advice of the Council may greatly restrict the power of the Council to give an effective opinion. Moreover, the Government department appears to claim the right to ignore advice tendered by the Council, its Executive Committee, or its President, as the case may be, and the regulations as finally issued may neither correspond to the draft submitted to the Council nor embody emendations suggested by it, although eventually the Government department concerned may claim that it has the approval of the General Medical Council. But, as the President observed, a Government department in a difficulty will use any argument. The discussion disclosed a defect in constitutional proceedings which ought to be remedied, but perhaps legislation by regulation has now fallen so much out of favour that this particular abuse of administrative power may not for the present recur. As has been said, the greater part of the time of the Council was occupied in the consideration of disciplinary cases, which, together with the decisions of the Council and the observations of its President on each, are or will be reported in the SUPPLEMENT. It will be observed that four of the eleven cases heard had to do with laxity or impropriety in certification, a duty which members of the profession cannot be too punctilious in performing.

#### THE WALLER MEMORIAL.

THE proposal to establish a permanent memorial to the Wallers will be welcomed by everyone who knew them. Augustus Waller was not only a physiologist of uncommon originality, among the first to blaze a path into several unexplored territories, but was also a most fascinating personality, a brilliant if erratic talker, with an enviable

faculty of making friends. His wife, who with complete self-forgetfulness ably helped in all his physiological work, possessed a gentle spirit which was the perfect complement of her husband's fiery temperament. She, too, had the faculty of making friends, and knew how to grapple them with hoops of steel. Their house in St. John's Wood, where was a large room with a table which contrived a double debt to pay, being convertible by the letting down of a counterpoised top from billiards to physiology, was always open to all physiologists, young and old, and the man or woman who went there was sure to return. Professor Sir Edward Sharpey Schafer was in the chair at a meeting held at the Royal Society of Medicine on June 1st, where the plans of the promoters of the memorial were made public. It was appropriate that he should preside, for he had watched the whole of Waller's career from a time before he began to teach physiology at the London School of Medicine for Women, and had known Mrs. Waller while she was yet a student there. Waller's great characteristic, he said, was a love of truth and hatred of humbug; his physiological work was extraordinarily original and always accurate, even when working over new ground. Mrs. Waller, a sympathetic friend and her husband's perfect helpmeet, having the keenest interest in his work, yet took her domestic place as wife and mother. It was impossible to think of one without the other, and in death they were not divided. Mrs. Waller, who had become seriously ill before her husband's death, survived him for only a few months. Professor Starling proposed a resolution to the effect that, in view of the life-long devotion to scientific research of Dr. and Mrs. Waller, and their connexion with the London School of Medicine for Women, the memorial should take the form of a research fund to be administered by the council of the school. He enumerated as the chief achievements of Waller his work on the electromotive changes of the heart, on the "characteristic" of muscle and nerve, and on the electromotive phenomena associated with psychical processes, as fundamental advances in physiology, which broke fresh ground and opened up new lines of investigation. His work would endure. It might be asked why a man who had contributed to the eternal fabric of science needed any other memorial. The answer was that those who remained desired some tangible memorial and reminder of their association with the Wallers in their great work. The motion was seconded by Miss Aldrich-Blake, Dean of the London School of Medicine for Women, who referred to Mrs. Waller's continuous interest in it, and by Miss Edgell, who had worked with Waller in the Physiological Laboratory of the University of London; she spoke particularly of Mrs. Waller's interest in education and her long period of service on the council of Bedford College. The resolution was carried unanimously. Professor W. C. Cullis and Professor J. S. Macdonald were appointed honorary secretaries, and Dr. J. A. Mellanby honorary treasurer. To him subscriptions may be sent at the Sherrington School of Physiology, St. Thomas's Hospital, S.E.1.

#### OCTOCENTENARY OF ST. BARTHOLOMEW'S HOSPITAL.

THE eight hundredth anniversary celebrations of the foundation of St. Bartholomew's Hospital began on Tuesday morning with a service at the Priory Church of St. Bartholomew the Great. The lesson was from Ecclesiasticus xlv, 1-15, and special thanksgivings were offered for Rahere, founder of the church and hospital, and for all who followed him in ministering to their fellow men. A special collect was adapted from the service in commemoration of founders and benefactors in the Latin Book of Common Prayer, issued in the year 1560, for use at

Oxford and Cambridge, and at Eton and Winchester. This was followed by an eloquent address by the Bishop of Chester, one of the sons of Sir James Paget. The next ceremony was held at noon in the hospital quadrangle in the presence of a large gathering. After a fanfare of trumpets, Canons Regular of St. Augustine, in the vestments of their Order, walked in solemn procession round the square singing the Latin hymn in honour of their patron saint; halted before the fountain to commemorate, with praise to God, the founding of St. Bartholomew's Priory by Canons Regular of St. Augustine near that spot in 1123; and retired chanting the 67th Psalm. A herald advanced and read, in ringing tones so that all could hear, a proclamation, declaring by command of the President, the Lord Mayor, and the Treasurer and Governors, that the ceremonies to mark so unique and auspicious an occasion should forthwith begin. Three episodes in the history of the hospital were then represented with excellent effect under the direction of Mr. Robert Atkins, to the sound of fanfares and other music by the band of the Welsh Guards. The first episode showed the return of Rahere from his pilgrimage to Rome, and his meeting with Richard, Bishop of London; the second showed the presentation by Henry VIII in 1544 of a Charter to the Lord Mayor and Commonalty of the City of London restoring to the hospital the lands alienated on the dissolution of the monasteries in 1537; the third illustrated the work of the hospital to-day and its war services. The figure of Rahere was admirably represented by Mr. Harvey, and Mr. Arthur Bourchier's Henry VIII was appropriately regal and haughty. The pageant was performed under a leaden sky, but no rain fell, and the sun smiled upon the later proceedings. After attending a luncheon party at the Mansion House the Prince of Wales, President of the hospital, visited the Guildhall to receive addresses from delegates representing the Archbishop of Canterbury and Bishops of the Church of England, the Universities of Great Britain and Ireland, the Universities of the Dominions and India, Universities of the United States, and the Learned Societies of Great Britain and Ireland and of America. The senior alderman welcomed the delegates on behalf of the Lord Mayor, whose recent injury prevented his attendance. Lord Stanmore, treasurer of the Hospital, presented to His Royal Highness a commemorative gold medal, and the Prince of Wales presented commemorative medals to the treasurer, to the chairman of the Octocentenary Grand Committee, Sir John Baddeley, and to Lord Bearsted to give to the Lord Mayor. The delegates—some sixty-five in number—then in turn mounted the dais and handed their congratulatory addresses to His Royal Highness. Next, brief messages were spoken by the Bishop of Worcester on behalf of the Church, by Sir Archibald Garrod on behalf of the home universities, by Sir Walter Fletcher on behalf of the learned societies, and by two other delegates, one (Dr. Alexander Primrose, of Toronto) chosen to represent the universities of the Dominions and India, and one (Dr. William Henry Welch, of the Rockefeller Institute and the Johns Hopkins University) representing the universities of the United States. The picturesque ceremony ended with an address of acknowledgement and welcome read by the Prince of Wales. The celebrations are being continued throughout this week.

#### MILK PROSECUTIONS.

LAST August we had occasion (vol. ii, p. 325) to comment adversely on the advice given by the Ministry of Health in Circular 325 with regard to the conditions under which prosecutions should be instituted in cases where adulterated milk samples had been obtained by local authorities under the Sale of Food and Drugs Acts. The circular was

understood by local authorities, in most cases county and borough councils, to direct that they should not prosecute a milk vendor found to be selling adulterated milk unless after examination of several samples he was found habitually to be adulterating his milk. From the point of view of the local authority this tended to render milk sampling under the Acts practically useless, and many local authorities have felt that if this were the intention of the Acts money spent on milk sampling would be wasted. Fortunately the present Minister of Health, who is a past Lord Mayor of the city of Birmingham, has had the good sense, no doubt as a result of his municipal experience, to see the hopeless position in which the local authority would have been placed had Circular 325 been acted upon. He has accordingly withdrawn Circular 325, and gives the following decision in Circular 399, dated May 16th, 1923: "From information which he has had before him it is evident that this Circular (325) has been widely misunderstood and to some extent misrepresented, with the result that it has not produced the effect which was intended. In the circumstances he has decided to withdraw the Circular, feeling that he can rely on the responsible local authorities to administer the Sale of Food and Drugs Acts with due fairness and consideration to the various interests concerned." This decision will be welcomed by all public health administrators; it should be regarded as evidence that in this matter the professional advisers of the Ministry have been consulted, and that their advice has been acted upon. Mr. Neville Chamberlain is to be congratulated upon the course he has followed.

#### SPIROCHAETES AND BLACKWATER FEVER.

LETTERS have been received from Dr. J. Gordon Thomson, Director of Protozoology, London School of Tropical Medicine, who is at present in Rhodesia investigating blackwater fever, in which he mentions that he has examined for spirochaetes the blood of six patients suffering from this disease. He adopted the method of triple centrifugalization of the blood used by Blanchard and Lefrou (1922), but so far has been unable to confirm their results or to demonstrate spirochaetes of any description. Examination of specimens with dark ground illumination, however, showed numerous fine threads or filaments, varying in length and thickness and possibly derived from the blood platelets, which simulated spirochaetes very closely indeed. Dr. Thomson has also attempted to make cultures—chiefly on Noguchi's medium—of any spirochaete which might be present, but his results have been negative. Inoculation of guinea-pigs has also failed to produce evidence of the existence of a spirochaete. Again, he makes mention of the fact that relapsing fever is fairly common among the native population, and that acute infective jaundice undoubtedly occurs, so it is quite possible that either of these diseases might be superimposed on an attack of malaria or blackwater fever. So far as he has gone Dr. Thomson is inclined to the view that blackwater fever is a manifestation of chronic malaria, and is due to some obscure haemolytic phenomenon caused by repeated attacks of malignant tertian malaria. In the parts of Rhodesia where malaria does not exist there is no blackwater fever, and, conversely, in the areas where malaria is prevalent blackwater fever is common.

#### WATER POISONING.

DR. J. S. HALDANE, F.R.S., who is director of the Mining Research Laboratory at Birmingham, has communicated to the Royal Society a paper by Mr. K. N. Moss on some observations made in that laboratory on the effects of high temperature and muscular exertion

upon colliers. They relate to the consumption of food and of oxygen, and to certain results of the profuse sweating induced. The mean daily energy value of the food consumed by the colliers investigated was 4,712 calories. Men working in hot mines consumed more food, and a larger proportion of salted food, than men working in cool mines. The oxygen consumption per minute in various kinds of work at the face by an efficient collier varied from about 1,300 c.cm. to 2,000 c.cm. In persons not acclimatized to heat the maximum amount of sweat lost per hour was about 1.4 lb., whereas in a collier accustomed to work in a hot place the maximum loss was 5½ lb. The actual loss per shift was obtained for a number of colliers. The sweat was found to contain about 0.2 per cent. of chloride, and the loss of chloride during a shift was very considerable. Men working in hot mines, at iron furnaces under certain conditions, and as stokers in ships, especially in the tropics, suffer greatly from a sensation of thirst, which appears to be in part due to a physical drying of the mucous membranes of the mouth and throat. They are therefore induced to take large quantities of water—so large as to be in excess of the real requirements of the body. They are subject to attacks of cramp, which they speak of as miners' cramp or stokers' cramp. The cramp is referred by the author and Dr. Haldane to a form of water poisoning of the muscles brought about by the combination of great loss of chloride by sweating, excessive drinking of water, and temporary paralysis of renal excretion.

#### HEALTH INSURANCE PROBLEMS IN AMERICA.

SINCE health insurance became a matter of State concern in Denmark, Germany, and Britain it has received much attention on the other side of the Atlantic, and in an essay lately issued<sup>1</sup> an American writer, Mr. Gerald Morgan, has discussed various aspects of the subject. His object is to arrive at a conclusion, or at least a judgement, as to what is best for his own country, and as an aid to this he passes in brief review what he understands to be the position in the European countries mentioned. As regards this country, however, his information is so incomplete and out of date and one-sided as to make comment needless. To Americans the essay will not give a correct representation of the position. While there is plenty of room for wide difference of opinion as to the merits and demerits of the British health insurance system, the writer, through lack of knowledge, does not give material on which his readers can form an unbiased judgement of their own. The later chapters of the book, however, are of real interest to students of health insurance. The author concludes that cash benefits should be entirely separated from medical benefits, because the contributions required for the former are actuarially calculable, while the cost of adequate medical benefit is bound to increase with advancing knowledge, so that even people above the wage-earning class cannot always be expected to be able to afford it. Cash relief, therefore, he holds, should be provided by insurance, while medical benefit should be State-aided for all concerned. He discusses two bills which have been before the legislature of the State of New York, one a Health Insurance Bill of 1920, and the other a Health Centre Bill of 1921; neither of them has yet become law. The second scheme in various respects brings to mind the interim report to Dr. Addison in 1920 by the Consultative Council on Medical and Allied Services. It is striking in respect that, as compared with the health insurance system in this country, it begins just at the opposite end, with hospitals, sanatoriums, dispensaries, laboratories, public health, nursing, periodical medical examination independently of illness, and the provision of

<sup>1</sup> *Public Relief of Sickness.* By Gerald Morgan. London: George Allen and Unwin, Ltd. 1923. (Crown 8vo, pp. 195. 7s. 6d. net.)

consultants and specialists. That is where it begins, and that is where it ends; it never gets down to the general practitioner, who as such seems outside of it, payment for his services being left to private arrangement between him and his patient, though the practitioner may in addition find a part-time place in the local health centre. Such centres would be established in suitable localities, and the cost would be borne by the State to the extent of about 25 to 35 per cent., and partly by the municipal authorities, while patients would contribute according to their means. Even in the United States, however, economy in public expenditure seems to have become an acute question, and, as already pointed out, the New York bill has not so far become an Act. The author considers various questions which would probably arise were the bill passed; they include the establishment of centres, the adequacy of treatment, and the relation of a centre to the patient, the doctor, and the taxpayer. The essay, in spite of its defects, is well worth perusal by those interested in the problems of medical sociology, which occupy so much attention in the present day.

#### ALMONER'S WORK.

THE annual report of the Samaritan Fund and the Lady Almoner's Department of St. Thomas's Hospital for 1922 contains an interesting account of the social service work of the hospital. The social service office was opened first in the casualty department, but in 1909 its work was extended to the wards with the assistance of trained workers supplied by the trustees of the Northcote Trust. The lady almoner rejoices in the "reproach" that is sometimes heard that "St. Thomas's Hospital makes a fetish of social work"; and her report certainly justifies her attitude. The work began with the appointment of an almoner to help the out-patients to carry out the recommendations of the medical staff, to arrange for convalescence, to raise funds for the urgent needs of the patient, as well as for the subsidiary purpose of directing patients ineligible for hospital treatment to suitable medical centres. As the work extended the governors placed the Samaritan Fund in the almoner's hands, so that its distribution might be based on an intimate knowledge of the patient's home circumstances. In the casualty department patients are sorted out, and many are returned to their panel doctors. Assistance, social advice, or financial help is given to convalescents. In the special departments for out-patients much work is done in supplying instruments, visiting and reporting on homes, keeping up attendances for physico-therapy, sending the district nurse to babies with ophthalmia, and so on. Work is done in connexion with a speech centre, a Northcote Trust hostel for women with venereal disease, and the tuberculosis department. Patients who have left the wards are followed up, and for this purpose the Northcote Trust office keeps a register of all cancer patients. The records of the lady almoner's office in maternity cases for the last ten years have been used in a special research for the Medical Research Council on the effects of maternal conditions and nutrition upon birth weight. From a perusal of the report the treasurer of the Samaritan Fund's pride in the thoroughness and efficiency of the lady almoner and her staff seems fully justified.

THE prizes at the London School of Medicine for Women were presented on June 1st by H.R.H. Princess Mary, Viscountess Lascelles. Miss Aldrich-Blake, Dean of the School, said, in an introductory address, that since the foundation of the school nearly fifty years ago more than 1,000 students had gone through it, of whom some 700 were at work in the United Kingdom and the rest in India, China, and the Dominions. Princess Mary subsequently took tea with the Dean and other members of the teaching staff, and afterwards the seven students who had taken the chief honours were personally presented to her.

#### BIRTHDAY HONOURS.

THE birthday honours list issued on June 2nd, in anticipation of the King's birthday on June 3rd, contains the list of honours the King has conferred on the recommendation of the authorities of the Navy, Army, and Air Force, of the Colonial and Foreign Offices, and of the Government of India.

##### K.C.B. (Military).

Major-General Owen Edward Pennefather Lloyd, V.C., C.B. (ret. pay), Colonel Commandant R.A.M.C.

##### C.B. (Military).

Surgeon Rear-Admiral Joseph Chambers, C.M.G.  
Colonel Walter Holland Ogilvie, C.M.G., I.M.S., Assistant Director of Medical Services, Presidency and Assam District, India.

##### Knighthood.

Dr. Hector W. G. Mackenzie, Consulting Physician to St. Thomas's Hospital, and a member of the Board of Examiners for the I.M.S.  
Professor William J. Ritchie Simpson, C.M.G., member of the Colonial Advisory Medical and Sanitary Committee.

##### C.M.G.

Dr. David Alexander, Director of Medical and Sanitary Services, Gold Coast Colony.

The Rev. Robert Laws, D.D., M.D., Principal of the Livingstonia Mission, Nyasaland Protectorate.

##### C.I.E.

Lieut.-Colonel Asher Leventon, Indian Medical Service, Superintendent, Campbell Medical School and Hospital, Bengal.

Lieut.-Colonel Thomas Hunter, Indian Medical Service, Civil Surgeon, Lucknow, United Provinces.

Lieut.-Colonel Robert McCarrison, Indian Medical Service, Medical Research Department, India.

Major David Patrick Johnstone, O.B.E., Surgeon to his Excellency the Governor of Madras.

##### M.V.O. (Fourth Class).

Henry Linnington Martyn, F.R.C.S.  
Frederic Jeune Williams, M.R.C.S.

##### O.B.E. (Military).

Major and Brevet Lieut.-Colonel Ralph Bignell Ainsworth, D.S.O., R.A.M.C.

Lieut.-Colonel Gerard Irvine Davys, M.D., I.M.S.  
Flight Lieutenant Christopher Thomas O'Neill, M.B., R.A.F.

##### O.B.E. (Civil).

Captain Thomas John Hallinan, R.A.M.C., M.O.H. Basra.  
Eldon Harvey, Medical Superintendent of the Lunatic Asylum and Health Officer, Western District, Bermuda.

Dr. Benjamin William Quartey-Papafio, Member of the Legislative Council of the Gold Coast Colony and formerly Assistant Colonial Surgeon.

##### M.B.E.

Captain Antonelli Francisco Bartholomeu Saldanha, I.M.S.  
Sardar Bahadur Divan Singh Duggal, Civil Surgeon, Punjab.  
Dr. Agnes Henderson (Central Provinces).

#### THE ETIOLOGY AND PREVENTION OF RICKETS.

OBSERVATIONS IN VIENNA BY THE BRITISH MISSION. Special Report Series, No. 77,<sup>1</sup> of the Medical Research Council, just published, gives the final and complete account of the investigations on rickets in Vienna, carried out from 1919 to 1922 by Dr. Harriette Chick and her colleagues under the auspices of a special joint committee of the Medical Research Council and the Lister Institute. It is, perhaps, the most complete study of human rickets from the side of prophylaxis that has ever been undertaken; and it is in the addition to our knowledge of those conditions of diet and environment that will prevent rickets that the greatest value of the report lies. But it also gives a careful description of the early clinical signs of rickets, controlled by radiographs of the bones, which constitutes a really important contribution to the diagnosis of the disease.

The appearance of this scientific clinical study of rickets is a counterpoise to the great mass of work on experimental rickets in animals in recent years, and may, perhaps, settle some points of controversy that have emerged from these laboratory investigations. Indeed, the first object of the Vienna inquiry was to investigate the influence of diet in the production of rickets, and especially with regard to the fat-soluble antirachitic vitamin of Mellanby; and only later was the scope of the inquiry broadened by the consideration

<sup>1</sup> Medical Research Council. Special Report Series, No. 77. *Studies of Rickets in Vienna, 1919-1922. Report to the Advisory Food Factors Committee of the Medical Research Council and the Lister Institute.* By Harriette Chick, D.Sc.; Elsie J. Daryll, M.B.; E. Margaret Hunter; Helen M. Mackay, M.D., M.R.C.P. (Brit. Memorial Fellowship); H. H. Smith, M.B.; Hans Wimbarger, M.D.; and M. Tarr, M.D. London: H.M. Stationery Office, 1923. (250 pages; 12 plates, and numerous charts and figures. 7s. 6d. net.)

of the various factors of environment and especially of sunlight.

Rickets was specially rife in Vienna after the privations of the war. The investigators were fortunate in being able to work in the University Kinderklinik under Professor Pirquet, where eventually sixty cots were allotted to them, in two separate hospitals, but under the same conditions of good hygiene and an altogether exceptional system of diet control. The fully organized investigation extended from November, 1920, to July, 1922; it consisted of a prolonged observation of some seventy young infants (the period of observation in most cases varied from six months to a year). They were the babies of poverty and the slums, and on admission the majority were in poor condition. They were all bottle-fed, and on one of two diets. Diet I consisted of the fresh undiluted milk of stall-fed cows, sterilized, and supplemented by large amounts of cane sugar; after 5 months of age, cooked starch was added as semolina and potato. Diet II was a full-cream dried milk, reconstituted by the addition of water, sometimes supplemented for young infants by addition of sugar, and at 6 months by addition of semolina, and at 9 months by potato. It was expected that this dried and tinned milk, obtained from grass-fed cows, would be richer in fat-soluble vitamin than Diet I; but actual experiment with rats showed that it had a low value in fat-soluble A, and in this respect was no better than the winter milk of the Vienna cows. Every infant on Diet II received also a daily ration of cod-liver oil, up to one and a half drachms daily of the pure oil, given in emulsion; so that Diet II, so supplemented, was notably richer in fat-soluble A than Diet I. Apart from their content in fat-soluble vitamins, the two diets differed in the proportions of organic constituents, expressed as percentages of the total calories, as follows:

Caloric Percentage.

	Protein.	Fat.	Carbohydrate.
Diet I ...	13	28	59
Diet II ...	20	45	35

The high carbohydrate content of Diet I and its lower content of protein and especially of fat will be noted. The caloric value of both diets was high; in both this exceeded the standards of Heubner and Holt; that of Diet I was 5 to 10 per cent. higher than Diet II, this being due to the heavy proportion of cane sugar in it. These diets were given to equal groups of infants, 34 on Diet I and 34 on Diet II, between November, 1920, and June, 1922; the two groups mingled indiscriminately in the wards, and enjoyed the same excellent hygienic conditions. If anything, the general health of the group on Diet II was better, and their rate of growth approximated more closely to the standard; it suffered less from respiratory troubles in the winter, but in summer was not less immune from gastro-intestinal disturbances than the Diet I group. But in both groups the standard of general health remained fairly good throughout. Freedom from rickets on admission was established both by clinical signs and radiographical diagnosis. Development of rickets took place as follows. Where the standard of diagnosis was the radiograph, no case occurred in Group II (that is, on Diet II); while seventeen cases occurred in Group I (Table 2, p. 43). Further, all these cases of rickets occurred in the winter season, between December 30th and May 2nd. The age in these positive cases was unusually young; of the seventeen, nine were under 6 months, and twelve under 7 months when diagnosed by x rays (p. 45). Thus, under similar and good conditions of hygiene in well lit and airy hospital wards, a marked tendency to rickets was shown by children on a special diet, but only during the winter season; the conditions of life in summer, the free exposure to sun and open air, neutralized the rachitic influence of diet.

It is important to add that when clinical standards of diagnosis—cranio-tabes, rib-beading, cranial bossing—were accepted, though radiographs were negative, there were additional cases. In summer ten such cases of clinical rickets occurred—five on Diet I, and five on Diet II; and two in winter on Diet I (p. 47). It is regrettable that detailed records of some of these cases occurring on Diet II—that is, on cod-liver oil—have not been included in the report. This question of the clinical stigmata of early rickets is of great importance to the practitioner; and the

careful and prolonged observations on cranio-tabes and the rickety rosary in young infants are not the least valuable part of the report.

Miss Daljoll and Miss Mackay lay special emphasis on cranio-tabes as the earliest sign of developing rickets, at least in infants under 6 months (p. 133); while enlargement of the costo-chondral junctions, though occurring later (between 5 and 6 months), was also of great value, though confusion might here be caused by physiological or by scorbutic enlargement. The records given show that in all cases diagnosed by x rays there were also present one or more of the clinical stigmata in the skull and thorax. It may be stated also that x-ray examinations of the ribs could not be made owing to technical difficulties; and one case is given where nine successive radiographs of the limbs failed to detect rickets, and yet at autopsy histological evidence of rickets at the costo-chondral junctions confirmed the clinical diagnosis of a rickety rosary (p. 48). In view of these facts on the clinical stigmata of rickets set forth in the report, the conclusion on page 66 that "in summer infants on both types of diet were protected from rickets" would seem to require some qualification.

The remainder of this absorbing report must be described more briefly. Treatment of rickets was studied in fifty-three cases, some admitted with the disease, some developing it on Diet I while in hospital. The standard of cure was radiographic evidence. Diet II (containing cod-liver oil) was curative in winter; Diet I failed to cure. Spontaneous cure was observed in spring and summer when the babies were much out of doors, on either diet. In winter and spring infants on Diet I were also cured by cod-liver oil, or by exposure to sunlight, or by the mercury vapour quartz lamp (p. 85). Treatment by sunlight (out of doors) was on the whole more efficacious than the mercury vapour lamp or cod-liver oil to open-air treatment accelerated cure (p. 84). health; but there was an impression that the addition of cod-liver oil to open air treatment accelerated cure (p. 84). It is important to note that excellent conditions of hospital hygiene in winter, with a diet of high caloric value (Diet I), did not effect a cure of rickets.

A portion of the report (Part III, No. 2, p. 115) deals with observations on rickets at the Landes Zentral-Kinderheim, a large institution for nursing mothers and infants. Here a study was made of a large number of breast-fed infants; but unfortunately radiographic diagnosis was not available, and where artificial feeding supplemented breast milk, this could not be so strictly controlled. Hygienic conditions also were less satisfactory. Nevertheless, the results were important, and on the whole confirmed those at the University Kinderklinik. In winter rickets was common, even in babies entirely fed on human milk; in summer, the disease was "not uncommon," but in a milder form. The use of cod-liver oil "greatly reduced the incidence of the disease in winter, but even in summer did not entirely prevent its appearance" (p. 128). "The imperfect protection afforded by cod-liver oil under less favourable dietetic and hygienic conditions" is admitted (p. 197); and in this connexion the development of slight cases of rickets at the Kinderklinik in children receiving cod-liver oil and in summer may be recalled (p. 47).

Part IV deals with laboratory tests on various milks in respect of their content of fat-soluble A vitamin, as tested by growth experiments on rats and guinea-pigs. These experiments, carried out by Miss Hume, though of rather negative character, were interesting and important (pp. 151, 152). They showed that the dried milk used in Diet II (at the time of testing it had been in tin for about two years) had a low vitamin A value—no higher than that of the average Vienna stall-fed dairy cows, either in winter or summer; also that the milk of special stall-fed cows on a controlled diet, both with and without green-stuff, was of low vitamin A value; and that the exposure of a stall-fed cow daily to sunlight did not increase the vitamin A content of the milk. Human milks obtained from the Landes Zentral-Kinderheim were also of low vitamin A value; the addition of butter and margarine to the mothers' diet produced no effect, but cod-liver oil after a considerable time produced definite improvement in some experiments. Suggestive results were obtained on rats fed on defective diets by radiations from the mercury vapour quartz lamp.

In conclusion, unstinted praise must be given to Dr. Wimberger for his account of the rachitic changes in the long bones, as revealed by x rays; and for the beautiful radiographs of rachitic processes, developing and healing. The successful reproduction of these delicate photographs is a real triumph. As to the other contributors who in association have furnished the body of the report, sincere congratulations and thanks are due. The best tribute to their work will be the honourable place which their report will certainly take in the literature of rickets. The generous hospitality of Professor Pirquet also will not be forgotten.

## VOLUNTARY HOSPITALS ASSOCIATION.

THE annual conference of the British Hospitals Association was held in Sheffield last week, when a number of subjects relating to the finances and administration of hospitals were discussed.

### THE FUTURE OF VOLUNTARY HOSPITALS.

A paper on this subject was read by Mr. H. J. WARING, surgeon to St. Bartholomew's Hospital, in which, after dealing with the origin and growth of voluntary hospitals, he urged that they should be expanded so as to provide satisfactory hospital treatment for those who could pay for what they needed but could not get it elsewhere. After noting the general practice of requiring contributions from patients he said:

The result of these contributions of patients to the hospital authorities and the payment by public bodies for medical services has changed the outlook as regards the medical staff. In the past, the medical staff of a voluntary hospital has given its services either entirely gratuitously or, in a few instances, each member of the staff has received a small honorarium for out-of-pocket expenses. It has always been understood, however, by the honorary medical staff of a voluntary hospital that the services given in this honorary capacity were to be for the necessitous poor, and not for patients for whom or from whom the hospital has received monetary consideration for treatment. Some hospitals in this way receive considerable sums of money. In my own hospital—St. Bartholomew's—last year the amount received in this way was nearly £30,000, about one-fifth of the annual hospital expenditure. On this account the position of the medical staff and finance ought to be reconsidered.

In the past resident members of the hospital staff and also junior members of the visiting staff have not been paid adequately for their services. . . . A newly qualified medical man has already spent in all probability five or six years in getting his qualification, and, having obtained it, it seems only right and proper that he should be properly paid for the services he renders to the hospital. The same statement holds good as regards the junior members of the visiting staff. In many cases they give a large amount of their time and energy to the investigation and treatment of hospital patients, often at a pecuniary loss to themselves. In my opinion, all junior members of a visiting staff of a general hospital ought to receive adequate payment for their services.

### VOLUNTARY HOSPITAL FINANCE.

SIR NAPIER BURNETT read a paper on voluntary hospital finance, in which he dealt with two sources of income—contributory schemes and insurance for middle-class patients within certain income limits. He quoted the definition of a voluntary hospital adopted by the Voluntary Hospital Commission—namely:

An institution managed by a responsible committee and partly or mainly supported from voluntary sources, the object of which is to provide medical and surgical treatment of a curative character.

It was, he thought, clear from this definition that the Commission desired to retain for hospitals government by a responsible committee and voluntary sources of support. Moreover, in his opinion, "any alteration in the character of the sources of support must in the long run tend towards alteration in the form of government."

### Contributory Schemes.

Sir Napier Burnett gave an analysis of the answers he had received from 105 hospitals which derive income from contributory schemes, and hoped thereby to help committees of management when considering the tendencies of this method of obtaining income. In 41 of the 105 hospitals contributory schemes had existed for over thirty years. "If payments by patients or potential patients are inimical to the voluntary system, a destructive process has (he said) been in progress at some hospitals for over fifty years." In many of these hospitals the organization of the contributory scheme is undertaken by

the hospital; in others by the local Hospital Saturday Fund, or by an outside committee. The rate of payment varies from a farthing to threepence a week. He had assumed that the aim was to raise an amount of money sufficient to cover the cost of treating contributory patients; if profit were aimed at the vexed question of the remuneration of the honorary staff would arise. Unfortunately few hospital authorities could give the number of the contributory patients treated, and fewer still even an approximate number of the contributors, so that it was difficult to estimate each hospital's liability. Sir Napier Burnett expressed the belief that doctors will continue to treat the indigent without payment; they will, he assumed, continue to treat gratuitously members of the class who had formed the great bulk of hospital patients for the last fifty years, most of whom now form the contributory class; but it could not, he said, be assumed that the medical profession will agree to any extension of free service. Detailed registration of patients by each hospital was, therefore, of the utmost importance, in order to estimate liability and to avoid friction in the future.

From the answers to his questions it appeared that in 74 of the 105 hospitals periodic payment entitles the contributor to free hospital treatment, in many cases covering also his dependants. Sir Napier Burnett suggested that a central body was needed to collect data, supply information, and bring the hospitals with contributory schemes into line. The fact that 70 of the hospitals imposed no limitation to the income of the contributors, and that collecting and contributing were on a varying basis or no basis at all, showed the need for a better understanding of the hospital situation. Of the 105 hospitals, 79 asked payment from patients who were not members of the contributory scheme; 44 hospitals did not attempt to correlate the support received with the district or area or contributing firm for which work was done.

Sir Napier Burnett summarized the inducements to join a contributory scheme as follows:

1. To help less fortunate comrades when in need of treatment.
2. To obtain treatment for the contributor and his family.
3. To enable the contributor to share in the management of the hospital.

Great care, he thought, should be exercised in according to contributors a share in management lest the scheme might result in handing over to one class in the community the entire control of the hospital. In order to maintain the voluntary system emphasis should be laid chiefly on inducement 1. In some newer schemes there was a tendency to pay too little regard to the older rules that only those suffering from complaints suitable for hospital treatment should be admitted, and then only if there was room. The hospital liability should be clear from the outset. Some schemes suffered from a failure to fix an income limit for contributors.

There were, he said, arguments in favour of each large hospital running its own scheme, but he thought this was less desirable with small hospitals, as the work required an organized staff and considerable expenditure. There was a lack of uniformity in the accounts. Sometimes the sums received from regular weekly contributions, from grants by employers, from social entertainments, and from church and chapel collections, were included under the heading "Contributory Scheme"; in other cases the money raised by two or three of the methods was added to "Donations."

Sir Napier Burnett concluded this part of his address by stating that a check upon the bona fides of the contributor was essential, and that apparently it would be necessary to return to some form of "letter" system.

### An Insurance Scheme for Hospital Treatment.

In the second portion of his address he outlined a scheme of insurance for hospital treatment for middle-class patients with incomes between £250 and £600 or £700 per annum. He proposed a premium of £2 a year. The cost of maintenance of all the insured patients in the hospital would be the first charge on the fund formed from these premiums. The second charge would be the remuneration of the medical staff for its services, an agreed percentage being paid into a medical staff fund. The balance, after paying these two charges, would represent the real insurance quota, or so-called profit of the

scheme. This should be utilized in the provision of increased accommodation and facilities for the treatment of middle-class patients. The amount of extra accommodation required for these patients would not be very large, and would be provided from the surplus funds as the scheme developed. He did not seem quite clear about the machinery required to run the scheme. He discussed the suggestion that some of the recognized insurance companies might provide the machinery of collection, but thought the company would seek to absorb the surplus funds as remuneration for its work. He hinted that the requisite machinery might be provided by the existing contributory scheme organization. Without further explanation he passed on to the advantages of his scheme—namely:

1. That a deserving section of the community would obtain the use of the equipment and facilities of the modern voluntary hospital.
2. That a fresh avenue of finance would be opened up.
3. That the hospital medical staff would obtain payment.

#### Some Comments.

In confining his remarks to the income side of voluntary hospital finance, Sir Napier Burnett has dealt with several controversial matters which are of interest to the medical profession. For example, there is the demand by contributors for representation on the board of management of the hospital. Sir Napier Burnett thinks that the demand can be minimized by emphasizing the first of his inducements to contribute—the assistance given to comrades in need of treatment. We are not sure that this will be effective, and we would have liked information about hospitals in places where contributors have already obtained considerable representation on hospital committees. Secondly, Sir Napier Burnett seems unaware of the proposals contained in the hospital policy of the British Medical Association. He stated that:

"Broadly the position of the medical profession with regard to hospitals is that: (a) they will treat without payment the indigent; (b) it may be assumed that they will continue to treat free those who have formed the great bulk of hospital patients for the last fifty years, and of whom the majority form the present contributory class."

This does not seem in accord with the opinion of the Council of the Association that:

"all payments made for hospital benefit (other than . . .) are in fact payments towards all the services of the hospital, whether medical or ancillary, and therefore a percentage of such payments should be passed" to a staff fund.

Again, Sir Napier Burnett predicts that "some return to the 'letter' system is inevitable." It would be interesting to know what kind of letter system he foresees. These and several other points are, to use Sir Napier Burnett's expression, slurred. Doubtless this was inevitable in the time allowed for his address.

The subject of the policy the profession should adopt with regard to voluntary hospitals will be discussed at the Representative Meeting of the British Medical Association at Portsmouth next month in connexion with the paragraphs in the Annual Report of the Council (SUPPLEMENT, April 28th, p. 143) and the numerous notices of motion contained in the provisional agenda published in the SUPPLEMENT of May 19th (pp. 199-200).

## Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

#### Mental Treatment Bill.

THE Mental Treatment Bill, introduced on behalf of the Government by Lord Onslow, was taken in Committee in the House of Lords on May 30th. The first clause, to enable a local authority to co-opt members on a visiting committee, providing that the number of persons so appointed should not exceed one-third of the committee, was approved with a drafting amendment.

In Clause 2, for extension of powers of visiting committees, Lord Onslow proposed a change in the subsection under which it was laid down that the visiting committee might undertake research in relation to mental disorder and its treatment subject to the approval of the Board of Control. It had been pointed out that this might be impracticable, and the reference to the Board of Control was therefore omitted.

In Clause 4, touching the temporary treatment of mental disorder without certification, Lord Phillimore moved to define a "minor" as "under sixteen years of age," his point being that

consent in respect of persons above that age should rest with the persons themselves. Lord Onslow said the Government would not be adverse from accepting the principle of the amendment, but felt that 16 was a rather early age at which to give this responsibility, especially in view of the possible state of health of the person to benefit. He suggested that 18 should be substituted and that the amendment should be withdrawn and considered again before report stage.

In Clause 5, relating to the discharge of persons detained in institutions under the measure, it is laid down that any person may at any time leave the institution upon giving the medical superintendent forty-eight hours' notice of intention so to do. Earl Russell moved to leave out "forty-eight hours" and to insert "three days." He said that if such a notice were given, say on Saturday at about midday, it might be impossible for the authorities to communicate with the friends of the patient, so that they should be ready to receive him as he should be received when discharged from actual care. The reason of the short period was doubtless to preserve the liberty of the subject, but that would not be seriously infringed by the change from two days to three, and as a matter of administrative convenience it appeared almost necessary. The Earl of Onslow said that at first he was very reluctant to accept this amendment, not because he did not admit the force of the argument, but that he did not wish it to be thought that it was desired through this bill in any way to restrict the liberty of a patient entering into these institutions in so far as it could be preserved with due regard to administrative convenience. But he had been much impressed by what Earl Russell had said, especially in regard to week-ends. He was therefore prepared to accept "seventy-two hours" instead of "forty-eight hours" as an amendment. This was agreed to.

On Clause 8 the Earl of Onslow moved an amendment to ensure that the Corporation of London should preserve its jurisdiction as a separate authority, and afterwards proposed a new clause to set forth that asylums provided by any public authority in England or Wales for lunatics or other persons of unsound mind should hereafter be called mental hospitals, and for reference in any public or local act or in any order, regulation, or other document issued the change should accordingly be made. The new clause was a small matter, but it introduced a new principle into the question of mental deficiency. Hitherto mental institutions had been described as asylums and the word had been associated with mental deficiency, and perhaps had contributed to the view that it was less a disease than an irremediable affliction. He had met the representatives of the nurses in mental institutions, who were anxious that this new nomenclature should be introduced into the statutes. Many alienists, and the Board of Control also, were anxious to adopt the title of mental hospital instead of asylum. The Ministry wished to emphasize the fact that mental deficiency was a disease like other diseases, and that institutions in which it was treated, and he hoped cured, were hospitals in the same way as other hospitals for bodily disease. Therefore he thought that if the title of these asylums were assimilated with the title usually associated with the hospitals for the cure of bodily disease popular misapprehensions might be corrected.

On the schedule Earl Onslow moved an amendment in the terms of statement to be annexed to a recommendation for treatment. The form as set forth in the bill began, "I am personally acquainted with, but am not related to, the above named XY." Lord Onslow proposed to substitute "The above named XY is personally known to me but I am not related to him." Thus a justice of the peace would not be prevented from giving a certificate through not being able to say he had known that patient for some time. The amendment was agreed to.

#### Education Estimates.

Presenting the Education Estimates, Mr. Edward Wood, on May 31st, referred to the grants for the higher education of ex-service men—a charge which has now ceased. Its results, he said, ought to have more than satisfied the keenest hope of those responsible. Out of all the entrants under that scheme to Oxford and Cambridge no fewer than 25 per cent. secured first-class honours, and in one particular college at Oxford, out of about fifty students, no fewer than six had been fortunate enough to secure Fellowships at other colleges. Two years ago the scheme was costing rather more than £2,000,000; last year £1,000,000; this year £300,000; and he was advised that about £100,000 spread over two years would wind up the last awards.

Mr. Wood said that the value of the school medical service was being increasingly realized by all concerned—the taxpayers, the ratepayers, the parents, the teachers, and the authorities. The total cost for the results obtained was not excessive. It worked out at something like 4s. 4d. a child in average attendance. In the opinion of those who had opportunities of judging, the prolonged trade depression had not had an adverse effect on the physique of the children. He could quote the opinion of more than one medical officer. For example, at Hull the school medical officer reported that in spite of the trade depression children were taller and heavier in the several age groups, and fewer children were reported by the teachers as mentally backward than in any year since the armistice. For the blind, the deaf, the physically and mentally defective among children of school age, provision could be made only through special schools. There were a large number of children for whom, at the moment, the Board was making no provision for any special schools. This was because the existing provision was so expensive. It was only by reducing the cost of these special schools to as low a figure as was compatible with efficiency that a substantial inroad could be made into the great blocks of children at present denied the benefits

to which they were entitled. With that object he had directed a review to be made to see whether the cost could be slightly lessened. In one respect it was in his power to bring some measure of assistance to areas financially hard pressed. In view of general economies which had been effected the Board proposed in the present year to extend the areas so helped.

Mr. Herbert Fisher (ex-Minister of Education) said that the presence of a large number of defective children in the elementary schools rendered it impossible for the education in those schools to be effective. As something like 40 per cent. of the mentally defective children in London schools were so trained as to be able to earn either the whole or a part of their living, he could not admit the proposition put forward in some quarters that the expenditure was unproductive. But only a very small portion of the field was covered. At the present moment 15,128 children were being educated in the special schools, day and residential, for the mentally defective. The total number of such children in England and Wales was 31,000. That meant rather less than half the number were being educated. If they could not be educated they should be handed over to the Board of Control.

#### Ministry of Pensions Estimates.

Major Tryon, on June 6th, presented the estimate of the Ministry of Pensions for the current financial year. The vote sought was for £73,655,246, as compared with an actual expenditure of £82,000,000 for the past year—a reduction of £8,344,754. The cost of administration had been brought down £2,000,000 a year for the last two years. This was attained by reduction in the numbers of the staffs and in salaries and bonuses in accordance with the fall in the cost of living. Pensions and allowances accounted for £65,533,000, divided as follows: for disabled officers and men, including allowances during treatment, £35,833,000; for widows of officers and men and orphan children £21,350,000; for dependants, £8,350,000. Causes of the decrease were the deaths of pensioners or their wives and children, the advance of children beyond the pensionable age, and the remarriages of widows. Two factors of increase were new claims, numbering 45,000 in 1922, as compared with 81,000 in the previous year, and larger pensions awarded by medical boards to pensioners whose condition had got worse. Major Tryon again touched on the charge made that secret instructions had been issued to medical boards to cut down pensions. He pointed out that this had been investigated by a committee, including ex-service men, who had unanimously found that the story was untrue; 95 per cent. of the doctors on medical boards were ex-service men. The average change in assessment was becoming less and less. In 1919 there was a net reduction of 0.8 per cent.; last year the net reduction was 3.9 per cent. The change was occurring mostly among the men with lighter disabilities. It was the result of medical and surgical skill, and ex-service men owed much to the medical profession in these respects. The Minister announced concessions in respect of the seven years' limit on widows' claims. The keystone of policy for the future should be stabilization and security for the pensioner.

Mr. Macpherson (ex-Minister of Pensions) observed that during the past three years the State had spent no less than £58,000,000 on medical treatment. He believed the boards were doing their work well; but it was said that some were wrong in their diagnosis and rough in their treatment of pensioners. The Ministry should make immediate and effective investigation into complaints.

Mr. Pielon, Unionist member for Stourbridge, who spoke standing by the aid of crutches, said that the Minister having assured them that pensions should be based on disability and not on earning capacity, he wanted to know why medical boards still asked whether a man was working.

After some further discussion, Captain Craig (Parliamentary Secretary to the Ministry) stated that the estimate of the cost of medical services for the year 1923-24 was £5,083,000, of which £3,797,000 represented the estimated cost of medical treatment and £1,286,000 represented boarding and administration. There would be a reduction this year of £1,502,000. On June 30th, 1920, the Ministry had 140,000 under treatment. In 1921 the number had risen to 155,000. In 1922 it was 110,000, and on March 31st of this year it was 80,000. The average cost per patient per day now was estimated at 8s. as compared with 8s. 5d. for the year 1922-23 and 9s. 7d. for the year 1921-22. The number of beds available was 8,000. Up and down the country there were 150 clinics and the Ministry had 37 hospitals devoted to various diseases. He referred to the achievements at Sidcup in dealing with cases of facial injury. He mentioned also that separate accommodation for mental cases was being provided by an institution lately established for the purpose in the west country. Already between 60 and 100 patients were accommodated there, and others were to be received elsewhere.

#### Insurance Medical Service.

In reply to Sir Kingsley Wood and Mr. Gilbert, on May 30th, Mr. Chamberlain said that a conference had been held with the Insurance Acts Committee of the British Medical Association to consider certain modifications in the terms of service of insurance practitioners, but no discussion has yet taken place with regard to the rate of remuneration after the expiry of the present payment, which fixed the rate at 9s. 6d. exclusive of payments in respect of drugs and mileage to rural practitioners. The improvement of the service had been a subject of consideration. Mr. Grundy asked whether it would be made a condition that similar treatment would be meted out to the panel patients as was given to

private patients, and that the queue that had to wait outside the surgeries should be accommodated with shelter. Mr. Chamberlain replied he thought that would be one of the terms of service under consideration.

Dr. Watts asked, on May 31st, whether the Minister of Health was aware that under their present arrangements panel doctors were compelled to keep records of their attendances and of the illnesses of their patients, which involved a great amount of clerical work and took up much time which might be occupied in examining their cases; and whether in framing the new terms of service the Minister would no longer require these records. Lord E. Percy said the Minister could not accept the suggestion that the keeping of the prescribed simple form of record need interfere in any way with the proper examination of patients, and he was not prepared to consent to the abolition of record cards.

In reply to another question, Mr. Chamberlain said that the scale of fees paid to chemists for dispensing insurance prescriptions would expire at the end of April next, and negotiations for its revision had not yet begun.

Lord Eustace Percy, on June 4th, said, on inquiry by Mr. Snowden, that the right to medical attendance was not affected by the previous neglect of an insured person to choose a doctor. Insured persons not infrequently put off selecting a doctor until they became ill, but they had a right to treatment immediately they were in need of it. The panel practitioners, therefore, were collectively at risk in respect of all insured persons entitled to medical benefit. The actual number of unassigned persons, which could not be precisely calculated, was roughly 700,000, but the proportion of those who did not avail themselves of the right to treatment when they needed it was relatively small and a diminishing number. The Minister of Health had no information as to the distribution of unassigned persons amongst different societies.

*The Deaths Registration and Burials Bill*, introduced by Dr. Salter on May 29th, was printed and issued on June 5th. It lays down that information of the death of any person is to be given to the registrar within two days instead of five as at present, and it must be stated whether or not such person has been attended in his last illness by a medical practitioner. A practitioner shall not be deemed to have been in attendance unless he has personally attended the deceased on at least two occasions, one such occasion to have been within eight days of the death. Where no practitioner has been in attendance the registrar is to give notice to the public certifier of deaths (an office to be created) and the latter shall, subject to the provisions of the Act, send to the registrar a proper certificate of death. A coroner holding an inquest shall, unless satisfied that some other practitioner will be present, require the attendance of the public certifier of deaths. The board of guardians of every Poor Law union is to appoint a public certifier of deaths for each subdistrict in the union. Only a registered practitioner may be appointed. There are a number of other provisions in the bill—touching the appointment and duties of public certifiers of death, conditions of burial, and forms of certificate. The measure has no prospect of passage this session, unless it were taken up by the Government.

*Cancer Research.*—Lord E. Percy stated, on June 4th, that financial assistance was at present given from public funds to cancer research through the Medical Research Council, which, in the last financial year, expended a sum of approximately £5,000 for this purpose, in addition to further large sums assigned to the support of other investigations not specifically directed towards the problem of cancer, but which might nevertheless provide the desired clue. The Council held on behalf of the Government a valuable stock of radium salt, of which fractions were in use for cancer research work at eleven different universities or hospitals in Great Britain and Ireland under co-ordinated schemes; and a special departmental committee was appointed by the Minister of Health in January last to survey the whole question and consider how the medical and administrative resources of the Ministry could best be utilized in the campaign against cancer. The question of further financial and expert aid would be considered from time to time as experience might show it could usefully be given.

*Pensions.*—The Minister for Pensions has stated (1) that there are only seven men from Scotland in the neurological institution at Ewell, and it would not be practicable to start a fresh institution for them in Scotland; (2) that the number of men on home treatment without allowances could not be stated, as home treatment was ordinarily obtained by a man from his panel doctor without the intervention of the Ministry; (3) that the Ministry is considering the propriety of acquiring from the disposals department the hospital at present empty at Gretna; (4) that a recent instruction from the medical branch was intended to secure in cases of alleged aggravation difficult to decide that an award under 20 per cent. should not be made without, where thought necessary, obtaining specialist advice as to the probable future of the case; (5) that members of the pensions appeal tribunals were for the most part whole-time doctors receiving yearly salaries—chairman £700, medical members £700, service members £250. Persons employed on a temporary basis were paid at the rate of three guineas a day in the case of chairman and medical members, and one guinea a day in the case of service members.

*Vaccination and Small-pox.*—At the instance of Mr. T. Williams, on May 30th, Mr. Chamberlain stated that the proportion of cases of small-pox in persons who had been vaccinated at some time in their life was 31.3 per cent. in 1921, 28.6 per cent. in 1922, and

19.5 per cent. in the first three months of 1923. The figures for the last two periods were subject to revision, but they tended to show that the bulk of the cases occurred in persons who had been vaccinated from forty to sixty years previously. The number of deaths attributed to vaccination, or to some complication following vaccination in the three periods, were 8, 7, and 5 respectively. No deaths had so far been registered this year as due to small-pox.

**Government Grants for Tuberculosis.**—Mr. Chamberlain stated, on May 30th, that the total amount paid from the Exchequer during the year ended March 31st last in respect of the tuberculosis scheme in England and Wales, including capital grant in aid of sanatoriums, was £1,985,042; the gross expenditure of local authorities in England and of the Welsh National Memorial Association during that year was estimated to amount to £2,945,155, exclusive of capital expenditure.

**Scarlet Fever and Milk.**—Captain Elliot informed Mr. Shinwell, on May 30th, that the Scottish Board of Health had obtained a report from the county medical officer regarding the outbreak of scarlet fever and other infectious diseases at Broxburn, West Lothian, and were making further inquiries. The number of cases was large. The outbreak of scarlet fever has been definitely associated with a milk supply which was sold over a wide area.

**Consumption of Methylated Spirits.**—Mr. Bridgeman informed Mr. Rhys Davies, on May 31st, that the number of cases in England and Wales in the year 1922 in which the condition of the person convicted of drunkenness was reported to have been due to drinking methylated spirits was 516 (250 males and 266 females). The figures were higher than similar figures for the previous two years. Statistics had been collected for only three years, and some part of the increase might be due to improvement in reporting. The denaturing of alcohol used for industrial purposes had always been considered, but extreme difficulty seemed to have been found in making this spirit unpalatable.

## England and Wales.

### KING EDWARD'S HOSPITAL FUND.

THE annual meeting of the President and General Council of King Edward's Hospital Fund for London was held on June 4th, with H.R.H. the Prince of Wales in the chair. According to the annual report for 1922, which was adopted unanimously, the total receipts for the year were £1,351,342, of which £250,000 was received from the Hospital of London Combined Appeal on account, £581,353 from the estate of the late Lord Mountstephen, £257,692 from the estate of the late Sir Thomas Sutherland, £73,720 from other legacies, £24,567 from gifts to capital, and £164,009 from general receipts. The total amount distributed to hospitals during 1922, including the first and second instalments of the special distribution from the Combined Appeal, was £470,000. Since the foundation of the fund a total net amount of over £4,286,000 has been distributed. The year under review has been exceptional owing to the large legacies received, the income from the munificent bequests by Lord Mountstephen and Sir Thomas Sutherland cannot fail to assist the fund greatly in its efforts to secure a permanent improvement in the financial position of the hospitals. During the year the amount spent on the administration of the fund was £8,607, or 15s. 8d. per £100 of the total received (apart from the Combined Appeal), as compared with £2 11s. 8d. per £100 in the previous year. Sir Alan Anderson, chairman of the Revenue Committee, presented the final report of the committee on the Hospitals of London Combined Appeal, which showed that the total receipts amounted to £481,639, and the total amount distributed to £413,214. Sir Cooper Perry, chairman of the Distribution Committee, presented its report on the final distribution of the proceeds of the Combined Appeal, with the list of suggested grants to hospitals, which the meeting approved; 120 hospitals in London and greater London participated in the grants. A report was presented from the Management Committee on the subject of hospital accommodation for accident cases, and it was recommended that a special committee should inquire and report on the methods at present employed for ascertaining where bed accommodation was available in hospitals in the metropolitan and neighbouring areas for accidents requiring admission, and on the proposal that daily reports of vacant beds should be supplied to the police and ambulance authorities. The Prince of Wales remarked on the success of the Combined Appeal, which was launched in a period of high taxation and severe trade depression. The sum of £500,000 had been set up as a sort of outside figure, and he did not

think that many people expected that the total actually raised would come to within £20,000 of that sum. The appeal succeeded, he said, first, because it had a good cause; secondly, because it had a good organization, and, thirdly, because this organization had a good personnel; he mentioned particularly the names of Sir Alan Anderson, chairman of the Organization Committee, and Sir George Lawson Johnston, chairman of the Executive Committee. In regard to the future, the hospitals were gradually succeeding in closing the annual gap between income and expenditure; the net aggregate deficit for the year was £380,000 in 1920, £210,000 in 1921, and £171,000 in 1922.

### LEEDS GENERAL INFIRMARY.

The Prince of Wales was in Leeds on June 1st, and, after visits to the University and the Ministry of Pensions Hospital, Beckett's Park, spent a considerable time at the General Infirmary. He was received by Mr. T. L. Taylor, chairman of the Board of Management, who presented Sir Berkeley Moynihan, senior surgeon, Dr. T. Wardrop Griffith, senior physician, and other officers. Arrangements had been made by which the Prince was able to make a thorough inspection of representative portions of the institution. A prolonged study was devoted to the range of operating theatres, where Sir Berkeley Moynihan explained in detail the arrangements for sterilizing the instruments, etc., the placing of the students for instruction, and the whole apparatus of modern surgery. The Prince then passed through groups of students and nurses to the new x-ray department, which is said to be one of the most completely equipped in the country, having been completely reorganized during the past two years. The equipment was explained by Dr. G. Cooper, director of the x-ray department, to whom the Prince put many questions as to the possibilities of the new x-ray methods of treatment of certain types of cancer, and the prospects of cure. The Prince afterwards stated that he had been much impressed by the complete organization of the institution, and expressed his interest in the correlation of modern science with curative treatment in all its branches.

### PUBLIC HEALTH AND EDUCATION.

A party of a hundred students from Leeds University, accompanied by Dr. Strong, professor of education, visited the West Riding County Hall at Wakefield on May 25th, in order to gain some insight into the work of the public health department. Dr. J. R. Kaye, county medical officer of health, in the course of an address, said that education of the public in health matters was now an essential feature of an efficient health department. The earlier public health Acts dealt with the grosser forms of insanitation, such as water, sewage, and environment. Now, however, measures of prevention were assuming a more personal or individual character. In proceeding along any lines of thought in relation to the prevention of disease or sickness it was necessary always to come back to the individual and his habits. Dr. Kaye then explained at length the work of the different departments, and the students inspected the county hall and the laboratories.

### SMALL-POX PREVALENCE.

In the four weeks ending May 26th, 107 cases of small-pox were notified outside of London. In the successive weeks the numbers were 33, 22, 34, and 18. The counties affected were Derby with 26 cases, Gloucester 28, Lancaster 9, Nottingham 11, and the North Riding of Yorkshire 5, the West Riding 27, and Lincoln (Kesteven) one case. In Derbyshire, Clowne had 9 cases, Heanor 8, Shardlow 8, and Bolsover 1; in Gloucestershire Cheltenham had 9 cases and various rural districts including Dean Forest 19 cases; in Lancashire, Nelson had 7 cases; in the North Riding of Yorkshire Middlesbrough had 5, and in the West Riding Doncaster had 8. The figures for May show a tendency towards reduction in the prevalence of the disease. The average weekly number of cases for the first thirteen weeks of the year was 40, for the four weeks in April 32, and for the four weeks to May 26th, 27. The total number of notifications outside of London since the beginning of the year has been 759.

## Scotland.

### SIR HENRY GRAY.

ON the occasion of his leaving Aberdeen, to become Chief of the Surgical Staff of the Royal Victoria Hospital, Montreal, a complimentary dinner will be given to Sir H. M. W. Gray by his medical friends on Wednesday, June 27th, at 7.15 p.m., in the Palace Hotel, Aberdeen. Mr. Wm. Anderson, F.R.C.S., 5, Albyn Terrace, Aberdeen, is acting as secretary of the committee which has charge of the arrangements.

### EDINBURGH ROYAL INFIRMARY PAGEANT.

The supporters of the Edinburgh Royal Infirmary have for some years past organized an annual pageant for the double purpose of collecting funds for this institution and of attracting public attention to its needs. The pageant held on May 26th, 1923, was on an unusually elaborate scale; there was a procession of bands, costumed figures, and decorated cars well over two miles in length, in which over 7,000 persons took part. The central feature was a pageant of the nations, in which twelve of the city schools participated; a great Red Cross drawn by six grey horses was also a striking part of the procession. The students of the University entered into the arrangements with great enthusiasm, and among other schemes they made an effort to collect a mile of pennies (representing £220) in Princes Street. The state of the collection was shown progressively by the position of the red posts along this street. Numerous friendly societies, unions, and individual commercial firms were represented by deputations on foot or in decorated cars representative of their special trades. A continuous collection was made from the crowd of spectators lining the route. The proceeds derived from the pageant on May 26th amount approximately to £3,200. Returns from entertainments, concerts, etc., held on the same day in outlying districts will, it is anticipated, yield another £1,000. The students of the University were particularly active, and raised over £480, including £72 representing one-third of the "mile of pennies" at which they had aimed in Princes Street.

### SCOTTISH ZOOLOGICAL SOCIETY.

The annual meeting of the Zoological Society of Scotland was held last week in the City Chambers, Edinburgh. Lord Salvesen, who presided, stated that in the course of the present summer the corporation electric tramways would be running past the gate of the Zoological Park at Costorphine, and a large area on the crest of Costorphine Hill, at present occupied by a golf course, would be added to the park. Accommodation would thus be provided for the gradually increasing stock of animals, and parts of the new ground would afford ideal surroundings for the carnivora, with backgrounds of rock and without bars. It was believed that the park would then be the largest zoological garden in Europe, and certainly, with its views over the Firth of Forth and the Pentland Hills, one with the finest situation. The council of the society had further come to the conclusion that, building prices being now stabilized, the time had come to proceed with the erection of a salt-water aquarium, which would occupy a site directly behind the main entrance. The financial result of the last year had been very satisfactory considering the adverse conditions of trade and the expenses entailed by the bad weather. Nevertheless expenditure had exceeded income by £390, but the income had increased steadily year by year since the commencement of the park ten years ago.

### LORD HIGH COMMISSIONER AT EDINBURGH HOSPITALS.

The Lord High Commissioner, Lord Elphinstone, as representing the King at the General Assembly of the Church of Scotland, last week paid a round of visits to the hospitals in Edinburgh. The institutions visited included the Royal Infirmary, where the wards of Sir David Wallace and of Professor B. P. Watson, as well as the hospital kitchen, were specially inspected; the Royal Maternity and Simpson Memorial Hospital; Chalmers Hospital; the Royal Blind Asylum; and the Church of Scotland Deaconess Hospital. At the last-named hospital

Lord and Lady Elphinstone were welcomed by Lord Sands, who stated that the hospital had been in existence for thirty years, having been founded as a memorial of Lady Grizell Baillie, the first deaconess of the Church of Scotland, and that one of its principal objects was to train workers for the foreign mission field and for mission workers in this country. The Lord High Commissioner, in reply, expressed the especial privilege that he felt in visiting the Deaconess Hospital on account of its connexion with the Church of Scotland; and Lady Elphinstone thereafter presented the prizes and certificates of training to the nurses who had been successful in examinations.

### ROYAL VETERINARY COLLEGE.

A large and representative gathering assembled in the Royal (Dick) Veterinary College, Edinburgh, when a memorial window was unveiled by Lord Provost Hutchison. Professor T. Hudson Beare presided, and in opening the proceedings said that the occasion was of exceptional interest since the college was about to celebrate the conclusion of its hundredth session. The memorial window was intended as a link between the old college and the new; it had been given by veterinary surgeons all over the world who had been trained at the old college buildings in Clyde Street.

## Ireland.

### HOSPITAL GRANTS AND PUBLIC HEALTH LEGISLATION.

IN reply to Sir James Craig, M.D., and other members of the Dail, the Minister (Mr. Blythe) for Local Government (Free State) said the responsibility for the matters raised had only just been transferred to his department, and he had not the time nor opportunity to give them very serious consideration. He admitted that the past few years had been very hard on these voluntary hospitals, but this was not the time to rush into proposals that might put a very serious charge on the State. He could promise, however, that the whole matter of hospitals and of medical assistance and relief would be considered very shortly in all its different aspects, and not, as it had been in the past, with one department looking after one section and another looking after another. Replying also to Sir James Craig, the Minister said a Public Health Bill was being drafted, but he could not say when it would be introduced.

### MEDICAL OFFICERS' SALARIES.

At a meeting of the Laoighis (Queen's) County Hospitals and Homes Committee the following resolution from the county dispensary doctors was received:

As your Committee intend rearranging the salaries of the dispensary medical officers of the county, the Leix medical officers consider it advisable that the salaries of each dispensary district be fixed on a homogeneous basis; and they would suggest an initial salary of £250, rising by £10 annually to £350 per annum, for each district; the same to be retrospective.

A member of the committee gave notice of motion to have the medical officers' application considered at its next meeting.

The medical officers of the Newtown-Hamilton and Crossmaglen (Northern Ireland) dispensary districts applied to the Commissioner administering the Newry Union that their salaries should be the same as those paid to the medical officers in the Newry Union, to which they had been recently transferred from the Castleblayney Union. The Commissioner decided, subject to the approval of the Ministry of Home Affairs, to place both medical officers on the Newry scale, which means an increase of £105 per annum for Dr. Dawson and £75 per annum for Dr. McBride, the two transferred doctors.

### MEATH HOSPITAL, DUBLIN.

At the annual meeting of the Meath Hospital the report submitted by the secretary stated that the year had been characterized by altered conditions necessitating drastic changes of policy, and by many disappointments. Bad trade and unemployment had affected the contributions

from employers and employees alike, while heavy taxation and the state of the country rendered it impossible for many subscribers to continue their support. The cost of upkeep of all hospitals had grown to an alarming extent, and the days of low or even moderate hospital charges had gone. The increased overhead expenses of a well appointed hospital were due in a measure to the costliness of the equipment and maintenance. For instance, the cost of the Meath Hospital nursing staff—wages, board, laundry, teaching, and examinations—now amount to more than the whole cost of the institution ten years ago. Although they started the year with a balance to credit of £201, the overdraft was £3,261. This was largely due to the amount received from patients—or perhaps it would be more correct to say on behalf of patients. During the year the amount paid by the War Pensions Committee for the treatment of ex-soldiers was £3,470, and for the year just closed the amount was only £993. The Ministry of Pensions had found that it was more economical and more convenient to send the ex-service men for treatment to two or three of the larger hospitals. There were on April 1st, 1922, 100 patients, and 1,376 were admitted during the year. Of these, 1,280 were discharged cured or relieved; 104 died, and 101 remained on March 31st, 1923. There were 6,584 accident cases treated as out-door patients, and the dispensary cases numbered 19,173, making a total of 25,757 extern cases.

## Correspondence.

### THE COUNTRY PRACTITIONER.

Sir,—All country doctors, and particularly the class known as village doctors, ought to feel grateful for a leading article in the *BRITISH MEDICAL JOURNAL* of May 26th, dealing with their position not only as panel practitioners, but as serving the country people in the rural districts. It is a truthful and sympathetic exposition of the situation, and nothing seems missed out.

The description of how he is being encroached upon, nearly squeezed out of existence by the changing conditions, social and economic, is only too true. Owing to excessive taxation the big country houses are standing empty; these, with their large staffs of servants, were once a main source of income to him. The new aristocracy of the present day, which has taken the place of the old, does not patronize the village doctor, neither does it trust him. They can, and do, bring their town's doctor when they need one, for twenty or thirty miles is nothing for a powerful car.

Then in these days the men in the country towns travel much further afield than in the days of horse and trap, and even the colliery doctors, who were never seen in the country districts, travel there by car to patients they have attended elsewhere. In other words, these men follow their patients, distance being of little object with perhaps only one reservation, which is that they are those who pay their bills; those who do not are left to be attended by the village doctor! To give one example only: a country town doctor with a good practice and a fairly large panel offered to attend a working man's wife eleven miles away in her confinement, where she lived two miles from a village doctor, but the woman did not know how she could get a message to him, say by night, if she took ill, and refused his offer; I rather regret to say he was an Englishman. It is an attempt to take the bread from another man's mouth. We have to live, certainly, but let us be not unmindful of others who have an equal right. The result of such incidents, which are increasingly common, is that the village doctor has a large number of poor people who are not worth running after by his distant neighbours, or who do not pay the bills they have received from the men who previously attended them. He has to be satisfied with "the crumbs which fall from the rich man's table."

I sincerely trust that all these facts will be remembered when the country doctor's case is under discussion at the forthcoming Conference.—I am, etc.,

May 30th.

"A VILLAGE DOCTOR."

### FROZEN SECTION OR LABORATORY INVESTIGATION OF CANCER OF THE BREAST?

Sir,—Dr. McKinstry, in a letter published on May 19th (p. 882), raises the question of the advantage of immediate diagnosis of tumours of the breast by frozen sections over the more methodical examination of the tumour in the laboratory. There is a great deal to be said for both methods, but grave disadvantages accrue to anyone who pins his faith always to one of them without realizing the limitations of each, for neither can always give the answer we require.

In the frozen section, if one gets a definite reply that the tumour is malignant, it is all the surgeon wants, and he can proceed with certainty. There is no doubt that this is a great advantage both to the patient and to the surgeon. But if the reply is that the section prepared in such haste is innocent, there should lurk in the back of one's mind the suspicion—which is a very real one—that another section might quite well give rise to a different opinion. I have had the verdict of innocence given me at an operation, though a more methodical investigation carried on later has reversed this opinion. It is a most unpleasant duty—it upsets the relatives and shakes their confidence—to tell them that all anxiety of malignancy is past, and then to rack their minds and the mind of the patient by demanding the performance of a more radical operation on account of the malignancy which has already been denied; yet this is the risk of the method.

For this reason all opinions given in such cases should be very guarded until the result of the more methodical examination is known; and this later investigation should always be carried out, and must be that by which the surgeon is ultimately guided. The recent work of Sir Lenthal Cheate has shown only too clearly that a mass may evince unmistakable signs of malignancy at one spot while showing nothing but innocent tissues at another, and that a very careful investigation of many sections is often necessary before giving a final opinion. In short, therefore, a positive reply by this method is final, but a negative reply is by no means so; this is a little difficult to keep in mind.

Frozen sections are, of course, easy to arrange in hospital work, but are not so handy or convenient in private practice, and therefore the methodical laboratory investigation is chiefly used. This has the disadvantage of making the surgeon rely to some extent upon the naked-eye appearances, and the fallacies of this I dealt with in a paper published in the *JOURNAL* (January 20th, 1923, p. 94) on "The diagnosis of indefinite masses in the breast." It may also lay the patient open to the risk of dissemination of the cancer cells through the cutting across of the infected lymphatics where the mass is supposed to be innocent and investigation later proves it to be malignant. The Johns Hopkins School goes so far as to state that if a person has a tumour removed, investigated in the laboratory, and the radical operation performed a few days later, that she will inevitably die of secondary growths started from this cause within three years. I have no hesitation in combating this view in the strongest possible manner, but nevertheless it has been seriously stated by enthusiasts.

I think, however, that reasonable precautions should be taken, and this may easily be done if the cut surface of the gland from which the segment has been removed is seared with the thermo-cautery. Even in cases where no suspicion exists, and the whole gland is removed subcutaneously, I am in the habit of applying the cautery to the axillary tail, which contains many lymphatics. If this procedure be carried out there can be no hesitation in waiting the two days necessary to receive the laboratory report.—I am, etc.,

DUNCAN C. L. FITZWILLIAMS, C.M.G.,  
M.D., CH.M., F.R.C.S.

London, W., May 28th.

### THE NATURE OF BLOOD SUGAR.

Sir,—We have Winter and Smith's own statement that their last publication<sup>1</sup> is "to correct any doubts which Hewitt's criticism may have caused," yet they devote more than half their article to adverse comments on certain work

<sup>1</sup>Winter and Smith: *BRITISH MEDICAL JOURNAL*, 1923, I, 894-895.

of my co-authors and myself. This work dealt with the behaviour of sugars in the intestine, and the question before us at present is the nature of glucose in blood. It may be briefly indicated now, however, that we confined our discussion to phenomena observed in relation to the intestine and did not extend our results to tissues generally, blood not even being mentioned. As to the validity of their calculations of amount of glucose absorbed, deduced by them from our Figures 1 and 2, I may point out that Fig. 1 does not refer in any way to the intestine, and Fig. 2 does not mention absorption. The basis of this criticism is thus imaginary.

Winter and Smith say that I have misquoted them as to their conclusion that the normal blood sugar is  $\gamma$  glucose. I admit that such may be the case, but perhaps there is some excuse, for on three consecutive pages of one paper<sup>2</sup> they consider this sugar to be:

- (a) "for the present undecided" (p. 109).
- (b) "some form of glucose" (p. 109).
- (c) "an unstable form of glucose" (p. 111).
- (d) " $\gamma$  glucose" (pp. 110 and 111), "and that it arises from the enolic form" (p. 110).

and now<sup>1</sup> they propound three additional conclusions—namely:

- (e) "that a reactive sugar is present in the blood"
- (f) "that there is no chemical evidence that  $\gamma$  glucose is formed in the body"
- (g) "that normal blood sugar is an equilibrium mixture of  $\alpha$ ,  $\beta$  glucose and a reactive sugar."

I agree that dogmatism is, perhaps, not desirable at present, but the above will indicate the indefiniteness of their conclusions, and in view of the accepted definition that  $\gamma$  sugars include reactive modifications with the oxygen ring displaced from the normal stable position, I leave to others the task of reconciling these contradictory conclusions.

Is it possible that Winter and Smith have adopted a nomenclature not in harmony with that in common use? Certainly their consistent employment of the expressions " $\alpha$ ,  $\beta$  glucose" or the " $\alpha$ ,  $\beta$  form" does not convey the impression that they imply a mixture of two distinct hexoses in solution. But perhaps they do not mean this. One of two alternatives seems unavoidable: either their terminology is unique, or they are dealing with sugars, so far as I am aware, not yet described in the literature. May I give one other example of perplexities with which any critic of these authors has to contend? They state<sup>2</sup> that they failed to obtain laevo-rotation, while in another paper,<sup>1</sup> discussing the same observations, they say, "in one experiment laevo-rotation was obtained."

Winter and Smith now quote the effect of insulin on blood sugar,<sup>1</sup> but as the action of insulin is, I believe, not yet satisfactorily elucidated, and as the nature of blood sugar is still obscure, I will refrain from joining with them in speculation as to how far the action of one unknown on another unknown supports any or all of their several conclusions. The production by insulin of a non-reducing dextro-rotatory sugar *in vivo*<sup>2</sup> is of more than ordinary interest, especially when one remembers the dissimilar results these workers had with the same materials *in vitro*.<sup>3</sup> My adverse criticism (objected to by Winter and Smith) of extravascular experiments with blood thus gains additional support. Incidentally, are they not in error when they state that destructive criticism invalidates experiment? The last word should surely be "inference."

It is well to point out that any mild comments of mine were made bearing in mind the known properties of hexoses, were on purely chemical grounds, and were directed to the method adopted by Winter and Smith for torturing the sugar of extravascular blood. One notes, therefore, with gratification that they now realize that their technique "admittedly is not perfect."

Perhaps it is now evident that any further discussion of the particular point at issue is of no value until we are in possession of experimental observations not only sound, but less fertile as a source of contradictory interpretation.—I am, etc.,

London, W.C., May 30th.

J. A. HEWITT.

<sup>1</sup> Winter and Smith: *Journ. of Physiol.*, 1923, 57, 1-10-112.

<sup>2</sup> Winter and Smith: *British Medical Journal*, 1923, 1, 12-13.

## WHAT IS A "DISEASED" TONSIL?

SIR,—I am prompted to ask this question after reading with great interest Dr. F. J. Poynton's most instructive lecture on "The prevention of heart disease." Under the heading of "Local Foci" he says, "I have no doubt in my mind that unhealthy tonsils should be removed in rheumatic children," and again, "it would be, in my opinion, a mistake to suggest the wholesale removal of tonsils in rheumatic children . . . when there is no evidence that they are diseased."

What is Dr. Poynton's definition of an "unhealthy" or "diseased" tonsil? It seems to me that this is a question of real practical value which has never been satisfactorily answered.

The presence of micro-organisms in the tonsillar crypts cannot be accepted as evidence of disease, for Davis has shown that although sterile at birth, they are infected within twenty-four hours and "plasma" cells make their appearance in the tonsillar tissue. Nor are we justified in assuming that because a tonsil is enlarged it is therefore "diseased." So eminent an authority as Mr. Mark Howell in the discussion which followed his paper on "Tonsillotomy versus tonsillectomy," read before the Laryngological Section of the Royal Society of Medicine in 1921, definitely stated that he did not consider enlargement *per se* evidence of disease. With this view many will disagree, but it is not possible that the enlargement is a physiological hypertrophy and evidence that the tonsil is effectually carrying on its function of resisting systemic invasion?

Again, is pus in the crypts sufficient proof that the tonsil is "diseased"? I think most of us consider that it is, but may not the pus be further evidence of the more or less effectual fight which the tonsil has put up against invasion? Personally, I think it often is, and my own small observations in the realm of comparative pathology would seem to suggest that this might be so. Tonsillitis in sheep is hardly mentioned in textbooks of veterinary surgery; we can, therefore, assume that it is a rare disease, and from the simple structure of the sheep's tonsils it is what we might expect; but in fully 50 per cent. of sheep's tonsils which I have examined *post mortem*, I was able to express a fluid showing all the characteristics of pus. This pus, I think, must be more physiological than pathological.

I am in entire agreement with Dr. Poynton when he says, "the wholesale removal of tonsils must mean occasional disaster to a healthy child, and the grounds for such a step as this must be absolutely sure." It is, therefore, all the more important to define clearly what is a "diseased" tonsil.

Personally, I regard a diseased tonsil as one which shows intracellular micro-organisms on section, but clinically I cannot always recognize it.—I am, etc.,

N. STUART CARRUTHERS, F.R.C.S. Edin.

Norwich, June 2nd.

## THE TREATMENT OF GENERAL PARALYSIS BY MALARIA.

SIR,—Dr. Templeton, in his interesting account in the *BRITISH MEDICAL JOURNAL* of May 26th, referring to the difficulty of obtaining the *Plasmodium vivax* in this country, says: "Attempts are being made to keep the parasite alive outside the body; so far it has not survived more than eight hours."

He does not refer to the cultivation of the parasites *in vitro*, but it has been cultivated in a suitable medium by several workers; and Drs. J. D. Thomson and H. P. Woodcock, writing in Byam and Archibald's *Practice of Medicine in the Tropics* (II, 1542), mention that "it is considered that there is no reason why the growth and multiplication of the parasites in the culture should not continue indefinitely, provided that fresh serum and corpuscles are added to the medium when necessary." Might not this method, then, give the necessary supply of the parasite for use in the treatment of general paralysis?—I am, etc.,

Aberdeen, May 25th.

GEORGE A. WILLIAMSON.

SIR,—In connexion with the article by Dr. W. L. Templeton (*BRITISH MEDICAL JOURNAL*, May 26th, p. 895) the following notes on the treatment as carried out in the Landes-irrenanstalt at Feldhoff-bei-Graz, Styria, may be of some interest. Here the malarial parasite has been transmitted through many successive patients in the asylum from the original stock obtained from a young malarial patient at Trieste.

From the median vein of a patient who has already received a malarial infection 2 c.cm. of blood are drawn during an interval free from fever; 1 c.cm. is injected subcutaneously over the shoulder-blade, and the remainder smeared over an area of about 4 cm. around the puncture after the skin has been excoriated with the needle. The first paroxysm takes place on an average eight days after inoculation. After nine paroxysms (in some cases the number may be twelve or thirteen according to the physical condition of the patient) daily doses of quinine are given, while salvarsan is administered concurrently.

The results are certainly remarkable. When visiting the institution on May 1st I was able to hear from a number of the patients themselves their own account of the treatment and its results. On admission the majority had been noisy, restless, and disoriented, and some had marked physical signs—for example, inequality of pupils, characteristic gait, etc. As a result of the treatment they had become quiet and rational, and capable of employment as shoemakers, clerks, etc., in the asylum. Some patients had been discharged to their homes, and had been able to resume their occupations.

It may, of course, be argued that the remission of the disease is temporary, but the fact that a restless, noisy, dirty patient can become quiet, docile, and clean in his habits is an enormous gain. The return to their homes and avocations, even if it lasts only four or five years, is a fact of great social importance and a tremendous saving of public money.

Figures, supplied by Dr. Weber, the chief medical officer of the section, show a remarkable reduction in case mortality. Since the treatment was begun, at the end of 1921, 56 cases of general paralysis have been treated at Feldhoff by this method. The following table shows the number of cases of general paralysis of the insane in the institution and the number of deaths amongst these patients in the successive years.

General Paralysis in the Feldhoff Institution.

Year.	No. of Cases.	Deaths			
		1920.	1921.	1922.	
1920	65	31	18	3	13 survive.
1921	75	—	32	14	30 "
1922	69	—	—	16	53 "

I understand that at Vienna Professor Wagner has treated 600 cases, and at Hamburg Professor Weygandt some 300 cases, with favourable results.—I am, etc.,

Birmingham, May 28th.

G. A. AUDEN, M.D., F.R.C.P.

#### MINERS' NYSTAGMUS.

SIR,—On May 5th (p. 757) under this heading I gave statistical evidence which conclusively demonstrated that in this district deficiency of light was not "the essential factor in the production of miners' nystagmus."

Last week I obtained details of the Plenmeller pit, the only pit I have discovered in this neighbourhood in which electric lamps are used alone. In 1922 there were 210 hewers, of whom 9 acquired nystagmus, and 304 underground non-hewers, of whom 4 acquired the disease. The percentage of nystagmus amongst the hewers compared with that amongst the non-hewers was therefore:

$$\frac{900}{210} : \frac{400}{304} = \frac{30}{7} : \frac{25}{19} = 4.2857 \text{ per cent.} : 1.3158 \text{ per cent.}$$

In my previous paper dealing with thirty-two pits, comprising 36,232 underground workers who used both oil

and electric lamps, the percentage of hewers who acquired nystagmus during 1922 was 0.9049, while the percentage of non-hewers was 0.2374.

The inference is that the percentage of hewers affected was 4.7 times greater, and that of the non-hewers was 5.5 times greater where electric lamps only were used. It may be thought that there is something special about the Plenmeller pit which I am neglecting; but to-day I heard from the representatives of the South Moor Colliery that twenty-five years ago electric lamps were used solely, and the percentage of their nystagmus cases was very high; but on abolishing electric lamps and installing oil safety lamps they had had no cases of nystagmus amongst the non-hewers, and hardly any amongst the hewers. Comment is unnecessary.—I am, etc.,

Newcastle-upon-Tyne, May 28th.

A. S. PERCIVAL, M.B.

#### ETHER VERSUS CHLOROFORM.

SIR,—Many years ago I pointed out again and again in the *BRITISH MEDICAL JOURNAL* that where ether is used, as in Dublin, New York, and throughout America, death under anaesthesia is extremely rare, whereas, where chloroform is used, as in London, death under anaesthesia is extremely common. And yet week after week the chloroform holocaust goes on.

It was Carlyle who said "Against stupidity the very gods fight in vain. There is in it an opulence of murky stagnancy, an inexhaustibility, a calm infinitude which will baffle even the gods—which will say calmly, 'Yes, try all your lightnings here; see whether my dark belly cannot hold them!'"

Can we wonder that it took Lister years to establish his principles in England, and that Jenner is still denounced by hundreds of thousands of his countrymen?—I am, etc.,

Kensington, W., May 26th.

J. McNAMARA, M.D.

#### DIPHTHERIA ANTITOXIN ON SUSPICION.

SIR,—Although the paramount importance of giving antitoxin in the early stage of the disease is well recognized by those who have seen much of diphtheria, there is evidence, unfortunately, that this fact is not so widely appreciated as it should be. A striking illustration is afforded by the experience obtained in one of the large metropolitan fever hospitals during the past year. Of 150 cases of diphtheria which proved fatal at this hospital during 1922, according to the report of the medical superintendent, no less than 46, or 30 per cent., died within twenty-four hours of admission, and 17 more, or 42 per cent., within forty-eight hours.

In view of the almost invariable success of antitoxin, if administered in the early stage of diphtheria, and the comparative harmlessness of the remedy even should its use subsequently prove to have been unnecessary, this record must be regarded as nothing short of deplorable. In some instances the delay in securing proper treatment is due to the failure of the patient's parents to call in a doctor, perhaps, on account of expense, or, possibly, by reason of their not realizing that he is ill. The general appearance of a diphtheria patient, especially in severe attacks, is occasionally very deceptive in the early stage, and even the medical attendant is apt to be misled, unless the throat be examined.

I am convinced, however, as the result of observations extending over many years of cases of diphtheria received into hospital, and a knowledge of the circumstances attending their removal, that the most frequent source of delay in treatment is the fatal practice of awaiting the result of bacteriological examination before deciding to give antitoxin, or sending the case into hospital. Hesitancy on the part of the practitioner to certify for removal before his diagnosis is confirmed is not unnatural, but the same objection does not apply to giving antitoxin. Until outside practitioners can be persuaded to administer serum on the mere suspicion of a case being one of diphtheria, the sad experience of patients being so frequently sent into hospital in a hopeless condition will continue to be a reproach to the profession.

It has been stated that a belief exists in the minds of a good many outside practitioners that the medical superintendents of the fever hospitals are averse to antitoxin

being given to patients before they are sent into hospital. I do not know on what foundation this belief exists, if, indeed, it does exist, but I do know that the fact is quite to the contrary. Speaking on behalf of all my colleagues in the Fever Service, I am able to assert that if serum were to be given to every case of suspected diphtheria at the earliest possible moment before being sent into hospital, such action on the part of the certifying practitioner would be warmly welcomed. It is with the object of removing any misconception on this point which may exist that I venture to trouble you with this communication.—I am, etc.,

F. FOORD CAIGER,  
Chief Medical Officer, Infectious Hospitals  
Service, Metropolitan Asylums Board.

London, S.W., June 1st.

### THE COASTAL MOSQUITO NUISANCE.

SIR,—I should be grateful if you would allow me to supplement briefly certain portions of the letter by Surgeon Commander D. H. C. Given, R.N. (May 26th, p. 915), in which he refers to the work of the Hayling Mosquito Control.

The "control" of mosquitos is a task which must be undertaken in three successive, and entirely distinct, stages. We have (1) to discover which kind or kinds of mosquitos are responsible for the nuisance existing in the district concerned; (2) to obtain the fullest information available relating to the life-histories, habits, etc., of the offending species, in addition to ascertaining to what extent such habits are influenced by local climatic and topographical conditions; and (3) to devise and apply measures of extermination based upon the knowledge thus gained.

As regards (1), special mention must be made of Mr. F. W. Edwards (Natural History Museum; London), who, as long ago as August, 1920, predicted that the salt water mosquito, *Ochlerotatus detritus*, would prove to be one of the species prevalent in a seaside district such as ours. Since that time a mass of evidence has been obtained showing this particular species to be practically the entire cause of the mosquito nuisance, not only of Hayling, but also of a large number of other seaside places on the south and east coasts of England.

As regards (2), any reference to the investigations carried on at Hayling would be incomplete, not to say misleading, unless associated with the name of Colonel S. P. James, of the Ministry of Health, the leading authority upon the subject of mosquito control. The assistance which we have been receiving from Colonel James during the past year and a half is of so diverse and extensive a character that it is impossible to do more in a letter such as this than to state that, but for the help in question, no work of any value could have been accomplished.

As regards (3), I need only mention that we are making steady progress with the task of applying the various remedial measures available, in the face of a variety of difficulties, of which those relating to the purely scientific branches of the work are perhaps the least formidable. Commander Given advocates that the inhabitants of mosquito-infested districts should proceed "on the lines initiated at Hayling and just recently adopted at Gosport, through the medium of a mosquito control committee consisting of interested residents assisted by the health authorities concerned." It is very important that the functions of public health officers in regard to the mosquito nuisance should be defined, for we should greatly welcome in Hayling any assistance which our health authorities might see their way to provide; up to now no aid of this kind has been forthcoming.—I am, etc.,

JOHN F. MARSHALL, M.A., F.E.S.,  
Hon. Director, Hayling Mosquito Control.

Hayling Island, May 27th.

### GENERAL PRACTITIONER AND CONSULTANT.

SIR,—There appears to be a growing tendency, especially among the younger specialists, to adopt a course, when patients are sent to them for consultation, which I and many other general practitioners consider objectionable. I refer to the practice of transferring a patient sent to them for their opinion to another specialist, without first

communicating with the patient's own medical man. This has occurred twice fairly recently in my own practice. The first case, a child sent to a physician, was transferred to a surgeon, without my knowledge and consent, an operation, which in my opinion was most inadvisable, being urged. Again, an obscure eye case sent to an ophthalmic surgeon was immediately transferred to a gynaecologist for examination and an opinion. The irony of this case was that the gynaecologist, not knowing that I was her doctor, wrote to and transferred her to a local colleague of mine. Now I am on the telephone and live within twenty-five miles of London and thirty-four minutes by rail, yet no attempt was made to consult my wishes in either case. I wrote expostulating to the ophthalmic specialist, and received a curt reply saying it had not even occurred to him to consider my opinion on a gynaecological point.

If this practice of transferring patients without their doctor's consent to another specialist is to grow, I am afraid it will make the majority of men in general practice less inclined to send their cases to their professional brethren, which, in my opinion, would be most unfortunate. One cannot help feeling that at a time when private clinics run by a number of specialists are being started in London, it would be most undesirable if the general practitioner felt that his cases would be transferred from one to another specialist without his consent. In conclusion, I should like to bear testimony to the fact that in my experience these cases are the exception, and that the majority of consultants treat one with every courtesy and consideration.—I am, etc.,

Woking, May 28th.

R. THORNE THORNE.

### REGISTRATION OF NURSES.

SIR,—The suggestion that women who have been nursing the sick for three years before November, 1919, should be admitted to the Register without taking any training into account seems to me deplorable. In my opinion the Register resulting will be absolutely farcical.

I suppose nurses, in self-defence, will have to register, but I hope they will one and all take good care to let the public know on every possible occasion that this registration is a "delusion and a snare."

The only status that a nurse should feel at all adequate to protect her high calling is membership of the College of Nursing. I for one will, on all occasions, draw a very material distinction between a so-called registered nurse and an adequately and fully trained nurse as proved by her membership of the College of Nursing.

May I appeal to the better instincts in our ranks to voice their indignation on behalf of those women who have taken the trouble to go through a course of severe and arduous training in our hospitals.—I am, etc.,

G. W. R. SKENE,

Chairman, Medical Committee, Willesden General Hospital.  
London, N.W., May 21st.

## Universities and Colleges.

### UNIVERSITY OF OXFORD.

At the commemoration to be held on June 27th it will be proposed in convocation to confer the honorary degree of Doctor of Science on Dr. Louis Lapicque, professor of physiology in the University of Paris, and on Sir Ernest Rutherford, F.R.S.

### UNIVERSITY OF CAMBRIDGE.

At a congregation held on June 2nd the following medical degrees were conferred:

M.D.—A. E. Clark-Kennedy.  
M.B., B.Ch.—L. B. Cole, C. C. R. Downing, C. P. Oliver, C. E. Whitting.  
M.B.—F. Allen.

### UNIVERSITY OF LONDON.

A MEETING of the Senate was held on May 16th. The following were constituted the boards of examiners for the first and second examinations for medical degrees in the session 1923-24; the examiners whose names are marked with an asterisk have been appointed chairmen of their respective boards:

*Chemistry*.—\*Mr. H. C. H. Candy (London Hospital Medical College) and Mr. J. A. Gardner (St. George's Hospital Medical School and London School of Medicine for Women), together with the external examiners.  
*General Biology*.—\*Dr. Doris L. Mackinnon (King's College) and Dr. E. J. Salisbury (University College), together with the external examiners.

**Physics.**—\*Mr. J. H. Brinkworth (St. Thomas's Hospital Medical School) and Mr. B. L. Worsnop (King's College), together with the external examiners.

**Anatomy.**—Professor E. Barclay-Smith (King's College) and Professor F. G. Parsons (St. Thomas's Hospital Medical School), together with the external examiners.

**Physiology.**—Professor H. E. Roaf (London Hospital Medical College) and \*Professor W. D. Halliburton (King's College), together with the external examiners.

**Pharmacology.**—Dr. V. J. Wooley (St. Thomas's Hospital Medical School) and Dr. O. F. F. Leyton (London Hospital Medical College), together with the external examiners (\*Professor A. J. Clark).

The following were appointed associate examiners for the M.B., B.S. examination for the session 1923-24:

**Medicine.**—Professor F. R. Fraser, Dr. Gordon M. Holmes, Professor F. S. Langmead, and Professor H. Maclean.

**Surgery.**—Mr. T. P. Legg, Mr. Gordon-Taylor, Mr. W. H. Clayton Greene, and Mr. H. S. Souttar.

**Obstetric Medicine.**—Dr. Eardley Holland and Mr. Miles H. Phillips.

**Pathology.**—Mr. T. W. P. Lawrence and Dr. S. Macdonald.

With reference to the medical curriculum for internal students it was resolved:

That, for the first medical examinations for medical students held in July and December, 1924, and for the second medical examinations, Part 1, for the internal students held in March and July, 1924, and March, 1925, arrangements be made to provide alternative sections of questions on the old and on the new syllabuses.

A similar resolution for external students was adopted by the Senate on March 21st, 1923.

Regarding the diploma in psychological medicine it was resolved:

That in the syllabus in anatomy, histology and physiology of the nervous system in the regulations for the examination for the diploma in psychological medicine for the words "Origin, chemistry and cytology of the cerebro-spinal fluid" the following be substituted: "Chemistry of the nervous system and cerebro-spinal fluid; Metabolism, vitamins and food in relation to nervous and mental diseases; Physico-chemical methods as applied to biochemical research; Blood and urine analysis; Acidosis, uraemia, uric acid; Physical concomitants of emotion; Methods of recording reflexes and tremors in man."

Regulation 3 for the diploma was amended as follows:

The examination for the diploma is open to any candidate whose name is in the *Medical Register*, provided that, before being admitted to Part B, the candidate shall have held for not less than six months a resident or whole-time appointment at an institution (or institutions) for mental diseases recognized for the purpose, or shall have attended for not less than twelve months the practice of such institution (or institutions), or such other practice as may from time to time be approved by the University.

The note prefixed to the regulations for the diploma in psychological medicine was amended by the addition of the following:

A candidate who has already been awarded the diploma in psychological medicine with special knowledge of either of the two branches, psychiatry or mental deficiency, will be permitted to offer himself for examination in Part B (ii) psychological medicine only at a subsequent examination, with a view to special qualification in the other branch of the subject, on payment of the full fee ordinarily payable for Part B of the examination, and if successful, shall have added to the diploma already awarded to him a statement that he has passed the examination with special knowledge of that branch also.

Sir Cooper Perry and Mr. H. J. Waring were appointed governors of the Imperial College of Science and Technology as representatives of the University.

Sir Joseph Verco, M.D., was appointed to represent the University at the Pan-Pacific Science Congress to be held at Melbourne in August next.

The following have been appointed staff examiners in the subjects of examinations for medical degrees for 1923-24:

**Anatomy.**—Professor T. Yeates and Professor E. Fawcett.

**Bacteriology.**—Professor J. W. H. Eyre.

**Chemistry.**—Professor W. H. Lewis and H. Forster Morley.

**Forensic Medicine and Hygiene.**—Professor A. Allison and Professor E. W. Hope.

**General Biology.**—Mr. A. Eastwood and Miss P. C. Esdaile.

**Medicine.**—Drs. J. Calvert, J. Fawcett, R. T. Williamson and C. R. Box.

**Mental Diseases and Psychology.**—Drs. R. H. Cole and W. H. B. Stoddart.

**Neurology.**—Sir Frederick Mott and Dr. E. Farquhar Buzzard.

**Obstetric Medicine.**—Professor T. Wilson and Dr. T. G. Stevens.

**Oto-Rhino-Laryngology.**—Sir William Milligan and Dr. Herbert Tilley.

**Pathology.**—Professor L. S. Dudgeon and Sir Bernard H. Spilsbury.

**Pharmacology.**—Professor J. A. Gunn and Professor A. J. Clark.

**Physics.**—Mr. A. Wood and Professor S. Russ.

**Physiology.**—Professor M. S. Pembrey and Professor G. A. Buckmaster.

**State Medicine.**—Dr. A. G. R. Foulerton and Dr. T. M. Legge.

**Surgery.**—Mr. O. H. Fagge, Mr. E. W. Hey Groves, Professor G. E. Gask and Mr. C. A. Nitch.

**Tropical Medicine.**—Dr. G. O. Low.

The following candidates have been approved at the examination indicated:

THIRD M.B., B.S.—†Una C. Garvin. †Winifred M. Gray. †Dulcie H. Lukis, †D. H. Patey (University Medal). Elsa Y. Adams, Sarah E. Andrews, O. A. Baker, J. C. Blake, Gladys L. Buckley, K. S. Captain, Gertrude B. G. Carden, Eva D. Cook, D. C. Corry, Eleanor M. Creak, A. J. Dodd, A. H. G. Down, Helen W. Duncan, V. Feldman, R. K. Ford, Christine P. Francis, A. J. Gardham, P. C. G. Garnham, F. A. Gaydon, G. N. Golden, Evelyn E. Gourlay, E. E. D. Gray, Gwenvron M. Griffiths, C. F. Harris, Marjorie F. Hayward, Evelyn N. Heather, Nancy M. Hield, E. G. Housden, G. H. Howells, Dorothy M. Howgate, Margaret G. Jones, Kathleen H. B. King, Edna I. Langston, B. L. Laver, E. A. Leviser, J. L. H. Livingstone, W. E. Lloyd, Barbara V. Lucas, A. N. Macbeth, Morland, A. C. Maconie, N. S. Macpherson, R. A. Madgwick, Phyllis M. Manson, Edith T. Marshall, Mary Michael, J. B. G. Muir, Ruth N. Parker-Gray, G. P. Patel, Enid M. Powell, Muriel Rawlinson, Dorothy S. Russell, Emily V. Saunders-Jacobs, C. D. Shapland, F. G. A. Smyth, Emma M. Store, R. O. Swaine, A. Walk, W. R. Ward, Cicely Weatherall, H. N. Williams.

\* Distinguished in Medicine.

† Distinguished in Surgery.

‡ Distinguished in Forensic Medicine. § Distinguished in Midwifery.

## UNIVERSITY OF MANCHESTER.

### Diploma in Bacteriology.

At the annual meeting of the Court of the University of Manchester approval was given to the institution of a special Diploma in Bacteriology. This is the first diploma in this subject instituted in this country, and the courses of instruction, which candidates will be required to attend before presenting themselves for examination, are designed to supply a thorough training in the general principles of the subject, together with advanced courses in one or more special branches.

Graduates in medicine and in science of any approved university may enter for the course, and the syllabus has been designed to meet the requirements of medical graduates who wish to qualify for bacteriological posts or to obtain a special knowledge of medical bacteriology, and of graduates in science who desire to take up some branch of bacteriological work.

The diploma will be awarded to candidates who have, after graduation in science or in medicine, attended the prescribed courses over at least one academic year, satisfied the examiners in the written and practical examinations, and presented a satisfactory thesis on an approved subject.

The course of study includes (a) courses of instruction in general bacteriology, including the morphology and physiology of bacteria and bacterial classification, the history of bacteriology, quantitative methods of bacteriological investigations, and elementary bacteriological chemistry.

(b) Special courses of instruction in two or more of the following subjects must also be taken (1) bacteriological analysis of water, milk, food, etc., (2) advanced bacteriological chemistry, (3) biometry, (4) parasitism, infection and resistance, (5) epidemiology, (6) comparative pathology.

The examination will consist of two written papers on the general subjects, together with an oral and practical examination, a written paper on each of the special subjects selected, together with such oral and practical examination as may be required by the examiners. Candidates must, during the second half of their course of study, select some subject to be approved by the professor, on which they must submit a thesis at the time when they present themselves for examination, or within three months from that date. This thesis must include a report on personal observations carried out in the laboratory.

The increased importance of bacteriology in human and veterinary medicine, in agriculture, and in other branches of applied science, makes it very desirable that an adequate course of training should be available for those who wish to undertake bacteriological work of any kind. It is impossible to include in the ordinary medical curriculum more than the rudiments of this subject, and practically no provision is at present made for non-medical students, such as those studying biochemistry and kindred subjects, to whom a knowledge of bacteriological methods would often be of the greatest service. It is hoped that the action of the University in instituting this new diploma will meet the needs of a considerable number of post-graduate students, for whom no adequate provision has hitherto been made, and will help to supply efficiently trained bacteriologists for the numerous posts for which they are now required.

### Delepine Research Fellowship.

Applications from medical graduates for the Sheridan Delepine Research Fellowship in preventive medicine, value £300 per annum, must be received by the Internal Registrar of the University by June 15th. The fellowship, which is for one year from October 1st, 1923, is founded in memory of the late Professor Delepine, and the candidate elected will be required to register as a research student of the University, and to devote the whole of his time to research in the department of bacteriology and preventive medicine.

## SOCIETY OF APOTHECARIES OF LONDON.

THE following candidates have passed in the subjects indicated:

**SURGERY.**—B. Basuny, W. A. Drake, E. W. Hicks, \*L. K. Htoo, W. J. Jameson, C. S. Laurence, J. Totton.

**MEDICINE.**—B. Basuny, A. J. Dowek, A. Gullertein, M. Hawke, J. Totton.

**FORENSIC MEDICINE.**—W. A. Drake, O. Sinanides, M. A. E. Somers, B. Zeitoun.

**MIDWIFERY.**—W. J. Jameson, W. R. H. Pooler, A. Vasudev, H. Whitby.

\* Section I. † Section II.

The diploma of the Society has been granted to Messrs. B. Basuny, M. Hawke, W. J. Jameson, C. S. Laurence, J. Totton, A. Vasudev.

A LONG series of post-graduate lectures in general medicine and surgery, and in various specialties, have been arranged by the University of Vienna for the months of July, August, and September. There will also be a refresher course from September 17th to 29th. Programmes can be obtained on application to the Bureau des Fortbildungskursus, Frankgasse 8, Wien IX.

THE Central Midwives Board for England and Wales met on Thursday, May 24th. A special meeting was held first, followed by the ordinary monthly meeting. Sir Francis Champneys presided at both. The business dealt with at the latter meeting consisted of the usual routine. The Standing Committee reported the receipt of a letter from the Registrar of the General Medical Council stating that the Penal Cases Committee of the Council, in a recent case before it, recognized the importance of ensuring that certified midwives should not be induced by medical practitioners to undertake operative procedure outside their province.

## Obituary.

JOHN CHIENE, C.B., M.D., LL.D., D.Sc., F.R.C.S.E.,  
Emeritus Professor of Surgery, University of Edinburgh.

A STRIKING figure of a past generation has gone with the death on May 29th of Emeritus Professor John Chiene, C.B., at the age of 80. Professor Chiene, since he gave up the Chair of Surgery in 1909, had lived in retirement at his country house, Aithernie, Davidson's Mains, near Edinburgh. His end was quiet and occurred after a few hours' illness, for he had been in excellent health on the preceding day.

Professor Chiene was born in Edinburgh on February 25th, 1843—a year celebrated in Scottish annals as the year of the "Disruption"; his father was Mr. George T. Chiene, an Edinburgh accountant, of a Fife family. He was educated at Edinburgh Academy, where at the ages of 16 and 17 he gained respectively the Ferguson and Mitchell Medals for Mathematics. Perhaps this early attention to mathematical studies directed his mind to trigonometry, for all his old pupils will remember his fondness in later life for the triangle. At school he played in the football "twenty" and in the cricket eleven, and at a later stage supported the Academical "twenty" of former pupils. A still more intimate interest in Rugby football was evinced by the fact that he was first President of the Scottish Football Union in 1873, and held the same office for a further period in 1877.

He spent a short period of study in Paris, Berlin, and Vienna, and after the usual medical course at Edinburgh took the M.D. degree with honours in 1865. The next year was spent as house-surgeon with Mr. Syme, then Professor of Clinical Surgery in the Royal Infirmary. Here one of his fellow residents was Mr. A. G. Miller. A previous house-surgeon with Professor Syme, eleven years before, had been Joseph Lister, who had left behind in Edinburgh an example of experimental work in surgery, controlling the results of his researches by microscopical observations. When Lister returned to Edinburgh in 1869 as successor to Syme in the Chair of Clinical Surgery, Mr. Chiene spent two hours or more daily in his wards, engaged in clinical study. This was repeated each year until Lister went to London in 1878, when Mr. Chiene was appointed junior surgeon to the Royal Infirmary. In the summer of 1875, when Lister was absent on the Continent, he left his wards and clinical lectures in charge of Mr. Chiene for two months. The nine years' association had an important effect on Mr. Chiene's work, for when later he became Professor of Surgery, one of the first developments he introduced was a laboratory for surgical pathology in connexion with the chair; he claimed that it was the earliest in Great Britain, and he continued to take a practical interest in it till his death.

During the period of his work in Lister's wards he was also engaged in teaching anatomy, and so he came under the influence of John Goodsir, another of the famous figures

in the Edinburgh Medical School. Shortly after graduation he had become junior demonstrator in Goodsir's class, and in a lecture entitled "Looking Back, 1907-1860," Professor Chiene gave the following account of his final association with Goodsir.

"In the end of February, 1867, my dear master, John Goodsir, sent for me, his junior demonstrator of anatomy, to his house at South Cottage, Boswell Road, Wardie, off the Granton Road. I found him lying on a camp bed in a narrow room (in which, I understand, Edward Forbes died), a small table at his side, and on the table his Bible and *Quain's Anatomy*. He asked me how his students were getting on, and bade me farewell. His last words were, 'Teach my students, Dr. Chiene. Good-bye.' He died shortly afterwards, on the 6th of March, and I have taken these words as my life-motto."

Goodsir was succeeded in the chair by William Turner (later Sir William), and by him Mr. Chiene was promoted

to the post he had held of senior demonstrator in the Anatomical Department of the University. Three years later, in 1870, Mr. Chiene began to lecture in the Extra-Mural School on operative surgery, and next winter on systematic surgery. In this course he tells us he introduced two things he had never seen before in a lecture room—coloured chalks for the blackboard, and a naked man on whose skin he delineated the flaps of amputations and other surface markings. The latter innovation was banned by some of the University authorities, though the prohibition was disregarded. The class was originally held in Minto House, which had been inaugurated by Syme and has been immortalized by John Brown as the scene of Ailie's operation in *Rab and His Friends*. As Minto House disappeared in the course of city improvements to make way for the new Chambers Street, Mr. Chiene and other lecturers found a resting place in the dwelling house at 27, Nicholson Square. Here the dining room of the house speedily proved too small for his growing class, and with the help of his fellow lecturers a classroom was run up in the front garden between a Friday and the following

Photograph by

[A. Susan Watson, Edinburgh.]

PROFESSOR JOHN CHIENE.

Tuesday. The class in surgery continued to grow and, beginning with 13 students, in a few years numbered 155, a large class for an extra-mural lecturer. In this he enjoyed the good fortune that had in several cases before his time proved the making of a young lecturer, since he was competing for the students' favour against the aged Professor Spence in the University, whose lectures, from the accounts of those who attended Chiene for instruction, were very dreary. In 1882 Mr. Chiene was elected to the Chair of Surgery in succession to Professor Spence, gaining the post by a narrow majority over the late Mr. John Duncan.

His early success with students was now shown to be due to special personal gifts as a teacher, combined with great simplicity and earnestness, a faculty for clear exposition, and a racy and genial humour. In the wards where his clinical teaching was carried out, sympathy and kindness of heart were characteristics that commended him both to students and patients. Along with this, however, he had a

capacity for direct speaking which gained for him among the students the sobriquet of "Honest John," and sometimes proved a cause of intimidation to the diffident or of offence to the high-spirited. He was dominated by his feeling of responsibility as a teacher. His lectures were directed towards inculcating the principles of surgery with relatively little regard for changing details of operations. As a result, to anyone reading over notes of Professor Chiene's lectures delivered thirty years ago, there appears to be very little requiring alteration in the light of fuller modern knowledge.

Another matter which receives, perhaps, too little consideration in present-day medical schools is that he taught rather with the object of rendering his students efficient for general practice than with the view that they should become specialists in surgery. The apophthegms which often cropped up in his lectures displayed a shrewd knowledge of human nature and keen perception of fundamental facts. Such sayings as "A pimple on a man's nose is of more importance to him than a sarcoma in his neighbour's thigh"; "Surgery is nothing but a knowledge of anatomy with common sense and a little bacteriology added"; "Find out all you can about your patient's lesion by asking questions with your hands behind your back; so soon as you touch him he begins to question you"; these were current coin with many generations of students. Favourite books were recommended to every class, such as Hilton's *Rest and Pain* and *The Meditations of Marcus Aurelius*; for Gilbert White's *Natural History of Selborne* Chiene had much the same lasting veneration that Sydenham entertained for *Don Quixote*. In clinical teaching Chiene was fond of drawing the attention of his dressers to two sketches hung in the side room of his ward for their benefit, one illustrating a mother bird feeding a nestful of gaping youngsters—the wrong kind of teaching—the other representing a new-fledged chick picking up grains of corn for itself—the correct method of gaining knowledge.

His publications were not many. A collection of *Lectures on Surgical Anatomy*, with 31 plates, was published in 1873, while he was still an extra-mural lecturer, and a small fasciculus entitled *Principles of Surgery* was issued in 1882, the year in which he was elected to the chair of surgery. He made also occasional contributions to periodical medical literature.

In 1900, when local patriotism was equipping hospitals in various parts of the country to aid the forces in South Africa, he went out as the senior surgeon of an Edinburgh hospital, becoming, soon after arrival in South Africa, Consulting Surgeon to the South African Field Force. A series of interesting letters recording his experiences were published in *The Scotsman* at the time, and he later received the decoration of C.B. in recognition of his services. In 1908 he received the degree of D.Sc. from Sheffield University, and in 1910, after his retirement, the Universities of Glasgow and Edinburgh both conferred the degree of LL.D. upon him.

An indication of the affectionate regard entertained for him was afforded by a dinner given in his honour in 1911 by the survivors of his sixty-two house-surgeons. Letters of appreciation were received from all, save one in a distant part of the world, and although some were dead and many were scattered to the ends of the earth, nearly forty were present in Edinburgh to celebrate the occasion. A plaque of his head cast in silver, the work of Mr. W. G. Stevenson, R.S.A., was presented to him at this time and a replica in bronze was provided for each of the old residents. About the same time his portrait was painted for a number of friends and admirers by Mr. Fiddes Watts, R.A.

In 1869 Mr. Chiene married Elizabeth Mary, daughter of David Lyall of Calcutta, who survives him, as well as two sons and one daughter. The elder son is a well known surgeon in Edinburgh.

The funeral took place on Friday, June 1st, at the Dean Cemetery, Edinburgh, and was attended by a large gathering representative of the medical profession and general public. At the grave a short service was conducted by the Rev. Dr. Stott, parish minister of Cramond. Among the pall-bearers were Principal Sir Alfred Ewing, K.C.B., LL.D. (representing the University of Edinburgh); Sir David Wallace,

K.B.E., C.M.G. (representing the Royal College of Surgeons, Edinburgh); and Sir Joseph Fayrer, Bt., C.B.E. (representing the Royal Infirmary of Edinburgh).

#### APPRECIATIONS.

By Sir HAROLD STILES, K.B.E., F.R.C.S.E., Regius Professor of Clinical Surgery, University of Edinburgh.

To one who has been pupil, house-surgeon, and subsequently for ten years a University assistant, to the late Emeritus Professor Chiene, it is a privilege, as well as a labour of love, to endeavour to pay tribute to his memory. That he possessed such a strong and many-sided personality, that he was such a well known and widely esteemed citizen, so highly reputed as a surgeon, so famous and beloved as a teacher, as well as so full of humanity, makes the task no easy one.

Chiene was appointed to the chair of systematic surgery in 1882. His reputation as an extra-mural teacher had been so great that the writer purposely delayed taking out a course of lectures in surgery until Chiene had become professor. One cause of his great success as a lecturer was the fact that he never wrote out his lectures in full. They were always thought out afresh each year. I well remember, when his university assistant, the mosaic appearance of his printed syllabus, which was crossed in all directions with jottings he had made at various times. Although he took a keen interest in the science and progress of surgery, he was not a laborious reader of the subject. He had, however, a great gift for weeding out the grain from the chaff of surgical literature. Like his great masters, Syme and Lister, he was an individualist; his lectures were founded almost entirely on his own observations and experience. He presented his facts in a simple, original, and logical manner and with such a fine sense of proportion that the student got a mental perspective of surgery and a grip of its principles well calculated to prove of lasting value to him in his future career. Few teachers accomplished so successfully the difficult task of lecturing to juniors and seniors in the same class, and few left such a deep and lasting impression of the principles which should guide the practitioner in dealing with the surgical conditions he would be most likely to meet with in general practice.

As a clinical teacher Chiene was equally successful and popular. It was a treat to see with what consummate skill he used to brush aside details and demonstrate how the cases illustrated the surgical principles he so forcibly laid down in his systematic lectures. No one could have been more earnest and conscientious in clinical teaching, and so convinced as he of its value, that it was a serious offence for a student to appear in his wards without his notebook and pencil ready to hand.

Chiene could not be regarded as a rapid or brilliant operator, nor would he have wished to be so considered. Having been a demonstrator, first under Goodsir and then under Turner, he was a good anatomist and could operate rapidly when the necessity arose, but he always put safety first, and anything in the shape of playing to the gallery was repulsive to him. His success as an operating surgeon was due in no small measure to the judgement—he knew what to do as well as how to do it. Unfortunately for him, however, in spite of his strong character and in spite of the fact that he had no lack of surgical courage, he was possessed of a sensitive and, in some respects, a nervous temperament, which made the strain of his operative work all the heavier; moreover, the anaesthetic was always a source of anxiety to him. It was this trait in his character that made him happier in the lecture room and wards than in the operating theatre.

When Lister left Edinburgh, it was Chiene who bore the brunt of the battle of "Listerism" which was being waged in the Edinburgh Royal Infirmary, just as it was Hector Cameron who fought it in Glasgow. Chiene's victory was all the more creditable considering the strength of the forces arrayed against him. Chiene was brought up in the school of anatomical surgery which prevailed at the time. His intimate association with Lister and the discovery of the tubercle bacillus by Koch in the same year as he was appointed Professor of Systematic Surgery, combined with his keen foresight and wide outlook, were doubtless the main

influences which determined him to set up a laboratory of bacteriology and surgical pathology in the University. This was the first teaching bacteriological laboratory in the United Kingdom, and, by establishing it, Chiene set the example, in the academic teaching of surgery, of cultivating the subject as a science so that its art might be better taught and promoted. Although he was not himself a laboratory worker, he spared neither time nor money to encourage research by his assistants. I am glad once again to state that I would not be occupying the Clinical Chair had it not been for the facilities which the laboratory afforded me for carrying on original investigations in surgical pathology and for the generous help and encouragement given by my chief.

During the later part of his occupancy of his chair, Chiene began to feel the effects of his strenuous life, and though destined yet to live beyond the allotted span, his honest and conscientious nature prompted him to sheathe his sword and hand over the command to a surgeon of the younger generation. That he felt the wrench keenly and sorrowfully is only human, and it was a great disappointment to his many friends that he so seldom emerged from the retirement of his charming retreat overlooking the Bruntisfield golf-links and the banks of the Forth.

Doctors, as a rule, have little time or inclination for public work outside their professional duties, but of Chiene it may truthfully be said that, in spite of his arduous routine work, he gave freely of his time and thought on behalf of many a project concerned with the welfare of the community. His commanding presence, his strong yet genial countenance, and his popularity made him a familiar figure to the citizens of Edinburgh. Chiene was more than a surgeon and teacher—he was a man of broad and statesman-like vision; he “reflected the human spirit always on the nobler side.” He possessed “those finer qualities of head and heart which count for so much in life,” and are such a valuable asset especially to a clinical teacher. It is safe to assert that his great natural ability, his strong individuality and lovable personality, would have assured him success in any sphere of life. He was an apostle of common sense, and was able to leave his lectures and clinics with an amount of shrewd and helpful everyday philosophy much appreciated by his pupils. The methods which he introduced and the influence which he exercised on the Edinburgh Medical School have been far-reaching in their beneficence. His name will go down to posterity as a man of wide sympathies and high ideals, as well as a great teacher and sound surgeon.

Chiene was a famous football player and the first President of the Scottish Football Union. To the present generation he was a familiar figure on the golf course and on the curling-pond. Like many of my contemporaries, I owe some of my happiest days and reminiscences to the foursomes in which I was privileged to take part with my old and revered teacher, in the days of old Luffness and later at Machriehish. The way Chiene played “with his head,” the moral support he gave his partner, and the miracles he performed with his “little black spoon” made him a tower of strength to his partner. He knew his Bible as well as most ministers, and many a text was quoted in his classroom and wards in support of a principle or rule of conduct. His favourite text for the golf links was: “In quietness and confidence shall be your strength”—the best motto also for a surgeon. If his partner should miss a short putt, he would say, “Never mind, Harold; just think how happy you have made Harry or Francis” (both of whom, alas! have crossed the bar before him). He loved to play a good old foursome because, as he said, it teaches us to “bear one another’s burdens.” He was a very “clubbable” man, and used to advise the young practitioners to join a social club as well as the local medical society. Full of pawky Scottish humour and a good raconteur, he was always a great asset to the several medical dining clubs for which Edinburgh has long been famous. Although not an orator in the true sense of the word, he was an original and attractive speaker.

Professor Chiene was particularly happy in his home life, which was very dear to him. Deep sympathy will be felt for his family, and for his devoted and courageous wife, who so ably and efficiently shared with him the burdens as well as the joys of a life so strenuous and useful, so full of honour, service, and achievement.

By Sir DAVID WALLACE, K.B.E., C.M.G., President of the Royal College of Surgeons, Edinburgh.

Mr. Chiene, prior to his appointment to the chair of surgery in the University, was a successful teacher in the extra-mural school, for which he always retained a keen interest, as he believed it went far towards equipping men for wider spheres of work. Teaching was his chief delight, and he was unflinching in his efforts to inspire students with the love of work. His ideals were high and always far removed from the merely commercial side of his profession. He inculcated them at every opportunity, both in the classroom and in the wards of the infirmary. He taught many generations of students; his classes in the eighties and early nineties were very large, and the members of them enthusiastic admirers of their teacher. His style was peculiarly his own—vivid and graphic pictures of the subject, and interest added to the description by whimsical and humorous illustrations and asides, many being Biblical in their origin. The human side was constantly kept in view, and in the wards the sympathy he showed to the patients, while keenly alive to the treatment of their physical ailments, was always apparent. Perhaps no teacher left deeper impressions upon his students than he did; his common sense and laconic statements being so much to the point and given in such a clear manner that they could not be forgotten. Innumerable doctors have been able, years afterwards, to recall his actual words and what he advised in the examination and treatment of cases, and have found them of inestimable value in their work. His teaching, while to a great extent based on anatomy, never lost sight of surgical pathology, in which early in his career he took a great interest.

Mr. Chiene never allowed private practice to interfere with his public services, and on many occasions refused to see a patient or go into the country in consultation, because he had his university lecture or infirmary work to do, and that he considered was his first duty. Nevertheless, for many years he had a large private practice; he gave much thought and care to his patients—many of whom became close personal friends. He early recognized the great importance of the mind over the body and that “a merry heart doeth good like unto a medicine.” He had numerous friends in many countries, who recognized his genial nature and appreciated the power of the man and his influence for good.

By A. G. MILLER, M.D., F.R.C.S.E., Consulting Surgeon to the Royal Infirmary of Edinburgh.

John Chiene was in the same class with me at the Edinburgh Academy. He was always well up in the class, of which the clerk was Alexander Moore-Stuart. He got a medal in mathematics. He was always good at games, in which he took an interest to the last. At college we did not see so much of each other because I began my medical studies a year before he did. We were more intimately brought in contact after graduation, when resident surgeons in the Royal Infirmary. He was with Syme, I with Spence. We were both hard worked, having charge of about seventy beds, but in the evenings we were often together. Chiene’s cheerful, kindly, and humorous disposition made him ever a welcome and pleasant companion. In many ways we were rivals, but always the best of friends, and this was largely due to his unflinching good nature.

Chiene’s devotion to anatomy and surgery made him well qualified for the posts he ultimately filled. I remember his saying to me in these early days of our professional life, “If you want to know a subject thoroughly, teach it.” For many years Chiene and Mitchell Banks and I exchanged greetings at the new year. After Banks’s death there were only the two who exchanged birthday greetings—for we were the same age all but two days.

After Chiene retired from active work I used to go down and see him occasionally at Aithernie. He was always the same—cheerful, friendly, and jocular. We often talked of the Academy days and of the sadly decreasing number of our old class fellows. It was a pleasure to see “Honest John” sitting in his easy-chair at the fireside with his little patience card-table at his elbow, and on the other side of the fire Mrs. Chiene with her kindly smile of welcome. Chiene married comparatively young, and had his home brightened by the charming lady who survives him. The two

were well fitted to each other. There was ever and evidently a strong and happy fellowship between them. In Chiene's character and conversation there was always a marked reverence and regard for holy things, as witness his little book, *The Master: His beliefs, His promises, His blessings, His prayers, His commands, and His warnings.*

Dr. FRANCIS RAYMOND MITCHELL HEGGS, of Mapperley, Nottingham, died from pneumonia on May 19th, aged 48. He was a native of West Bromwich, and received his medical education at the University of Birmingham and at St. Mary's and the London Hospitals. He obtained the L.S.A. in 1896 and the diplomas of M.R.C.S.Eng., L.R.C.P.Lond. in 1900, and subsequently served as house-surgeon to the Wolverhampton and Staffordshire General Hospital. He took great interest in army medical work, and while in the Isle of Wight served as captain in Princess Beatrice's Rifles. He received the thanks of the late Prince Leopold and Princess Beatrice for the assistance he rendered when the Prince was thrown from his horse. On the outbreak of war in 1914 Dr. Heggs, who attained the rank of major in the R.A.M.C.T.F., was among the early volunteers; he commanded the third 1st Notts and Derby Mounted Brigade Field Ambulance, and saw much service in France. He was severely gassed, and in consequence suffered from chronic bronchitis. Dr. Heggs, who was a member of the Nottingham Division of the British Medical Association, was by nature quiet and retiring. He was very popular with all with whom he came in contact. He is survived by his widow, three sons, and a daughter. Many friends and patients attended the funeral service.

## The Services.

### PENSIONS APPEALS.

We have received the following statement from the Ministry of Pensions, with a request for publication.

The Minister of Pensions desires to correct a misunderstanding which has arisen regarding the action of the Ministry consequent upon certain decisions by the Pensions (Assessment) Appeal Tribunals on appeals against final awards. It is erroneously supposed that the setting aside of a final award by a Tribunal implies that the award will be increased, or, if the appeal was against a nil disablement award or final weekly allowance, that a fresh award will be made at once. This is not the case. Under the War Pensions Act, 1921, the Tribunal is empowered to confirm, increase, decrease, or set aside a final award, and its decisions are equally binding on the Ministry of Pensions and the appellant. The setting aside of a final award ordinarily means that the Tribunal, without challenging the assessment, considers that the time has not yet come for the making of a final award. It does not necessarily follow that an increase in the current award will be due, or that a fresh award will be made if none is current. The man reverts to the position he was in before the final award was made. His case falls to be reconsidered under the Pensions Warrants by the Ministry, and where it is necessary to obtain a further assessment by a Medical Board of his degree of disablement this is done. In any event he has the right to claim re-examination on the ground that his condition has deteriorated. If the man's condition is found to have deteriorated, a fresh award is made; but if his condition has not deteriorated the current award remains in force. At a later stage, however, his case will again be considered with a view to a final award being made, and if the man is dissatisfied with such final award he can avail himself of a further right of appeal to the Pensions (Assessment) Appeal Tribunal.

### OPERATIONS IN WAZIRISTAN, 1920-21.

THE names of the following officers have been brought to notice for distinguished service during the operations in Waziristan, 1920-21, by His Excellency Lord Rawlinson of Trent, Commander-in-Chief in India, in a dispatch dated October 23rd, 1921:

**Commands and Staff.**—Colonel W. E. Hudleston, C.M.G., C.B.E., D.S.O. (late R.A.M.C.).  
R.A.M.C.—Captain (Acting Lieut.-Colonel) A. G. Biggam, O.B.E., Captain (Temporary Major) W. M. Cameron, Major (Acting Lieut.-Colonel) H. Harding, Captain (Acting Lieut.-Colonel) G. M. Ingoldby, Captain (Acting Major) J. M. MacKenzie, M.C., Captain (Acting Major) O. Popham, Captain (Acting Major) M. P. Power, M.C., Captain T. H. Sarsfield, Captain B. C. O. Sheridan, M.C., Captain R. I. Sullivan, M.C.  
**Indian Army Medical Services.**—Lieut.-Colonel (Acting Colonel) C. Hudson, C.I.E., D.S.O., Captain (Acting Major) J. B. Vaidya, I.M.S., Temporary Captain G. D. D. Wijesekere, I.M.S., 2nd Cl. Asst. Surg. W. G. Sherard, I.M.D., 3rd Cl. Asst. Surg. C. J. Smith, I.M.D., 1st Cl. Sub-Asst. Surg. Bashir Ram, I.M.D., 2nd Cl. Sub-Asst. Surg. Dayal Singh, I.M.D., 2nd Cl. Sub-Asst. Surg. Jawala Singh, I.M.D., 2nd Cl. Sub-Asst. Surg. Nand Lal Wig, I.M.D., 3rd Cl. Sub-Asst. Surg. Santan Singh Bisht, I.M.D., 3rd Cl. Sub-Asst. Surg. Somasundar Mudaliar, I.M.D.

Dr. Oguntola Sapara, Medical Officer, Nigeria, has been appointed to the Companionship of the Imperial Service Order.

Third class Assistant Surgeon George David Rodrigues, Indian Medical Department, has been awarded the medal of the Military Division of the Order of the British Empire, for services rendered in connexion with the military operations in Malabar, 1921-22.

### DEATHS IN THE SERVICES.

LIEUTENANT-COLONEL HENRY BRUCE MELVILLE, Bengal Medical Service (retired), died suddenly at Tain on April 15th, aged 59. He was the son of the late Robert Hayes Melville, of Partick, Glasgow, and was educated at the University of Glasgow, where he graduated M.B. and C.M. in 1885, also a member of the Medico-Psychological Association. After serving as a senior medical officer at the Crichton Royal Institution, Dumfries, he entered the Indian Medical Service as surgeon on September 30th, 1889, passing into Netley second and passing out first of his term. He became lieutenant-colonel after twenty years' service and retired on January 22nd, 1921. Most of his service was spent in civil employ in the United Provinces, where, at various times between 1898 and 1917 he filled the posts of civil surgeon of Fatehgarh, Faizabad, Masuri, and Naini Tal, and superintendent of the Lucknow Central Gaol, and from 1913 to 1915 that of civil surgeon to the new capital, Delhi. In May, 1917, he was appointed civil surgeon of Lucknow, and professor of midwifery in Lucknow University, and six months later residency surgeon of Kashmir, where he finished his service. He served on the North-East Frontier of India in the Lushai campaign of 1890.

Lieut.-Colonel John Stevenson, R.A.M.C. (retired), died recently at Hove, aged 75. He was educated at Glasgow University, where he graduated M.B. and Ch. in 1874; he took also the D.Sc. in 1875, the Fellowship in 1883 and 1890. After serving as resident medical officer at the Edinburgh Royal Infirmary he entered the army as surgeon on August 4th, 1878, became lieutenant-colonel after twenty years' service, and retired on November 2nd, 1898. After retirement he was employed at Berwick in 1889 and at Aberdeen in 1902-03.

Lieut.-Colonel Ernest Albert Churchward Matthews, D.S.O., I.M.S., died on May 8th, aged 40, from injuries received in a motor accident near Jerusalem. He was born on August 3rd, 1873, and educated at Cambridge, where he graduated B.A. in 1894, and M.A., M.B., and B.Ch. in 1899; he was a student at St. Bartholomew's, and took the M.R.C.S. and L.R.C.P.Lond. in 1898. He entered the I.M.S. on January 27th, 1900, and became lieutenant-colonel after nineteen and a half years' service. He served in the Mohmand campaign of 1908, on the North-West Frontier of India, receiving the frontier medal with a clasp; and in the recent war, in the operations in France and Flanders from December, 1914, to March, 1918; and with the Egyptian Expeditionary Force from April to October, 1918, being mentioned in dispatches (June, 1916, and May, 1918), and receiving the D.S.O.

Lieut.-Colonel William Malloch Hart, M.C., Canadian Army Medical Corps, died at Ottawa, after an operation, on April 17th. He graduated as M.B., Manitoba University, in 1907, and took the diploma of M.C.P.S., Manitoba, in the same year. He served in the C.A.M.C. throughout the war, becoming major on December 5th, 1916, and lieutenant-colonel on May 17th, 1918, and received the Military Cross on January 10th, 1917. He was employed on soldiers' civil re-establishment work at Ottawa.

Brevet Colonel Henry Aymer Haines, R.A.M.C. (retired), died at Strood, Kent, in April, aged 61. He was born at Mallow, and educated at Queen's College, Cork, graduating in 1882 as M.D., M.Ch., and M.A.O. of the Royal University, Ireland. He entered the R.A.M.C. as surgeon on January 31st, 1885, became lieutenant-colonel after twenty years' service, and received a brevet colonelcy on January 1st, 1917, retiring on May 2nd, 1918. He served in the Chitral campaign on the North-West Frontier of India in 1895, and received the frontier medal with a clasp.

Surgeon Lieut.-Colonel Hopetoun Currie Collier, R.A.M.C. (retired), died at Paignton, South Devon, on May 10th, aged 82. After taking the L.R.C.P. and S. Edin. in 1862, he entered the army as assistant surgeon in September, 1863. He became surgeon major on April 28th, 1876, and retired with an honorary step of rank as brigade surgeon in March, 1886. He served in the Abyssinian campaign of 1868, was present at the action of Arogee and at the capture of Magdala, and received the medal. In the old regimental days he served in the 4th Foot, the King's Own Royal Lancaster Regiment, and in the 16th Foot, the Bedfordshire Regiment, then known by the nickname of "the Peacemakers."

Captain Thomas Copeland Storey, M.C., R.A.M.C., died at Cologne on April 25th, aged 32. He was educated at the Middlesex Hospital and at Durham University, where he graduated M.B. and B.S., with honours, in 1912, and M.D. in 1916. He was in the Special Reserve of the R.A.M.C. before the war, having attained the rank of captain from April 1st, 1914; subsequently he took a permanent commission, being ranked as captain from April 1st, 1915. He served throughout the recent war, and received the Military Cross on July 26th, 1918.

Flight-Lieutenant Harold Wilbert Street, Royal Air Force Medical Service, died of pneumonia at Constantinople on April 21st. He was a Canadian, and was educated at Toronto University, where he graduated M.B. in 1918. He had only recently entered the service.

## Medical News.

EXCELLENT work has been done on behalf of the chemical industries of this country by the Association of British Chemical Manufacturers during the short period of its existence as an organized body. The members of the association are manufacturers, but the association is not a trading institution and is not concerned with profit earning for itself; its principal object is the advance of British chemical manufacturing industries as a whole. Nearly one hundred and fifty firms, representing a capital of over £100,000,000, are members. A sign of the activity of the association in promoting business facilities between manufacturers and purchasers is seen in the issue of a directory of its members with a classified list of their products and manufactures, including many medicinal articles and fine chemicals. Under the name of each article in the list appear the names of the firms who manufacture it. The directory also contains indexes to the list in French, Spanish, Italian, Portuguese, and German. The association offers to advise on all matters relating to the chemical trade and to make inquiry on behalf of intending purchasers for materials they have had difficulty in obtaining.

IT will be remembered that last year (JOURNAL, July 1st, 1922, p. 26) the Council of the British Medical Association made an appeal for the starving doctors of Russia, and this appeal was repeated at the end of December (SUPPLEMENT, December 30th, 1922, p. 233). Subscriptions were limited to five shillings, and nearly £2,000 has been raised. The condition of the members of the medical profession in Russia has not improved in the meantime, but, if anything, their want and misery have become worse. An appeal is being made in aid of Russian doctors and Russian medical institutions by an influential international committee; subscriptions should be sent to the secretariat of Dr. Fridtjof Nansen, 54, Rue du Rhône, Geneva, Switzerland. Another appeal, in aid of the Russian doctors and medical staff in the famine-stricken regions, has been issued by the Medical Aid Committee, of which Miss Margaret Llewelyn Davis is president; donations in money and in kind should be sent to the secretary of the Medical Aid Committee, 68, Lincoln's Inn Fields, London, W.C.2. It may not be amiss also to remind our readers that the fund opened by the Council of the British Medical Association is still open; subscriptions (of five shillings and multiples of five shillings) should be sent to Mr. Ferris-Scott, Financial Secretary, British Medical Association, 429, Strand, London, W.C.2.

THE annual meeting of the University of Durham Medical Graduates Association will be held in the College of Medicine, Newcastle-on-Tyne, on Monday, June 25th, at 5 p.m. The annual dinner will be held the same evening in the King's Hall, Armstrong College, Newcastle-on-Tyne, at 7.45 p.m. Durham medical graduates who are not already members of the association and who desire to join are requested to communicate with the Hon. Secretary (North), Royal Victoria Infirmary, Newcastle-on-Tyne.

In connexion with the courses of lectures arranged by the Fellowship of Medicine to which reference was made last week (p. 957), courses in ophthalmology have been arranged at the Royal London Ophthalmic Hospital and in dermatology at the St. John's Hospital for Diseases of the Skin, beginning on Monday, June 11th. These courses will consist of lectures and clinical demonstrations each day in the wards and outpatient departments. The programme for July includes a refresher course at the Royal Northern Hospital, in conjunction with the Central London Ophthalmic Hospital and the Royal Chest Hospital, from July 2nd to July 14th; a fortnight's intensive course in cardiology at the National Hospital for Diseases of the Heart, commencing on July 2nd; and a course of dermatology at the Hospital for Diseases of the Skin, Blackfriars, from July 16th to July 28th. Full particulars can be obtained on application to the Secretary, Fellowship of Medicine, 1, Wimpole Street, W.1.

THE League of Nations Union has arranged a conference on the international labour organization and industrial health to be held at the Royal Sanitary Institute, 90, Buckingham Palace Road, S.W.1, on June 19th and 20th. The conference will meet each day at 10.30 a.m. and adjourn at 1 p.m. for luncheon; it will reassemble at 2.30 p.m. and continue its sitting till 5 p.m.

A POST-GRADUATE course on tuberculosis (including surgical tuberculosis, by Professor A. Broca) will be held at the Hôpital de la Charité, Paris, under the direction of Professor Émile Sergent, commencing on June 13th. The fee is 150 francs.

PROFESSOR LEATHES is unavoidably prevented from delivering the Croonian Lectures before the Royal College of Physicians on the dates announced. The course is therefore postponed.

MR. NEVILLE CHAMBERLAIN, the Minister of Health, was the principal guest at the annual dinner of the Federation of Medical and Allied Services, which took place at the Langham Hotel on May 29th. Sir Berkeley Moynihan, who presided, referred to the family tradition of public service in this country as exemplified in the Chamberlains and others. It was surely a remarkable thing that Queen Elizabeth's great Minister should have had a direct descendant to serve Queen Victoria, and that the son (Lord Robert Cecil) of the Victorian Minister should be the latest but not by any means the weakest of the recruits to the new Ministry. Of all the men in the Government, Sir Berkeley Moynihan thought that the Minister of Health was least to be envied. Around the question of health had arisen many conflicts of opinion, and the Minister had to walk warily. On many questions upon which the medical profession had a right to pronounce, any further progress was limited by the extent to which the public was willing to co-operate; he instanced the campaigns against cancer and against tuberculosis. Mr. Chamberlain, in responding to the toast of his health, remarked that he had heard it said of a certain journal that it contained more truth on its cover than in its pages, and so far as his experience at the Ministry of Health had gone, he began to think that there was more "health" in its title than in its functions. He gave an amusing list of the varied questions, chiefly rent and rating matters, with which he had had so far to deal, and expressed the hope that presently he might arrive at some questions of health. Ever since he had taken any interest in public work he had felt that there was no greater benefit which statesmanship could confer than some measure which might lead to a general improvement in the health of the people, for upon their health depended their enjoyment of life and their prosperity. He was specially impressed by the extent to which research stood in need of encouragement. He once asked an eminent authority why there were so many more specialists on the Continent than in this country, and he was told that on the Continent there were many more endowments, whereas men in this country who were fitted for research had to carry on general practice for a livelihood. Some day a complete health policy for this country might be forthcoming, but it would have to be under a Minister who was fortunate enough to remain in office for more than a few months. It would require more adequate institutional accommodation, or, rather, a better distribution of the institutional accommodation already existing. We had in this country physicians and surgeons second to none, but the best use was not being made of their services. Sir Thomas Horder proposed the health of the other visitors, and responses were forthcoming from Lord Riddell and from Sir William Hale-White. The toast of "The Chairman" was proposed by Mr. Ernest Clarke and very heartily honoured.

THE KING has sent a donation of £100 to the fund that is being raised by the British Empire Cancer Campaign.

AT a meeting of the Royal Sanitary Institute, to be held at Cambridge on June 23rd, Mr. J. E. Purvis, M.A., Secretary to the State Medicine Syndicate, will open a discussion on the grading of milk.

THE Association of Economic Biologists will hold its annual field meeting at Cambridge on Friday, June 15th. Visits will be paid to the School of Agriculture, the National Institute of Agricultural Botany, and the University Farm and Plant Breeding Institute.

THE Section for the Study of Disease in Children of the Royal Society of Medicine will meet in Bristol on June 22nd and 23rd. On Friday afternoon (June 22nd) cases will be shown at the Bristol Children's Hospital, and afterwards, at a meeting in the department of pathology of the university, papers will be read by Dr. J. A. Nixon on the Schick reaction and diphtheria anaphylaxis, by Dr. O. C. M. Davis on certain urinary conditions in childhood, and by Mr. E. Watson-Williams on acute sinus disease in young children. There will be a dinner in the evening, and on Saturday a visit will be paid to Mr. Vesey's farm, Wincanton, to see the production of certified milk.

MESSERS. WATSON AND SON (43, Parker Street, London, W.C.2) have issued a list of second-hand x-ray and electro-medical apparatus.

APPLICATIONS for the Henry George Plimmer Fellowship in Pathology must be sent to the Rector, Imperial College of Science and Technology, South Kensington, S.W.7, by June 25th. Candidates must be qualified to pursue research in pathology (including morbid anatomy, protozoology, bacteriology, and allied subjects in either zoology or medicine or botany).

## Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

IN order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Aitiology*, Westrand, London; telephone, 2630, Gerrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate*, Westrand, London; telephone, 2630, Gerrard.
3. MEDICAL SECRETARY, *Mediscera*, Westrand, London; telephone, 2630, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus*, Dublin; telephone, 4737, Dublin), and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: *Associate*, Edinburgh; telephone, 4361, Central).

### QUERIES AND ANSWERS.

#### ACCIDENT OR ILLNESS.

DR. CLEMENT DUKES (Rugby) writes: In reply to the question of "Pasce" I am able to give him the information he seeks, as I have always kept accurate records of anything that concerned me in my life. I am insured in the Railway Passengers' Accident Assurance for £1,000, on the terms of £6 a week for total disablement, and £1 10s. a week for partial disablement. In December, 1889, I poisoned my thumb during an operation, and was partially disabled for fourteen days, and received £3. In February, 1915, I poisoned a finger in a similar way, was partially disabled for five weeks, and received £7 10s. Again, in May, 1920, by another poisoned finger from the same cause, I was partially disabled for three weeks, and received £4 10s. Further, on one of these latter occasions, when totally unfit for my work from my septic state, *The Practitioner* treated me with more than generosity from their fund.

#### INCOME TAX.

"EXES" has bought a half share in a practice previously worked by one practitioner only; the receipts have not yet materially increased, and "Exes" inquires what would be a reasonable addition to make to the expenses.

\* \* The liability to assessment is determined by the average profits of the practice during the three years previous to the year of assessment. If owing to the succession of the present firm to the previous proprietor of the practice the actual earnings for that year fell short of the sum assessed the firm can claim an adjustment to the actual profits. In neither case is any estimate of expenses required, inasmuch as either on the three years' average or on the current year's basis it is the amount of the profits after deducting actual expenses that is in question. Among the expenses to be included will be the cost of running and repairs of the additional car, together with the wages, etc., of a chauffeur, and a proportion of the expense of upkeep of our correspondent's house, provided that patients are seen there as well as in the surgery belonging to the practice.

"SIMPLEX" qualified in March, 1921; between that date and September, 1922, he earned sundry amounts as assistant or locumtenent; since then he has been in partnership. He is about to purchase a car and inquires as to the basis of his return and the allowance due for the cost of his car.

\* \* The firm is assessable in one sum—less the appropriate allowances for each partner—on the average profits of the practice after deducting expenses, for the previous three years. The tax payable by "Simplex" on that assessment will be on his fractional share of the assessment less his own allowances and reliefs. So far as the car is concerned, no allowance is legally due, as it cannot be regarded as an expense for income tax purposes; the cost of the car is an outlay of capital, and the

only allowance that arises out of the transaction is the inclusion of the net cost of replacement in any future year, when the car is replaced, among the firm's professional expenses.

#### Car Transaction.

"A. L." bought a 15.9-h.p. Star in July, 1914, for £375; he sold it in March, 1919, for £250, buying a Ford for £250. In December, 1919, a second (Ford) car was bought for £425, and in March, 1922, the first was sold for £90 and a 13.9 Calcott bought for £450.

\* \* In the circumstances we suggest that the car equipment may fairly be dealt with as a whole, the result being as follows:

1919.				
Expenditure	£250 + £425	...	...	£675
Less amount received for Star	...	...	...	£250
				£425
Deduct "improvement" cost, £575 - £375	...	...	...	£200
Amount allowable	...	...	...	£125
1922.				
Expenditure	£450 - £90	...	...	£360
Deduct "improvement" cost, £450 - £250	...	...	...	£200
Amount allowable	...	...	...	£160

### LETTERS, NOTES, ETC.

#### RAT-BITE FEVER.

DR. R. ROW, O.B.E., consulting physician, Gokuldas Hospital, Bombay, writes regarding a recent inquiry as to the occurrence of an eruption in rat-bite fever (JOURNAL, March 24th, 1923, p. 542) and encloses reprints of two articles published by himself upon the subject in the *Bulletin de la Société de Pathologie Exotique* (vol. xi, No. 3, 1918, p. 188) and the *Transactions of the Royal Society of Tropical Medicine and Hygiene* (vol. xvi, No. 4, October, 1922, p. 203). Dr. Row refers in the first article to the writings of Waghbhatt, who flourished twenty-three centuries ago, in which the cutaneous lesions produced by rat-bite are described (according to the Marathi translation) as follows: "Burning in the patches; nodular and urticarial eruption; petechial and even haemorrhagic patches on the body; oedematous condition, discoloration, and even ulceration of the nodules; lividity of the mucous membranes and haemorrhages." Dr. Row (in the *Bulletin*) goes on to say that, in his experience of the condition, after a definite incubation period of seven to ten days from the time of the bite a "secondary eruption" appears on the skin, consisting of a few purple spots or nodules (sometimes an extensive eruption), of an urticarial nature, tender on pressure. He gives photographs of a typical case.

#### SMOKING AND CANCER: PIPE OR CIGARETTE?

DR. FITZJAMES MOLONY (Porlock, Somerset) writes: An appeal from the British Empire Cancer Campaign states that one in every seven deaths over 30 years of age is caused by cancer, and that the latter is the most frequent cause of death after that age. It is a question whether cancer of the tongue and throat need be so prevalent. It is largely caused by pipe smoking. I have never seen a case in men or women who smoke only cigarettes, while it is increasingly frequent in men who smoke pipes. The explanation is simple enough. The force of a current of hot air or smoke is in inverse ratio to the size of the bore. In a small-bore pipe the current of air is strong enough to strike the epithelium of the tongue or throat with great force, and it may well be the starting point of cancer. For many years I have advised men over 40 years of age to give up their pipes and take to cigarettes. A pipe with an unusually wide bore is the only relatively safe pipe to smoke. A cigarette should be smoked without a tube or with a very wide-bored one.

#### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 28, 29, 30, 31, 34, and 35 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 32 and 33.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 243.

### SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Six lines and under	...	...	0 9 0
Each additional line	...	...	0 1 6
Whole single column (three columns to page)	...	...	7 10 0
Half single column	...	...	3 15 0
Half page	...	...	10 0 0
Whole page	...	...	20 0 0

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, W.C.2, not later than the first post on Tuesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive *postes restantes* letters addressed either in initials or numbers.

## A Post-Graduate Lecture

ON THE

## TREATMENT OF UTERINE FIBROIDS:

## OPERATION OR RADIATION?

DELIVERED AT THE MANCHESTER ROYAL INFIRMARY

BY

WM. FLETCHER SHAW, M.D.,

LECTURER IN OBSTETRICS AND GYNAECOLOGY, VICTORIA UNIVERSITY,  
MANCHESTER; HONORARY ASSISTANT GYNAECOLOGICAL SURGEON,  
MANCHESTER ROYAL INFIRMARY; SENIOR HONORARY  
ASSISTANT SURGEON FOR WOMEN, ST. MARY'S  
HOSPITAL, MANCHESTER.

DURING the last few years there has been a flood of literature, chiefly from radiologists, pleading for radiation treatment of uterine fibroids rather than operation, and making the claim that the haemorrhage can be controlled by this means without any mortality; but from the first the more reliable authorities have recognized certain complications of fibroids as a contraindication to radiation, and this note of warning has been sounded more and more vigorously until now, when many of the radiologists advise operation in all cases in which there is no special contraindication to it.

At first sight radiation would seem to be a great advance in our method of treatment, but when the subject is considered more seriously there are found to be many fallacies and reservations.

In the first place, these papers usually discuss the subject as though haemorrhage was the only symptom. In the majority of instances it is the most obvious symptom, but it is by no means the only one to be considered, and in reviewing the whole subject the others must be conceded their due importance. Fibroids are very prone to undergo degeneration, and this is especially common about or after the menopause, so that many women who have safely passed the menopause require operation, and often an urgent operation, because of this complication. Along with this must be considered the liability of a fibroid uterus to become malignant: there is a considerable divergence of opinion upon the percentage of fibroids which become malignant, but there is no doubt that uteri with these tumours are more prone to this disease than normal uteri.

This aspect of the subject is entirely overlooked by many of the radiologists, who record their cases at too recent a date to allow this change to occur. There is no reason to suppose that when the menopause has been produced artificially by radiation the uterus is less liable to degeneration or malignant disease than one which has passed it naturally. Although my experience of radiation treatment of fibroids is small, I have once had to perform hysterectomy for urgent symptoms of degeneration six years after the menopause had been produced by this method. Before claims so extensive as those advanced by some authors are made it would be well to wait ten or fifteen years before recording the after-results. Moreover, good results are not claimed in the treatment of all fibroids. The cases must be carefully selected and radiation must not be used if the tumour is already undergoing degeneration or is complicated by inflamed appendages. How these conditions are to be diagnosed with certainty is not stated; the responsibility is to be left to a gynaecologist in each case, but, as every gynaecologist knows, it is often quite impossible to say before operation whether a fibroid is undergoing degeneration or is complicated by inflamed appendages.

One further point against treatment by radiation is the method of its action, which is supposed to stop menstruation through the action of the rays on the ovaries. In this way a young woman is as effectually sterilized as by a radical operation; whereas, if operation is undertaken instead of radiation, it is frequently found possible to do a myomectomy and leave a sound functioning uterus and ovaries.

Quite recently Giles<sup>1</sup> and Bonney<sup>2</sup> have usefully called attention to the advantages of myomectomy and pleaded for its more frequent use, although I think the operation is done much more frequently than they believe. It is such a well recognized operation that surgeons perform it in certain classes of case but do not trouble to write about it. In the

figures I quote later I am considering solely the advantages and disadvantages of operation and radiation, and as the risks and complications of myomectomy are about the same as those of hysterectomy I have not separated them. For these reasons I have always considered operation much the safer method of treatment, and would not consider radiation except in rare and carefully selected cases.

The only serious risk in operation for fibroids is the occurrence of embolism—fortunately a very rare accident, but a risk which is ever present, although an operator is lulled into a feeling of false security when no case has occurred for a long period. From this comfortable feeling of security I was rudely awakened by two fatal cases of embolism which occurred quite close together in my practice, and I was compelled to reconsider the whole subject very carefully, as it is a tremendous responsibility to advise a method of treatment which may be dangerous if there is an alternative treatment quite free from danger.

To form a reliable opinion of the relative results of these two methods of treatment it is useless to take a few picked cases; a sufficiently long series of consecutive cases must be taken, all treated by the one method, and the failures recorded. With this object I abstracted the notes of all the cases of uterine fibroids I had seen in the two years 1920-21—a period which included my two cases fatal from embolism.

In several of these cases the fibroids were so small and gave rise to so few symptoms that no treatment was advised, while in the remainder the only method of treatment was operation; so this can be taken as a consecutive series of cases treated by operation, and the number (138) is sufficiently large to give a fair average percentage of the risks of operation and the incidence of malignancy, degeneration, and other complications if the tumour is not removed. Amongst these cases were a certain number, undiagnosed before operation, with complications which could only have led to a fatal result if the whole series had been treated by radiation.

## Mortality.

In this series of 138 operations (hysterectomy or myomectomy) there were four deaths (2.9 per cent.)—two from embolism, one from shock within twenty-four hours of the operation, and one from acute nephritis. Operations upon uterine fibroids have a somewhat greater risk than other simple abdominal operations owing to the anaemic condition of so many of the patients. In this series I find recorded in the notes of five of these patients that they were so anaemic I hesitated to operate, and in three instances kept the patient in bed some time before operation; amongst these five occurred three of my fatal cases, two of embolism and one of shock. If these cases had been handed over to the radiologist the only fatal case would have been the one from acute nephritis, the cause of which was obscure.

However, in trying to hold the balance evenly between the two methods of treatment I must put these four deaths against operation, and I am also accepting the statement that with radiation there would have been no primary mortality.

## Malignant Disease.

Unfortunately, a microscopical examination was not made of all the specimens removed and it is quite possible that some cases of unsuspected malignancy were overlooked. Amongst those which were examined were five specimens of malignant disease of the body, all in women over 50 years of age, so it is quite probable the incidence would have been greater if all these fibroids had been unoperated upon until the patients had reached this age. In two of these cases the patients had ceased to menstruate and so the malignancy was suspected, but in the others there had been no period of amenorrhoea and the malignancy was only discovered in the laboratory.

If all this series of fibroids had been treated by radiation rather than operation the growth would have run its course and there would have been five deaths from this disease as against the four deaths from operation.

In addition to these five cases of malignant disease of the body there were three other cases with carcinoma of the cervix occurring along with fibroids of the body. I have separated these two groups as it is much easier to diagnose carcinoma of the cervix; nevertheless two of these patients

were referred to me by their own doctors on account of the fibroids, the carcinoma of the cervix having been overlooked in each case; had radiation been the recognized treatment for fibroids, the probability is that these growths would have remained undiscovered until a much later period, as the radiologist has no more special training in gynaecological diagnosis than the general practitioner.

#### *Degeneration.*

A degenerating fibroid may cause serious symptoms, either from the effect of the degeneration itself as in red degeneration, or because the degenerated tissue has become infected with organisms, or merely from the absorption of the products of degeneration. This last is, I think, much more important than is usually recognized, and accounts for the profound anaemia, often out of all proportion to the amount of blood lost, and the general ill health from which these patients suffer.

Unfortunately not all the specimens in this series were examined in the laboratory, but of those which were, twenty-one were reported as having undergone degeneration—cystic, red, calcareous, etc.; these degenerations occur much more frequently in fibroid uteri after the menopause when the blood supply is much diminished.

How often degeneration occurs in a fibroid after an artificial menopause produced by radiation I cannot say, my personal experience of this method of treatment being very small, but I see no reason to suppose its incidence to be less than in fibroids after a natural menopause, and I have seen one case which required operation six years after an artificial menopause produced by x rays. This complication is often overlooked in the papers advocating radiation, as the cases are too recent, and it would be useful to have some of these series reviewed ten or twenty years later.

It is impossible to say what would have happened to all these cases if they had been treated by radiation; I do not suggest all would have ended fatally, though probably some would; and certainly some would have required operation at a later date for urgent symptoms, when the patient's condition would make operation a much more serious matter. This danger is recognized by many radiologists, and the more experienced of them advise all cases of fibroid to be examined by a gynaecologist so as to eliminate degenerations of the tumour; but the great difficulty is to be sure without operation that a tumour is not undergoing degeneration, and the instances must be few in which a competent gynaecologist will take the full responsibility of saying there is no degeneration.

#### *Inflamed Appendages.*

This is a complication which precludes treatment by radiation, according to the authorities on this method of treatment. Of course, acute inflammation will usually give rise to acute symptoms which are easily recognized, but there are cases which only come under treatment after the acute symptoms have subsided. In this series there was only one case which could not be included in one or other of the categories, but there were several others with inflamed appendages complicated with degenerating fibroids or with adhesions to rectum or intestines.

#### *Adhesions.*

Adhesions firmly binding rectum, bladder, or intestines to the tumour contraindicate the use of radiation, and yet how often do we unexpectedly find these adhesions during an operation! The following case—one of the last in this series—is an instance:

An unmarried woman, aged 49, one year past the menopause, with no previous history of inflammation, was brought to me because of recurring haemorrhage. Examination revealed the presence of a fibroid uterus about the size of an orange, apparently quite mobile; there were no symptoms or signs suggesting degeneration, and it was just the case which would be referred to the radiologist if this form of treatment were used. I opened the abdomen and found both tubes and ovaries firmly adherent to the back of the uterus, but before I could find the tubes and the uterus, I had to separate the rectum and bladder from these organs and from each other. These adhesions were so firm that the rectum had to be cut off from the uterus and appendages, not stripped, as is usually possible.

In all probability these cases with unsuspected adherent rectum and intestines explain the damage to these organs which is occasionally reported after the use of x rays. In this series five cases are noted as having adhesions between the uterus and abdominal viscera. Though the number is

not very great, the frequent impossibility of diagnosing the presence of adhesions before operation greatly increases their importance.

#### *Retention of Urine.*

Seven patients, all about or past the menopause, were operated upon for this condition alone. In each case the uterine fibroid filled the pelvis, and had been allowed to drop into this position through atrophy of the tumour due to the menopause. I cannot say how far x rays would have still further diminished the size of the tumours and relieved the symptoms, but their application would have taken some little time, and have necessitated catheter treatment in the meantime. We must also bear in mind the action of radiation upon larger tumours, as the atrophy set up by this treatment may cause a fibroid situated above the brim to descend into the pelvis and set up acute symptoms.

#### *Wrong Diagnosis.*

Every gynaecologist knows the difficulty of making a correct diagnosis in these cases of pelvic tumour. This is recognized by the radiologists who have published their work up to this time, and the majority insist upon the necessity of an examination by a gynaecologist before x-ray treatment. I doubt whether this will be so in future. Even if a gynaecologist is consulted the risk is not entirely eliminated, and I have to confess to two bad mistakes made during the last two months. In both cases I diagnosed uterine fibroids, and fortunately advised operation, and in both cases the solid tumour proved to be carcinoma of the ovary. In both cases the tumour was not adherent and was removed, so that the patients have a very fair chance of being cured, which they would not have had with x-ray treatment.

#### *Conclusions.*

1. Small fibroids, not larger than an orange, which are not producing any symptoms may be left alone, but the patient should be kept under observation, as there is a possibility before the menopause of the tumour causing increased haemorrhage or increasing in size, and after the menopause of becoming malignant.

2. If the patient is very anaemic the tumour should be treated by radiation to stop the haemorrhage and allow her general health to improve, but the tumour should be removed later.

3. In all other cases the tumour should be removed by hysterectomy or myomectomy—myomectomy being preferred for women in the child-bearing period who desire a family and when a useful uterus can be left, panhysterectomy for cases with a badly lacerated cervix in addition to the fibroid, and supravaginal hysterectomy for the remainder.

## The Oliver-Sharpey Lectures

ON

## THE ACTIVITY OF THE CAPILLARY BLOOD VESSELS,

AND ITS RELATION TO CERTAIN FORMS OF TOXAEMIA.

DELIVERED BEFORE

THE ROYAL COLLEGE OF PHYSICIANS OF LONDON

BY

H. H. DALE, M.D., F.R.C.P., F.R.S.,

HEAD OF THE DEPARTMENT OF BIOCHEMISTRY AND PHARMACOLOGY UNDER  
THE MEDICAL RESEARCH COUNCIL.

### LECTURE II.

BEFORE we pass to some of the pathological applications of the knowledge now available concerning the active contractility and tone of the capillary blood vessels, there are a few additional points concerning its normal physiological significance which ought to be passed in review. Professor Richards of Philadelphia has found it possible by means of special lighting arrangements to see the capillaries between the tubules and in the glomeruli of the living frog's

kidney.<sup>4</sup> Dr. Leonard Hill<sup>2</sup> has independently, and for a somewhat different purpose, made observations on the same object. Richards and Wearn have noted the highly active contractile function of the glomerular tufts, some shrinking to small compass while others, previously shrunken, expand so as almost to fill Bowman's capsule. The fact which I have already emphasized, of the varying permeability of the capillary endothelium, with changes in tone of the supporting, contractile cells of Rouget, must surely have some bearing on these pronounced variations of tone in the capillaries of the kidney; but its exact significance remains to be explored.

Since Gaskell's<sup>3</sup> work on the regulation of the blood supply to skeletal muscle the association of vaso-dilatation with functional activity has been clearly known. The work of Chauveau and Kauffmann<sup>1</sup> on the masticatory muscles of the horse demonstrated the same phenomenon. Until recently, however, this dilatation was assumed to concern the arteries alone, and the chief matter of discussion was the relative importance in its production of nervous impulses and of the chemical stimulus of metabolic products. As we have already seen, there can be no doubt now as to the important part played, in this adjustment of blood supply to metabolic requirement, by intrinsic relaxation of the capillaries, or as to the control of the tone of these vessels by nervous impulses. When we come to the question of chemical control the evidence is not yet so clear. On the one hand, it is obvious that the capillaries, with their intimate relation to and constant chemical interchange with the tissues, must be specially exposed to any influence on vascular tonus which the products of metabolism may exert. On the other hand, the particular product of metabolism, carbon dioxide, which, since Gaskell's<sup>3</sup> experiments again, and as the result of repeated confirmation of his results (Bayliss,<sup>6</sup> Hooker,<sup>7</sup> Anrep<sup>8</sup>), has been credited with a potent vaso-dilator action, has not been demonstrated to have a pronounced effect on capillary tonus. Krogh,<sup>9</sup> indeed, as the result of recent experiments, comes to the conclusion that such acidity, due to increased tension of carbon dioxide, as can occur during life, "probably plays no part whatever as a regulator of the capillary circulation." Yet, since the time of Roy and Graham Brown<sup>10</sup> it has been obvious that capillary tone is powerfully depressed by some product of cellular action, which accumulates during brief stoppage of the circulation, so that the capillaries dilate widely when the blood is readmitted, and is formed with abnormal rapidity if the tissue is injured. What can such a product be? It will, I think, be quite obvious, from what I said in the last lecture, that a substance having the histamine type of action would fill the requirements; and the tendency to speculate in this direction is reinforced by the observation that a simple watery extract of almost any tissue in the body contains a substance, or substances, producing this type of effect. At the same time, in the absence of direct chemical evidence—which, it must be admitted, is practically beyond hope of attainment with methods yet available—I think that there is no warrant for the assumption which some have been ready to make, that small quantities of histamine are actually formed in metabolism.

In somewhat closer contact with experimental reality is the evidence as to the factors, other than nervous impulses, concerned in the maintenance of the normal, average tone of the capillaries. You will remember that Richards and I found that the presence of a small proportion of adrenaline in the perfused blood was necessary, in order to enable us to demonstrate the vaso-dilator effect of histamine with an artificial circulation. This suggested to us that a normal function of adrenaline, as continuously secreted into the blood in minute quantities, was the maintenance of a healthy capillary tonus against the dilator effect of metabolic products. The view was supported by an observation of my own,<sup>11</sup> that a cat which has been deprived of its suprarenal glands becomes extraordinarily sensitive to the shock-like effect of histamine, being killed by an injection which, in the normal animal, would produce only an evanescent, vaso-dilator fall of the arterial pressure. My former colleague, Dr. Kellaway, and Dr. Cowell<sup>12</sup> have confirmed this observation, and have given it much greater precision, in studying the effect, on the reaction to histamine, of destroying the

medulla of the suprarenal glands in cats, leaving sufficient intact cortex to enable the animals to survive, and to keep in most ways healthy, for weeks or months. They observed in such cats the effects of injecting, into the ear vein, a small dose of histamine, such as in a normal cat produces barely perceptible symptoms, with at most a slight evanescent rise in the corpuscular content, due to temporary loss of plasma from the circulation. In cats lacking the suprarenal medulla such injections of histamine caused pronounced collapse and long persistent rise of the corpuscular content of the blood. But such cats could be rendered for the time being normal, in their response to histamine, by preliminary treatment with hypodermic injections of adrenaline.

There is evidence, then, at least of an antagonism to, or a moderating influence on, the reaction of the capillaries to histamine, produced by the presence of adrenaline in the blood, in such concentrations as do not perceptibly influence the arterial blood pressure. The fact that in many animals the capillaries are under motor control from sympathetic nerves would lead to an expectation of such a tonic influence of adrenaline. Direct evidence, on the other hand, points rather to another hormone as concerned with the chemical maintenance of capillary tone. Krogh and Harrop,<sup>13</sup> in their perfusion experiments on the frog's leg, found evidence of the presence of some substance, not adrenaline, in mammalian blood serum, the presence of which maintained a good tone and normal permeability of the capillaries, while in its absence they became dilated and allowed the escape of fluid into the tissues. Krogh and Rehberg<sup>14</sup> have demonstrated a suggestive similarity, in several properties, between this diffusible substance in serum and an active constituent of the posterior lobe of the pituitary body. They resemble one another in stability, in their solubilities, their diffusion through membranes, and, apart from their tonic action on capillaries, in both showing the dilator action on the melanophores of the frog's skin, which Hogben<sup>15</sup> first observed with the pituitary extract. Finally, it should be noted that Pohle<sup>16</sup> had previously shown that removal of the pituitary gland in frogs was followed by cutaneous oedema. I do not think that the evidence for identification of the substance in serum with the pituitary extract is complete. In view, moreover, of the very wide differences exhibited by the capillaries of different species in their reaction to histamine and other substances, I think that Krogh is wise in deprecating a hasty assumption that all capillaries, in all species, are dependent for the maintenance of normal tone on the presence of traces of the pituitary hormone in the blood. This question of the relation of hormones to the functional condition of the capillaries is, indeed, only just being opened; and it is at least of interest to note that, in the case of both the endocrine glands which have yet been investigated in this connexion, the suprarenal and the pituitary gland, a presumption is already established in favour of their normally exercising an important influence on capillary tonus.

There is an intimate connexion between this question of hormonal control and some puzzling, but highly significant, observations recently made and published by my colleague Dr. Burn.<sup>17</sup> His observations were primarily directed to an entirely different question—that of the relation between the response of the sweat glands to pilocarpine and the integrity of their nerve supply. He found that degeneration of the secretory nerve fibres to the sweat glands of a cat's foot, produced by post-ganglionic section of the sympathetic fibres to the limb, in no wise impaired the sweating caused by pilocarpine. When, on the contrary, the whole of the mixed nerves to the foot were cut, so that sensory as well as sympathetic fibres were divided and degenerated, sooner or later the effect of pilocarpine on the sweat glands of that foot was, in the majority of cases, greatly reduced or obliterated. This was not due to the disappearance of other secretory fibres to the sweat glands, since it was clearly proved that none but those from the sympathetic system exist. A close association, however, was detected between the response of the sweat glands to pilocarpine and the dilator response of the capillaries in the same limb to histamine. When, as after degeneration of the sympathetic fibres only, the sweating response to pilocarpine was

maintained or exaggerated, the dilator response of the vessels to histamine was abnormally pronounced. When, after section of the whole nerve supply, the sweating produced by pilocarpine was reduced or suppressed, the dilator reaction to histamine had disappeared, although the arterial dilator reaction to acetyl-choline was produced as usual. I do not think that the meaning of this change in the capillary reaction, corresponding with the failure of the gland cells to respond to pilocarpine, is yet clear. Burn, adopting a line of argument which Richards and I had used, is inclined to ascribe it to loss of the normal tone of the capillaries. I do not think there is evidence, from the appearance of the skin, that the capillaries are abnormally relaxed. What Burn's results clearly show is that they have lost their normal responsiveness to histamine, and his further experiments bring out the very important point, that the dilator reaction to histamine can be restored, and with it the response of the sweat glands to pilocarpine, if the cat is treated for a few days with daily hypodermic injections of adrenaline. Again, therefore, we have suggestive evidence of an association between a high content of adrenaline in the blood and a satisfactory tone or responsiveness of capillaries, in this case of capillaries deprived of their normal nerve supply. The simultaneous loss of the normal response of the sweat glands, and its restitution by adrenaline, are probably, therefore, to be ascribed to varying states of nutrition of their cells; and this suggestion is confirmed by Burn's further and highly significant observation, that the loss of the dilator reaction to histamine is associated, not only with this depressed response of the sweat glands, but with a generally impaired vitality of the skin of the whole foot. Wherever this is exposed to pressure or friction in walking, the hair is lost, the skin becomes oedematous and loses its normal flexibility, and there is a tendency to ulceration. With the recovery of the reaction to histamine, under the influence of slowly absorbed doses of adrenaline, this malnutrition of the denervated skin disappears, and any ulceration begins to show signs of healing.

This obviously opens up very important questions as to the nature of the trophic changes in the skin following nerve lesions, and particularly of lesions involving the sensory fibres, with their function in relation to vaso-dilator reactions. The case of tabes dorsalis naturally suggests itself, and I believe there are many such conditions in which a systematic investigation of the capillary response to mechanical and chemical stimuli would be highly instructive. The naked skin of the human subject is far more suited to this type of investigation than that of any of the hairy animals usually available for laboratory experiment. The readiness with which the skin capillaries of the normal man react to histamine has been amply demonstrated by Eppinger,<sup>18</sup> and by Sollmann and Pilcher,<sup>19</sup> the latter observers recording the appearance of a capillary flush, followed by an oedematous wheal, when histamine was applied to the very lightly scarified skin, in dilutions as high as one part in 10,000. The modification of this type of reaction by defective innervation of the skin lies open to study, which could not fail, I think, to give instructive results.

There must, I suppose, be some kind of relation between this loss of dilator response, studied by Burn, and the failure of the inflammatory reaction to local irritation, demonstrated some years ago in Hans Meyer's laboratory by Ninian Bruce.<sup>20</sup> Bruce found that the inflammatory hyperaemia and oedema of the conjunctiva, following the application of mustard oil to the eye of a rabbit, was not perceptibly modified by previous section of the roots of the Gasserian ganglion. When the trigeminal nerve was cut peripherally to the ganglion there was no immediate modification of the inflammatory response, but, when time was allowed for degeneration of the sensory fibres with their terminal branchings, the inflammatory reaction to mustard oil was practically abolished. The same depressant effect on the inflammatory response was produced by local anaesthetics. Clearly, then, the reaction was not a central reflex; it persisted without impairment after the connexion with the brain had been broken, but could be abolished by peripheral sensory paralysis, with the central connexion intact. Bruce argued that it must be due to a peripheral

reflex of the axon type, through a branching of the sensory fibre to sensory endings, on the one hand, and to the blood vessels on the other, as Bayliss<sup>21</sup> had previously suggested in explanation of the vaso-dilator effect of peripheral stimulation of sensory fibres—the so-called antidromic vaso-dilatation.

Bruce's results were confirmed by Bardsy,<sup>22</sup> who only differed from Bruce in that he found that the inflammatory reaction was reduced to small proportions, not altogether abolished, by degeneration or peripheral paralysis of the sensory nerve fibres. Breslau<sup>23</sup> has more recently found that even the local inflammatory reaction to mustard oil of the human skin fails to appear if the sensory nerves to the area are degenerated, or paralysed by a local anaesthetic. At the time when Bruce and Bardsy's observations were published the arteries were still regarded as the only part of the vascular system presenting variations of tone having any significance. Arterial dilatation is, doubtless, a factor of importance in typical inflammation, but it can hardly be doubted, I think, that that of the capillaries is more important still. It is very questionable whether arterial dilatation alone, without relaxation of the capillaries, could produce a condition at all like that seen in inflammation. Axon reflexes to the capillaries are probably at least as important as those acting on the arteries.

In addition to this nervous action we have to take into account a chemical stimulation of the capillaries to dilatation; and this may appear almost immediately if the substance applied has itself such an action on capillaries, or as a later, indirect effect of dilator substances set free from injured or dying tissue cells, directly attacked by the irritant. Obviously the whole reaction, taking into account all these possibilities, may be a very complex one, and in different cases one or other of the various possible factors may be predominant. The whole question of the vasomotor mechanism of inflammation needs a newer and closer analysis, in the light of knowledge, of which some is already available, and much still to be obtained. I think it can hardly be doubted, however, that the result will be to bring active changes of capillary tonus into the centre of the picture.

Discussion of local skin reactions naturally brings to mind a whole series of trophic changes, erythematata and eruptions, with which the physician is familiar, and in the ultimate analysis of which a knowledge of capillary function will obviously play a principal part. I have not the time, if I had the knowledge, to enter upon a consideration of them now. I will merely point to the importance, in this connexion also, of the knowledge, newly accumulating, as to the close similarity in effect upon capillaries of appropriate nervous impulses on the one hand, and chemical stimuli on the other. Dilatation of capillaries, leading to excessive permeability and local oedema, has been experimentally demonstrated as the result of nerve stimulation, and as the result of the action of poisonous substances. There are many instances in which it may be impossible to determine which type of stimulus is at work. Even the correspondence of an eruption with the distribution of particular nerves is not absolutely decisive, if we admit the possibility that a virus or a toxin might descend from the centre to the periphery along the nerves, as the virus of rabies and the toxin of tetanus have been shown to ascend from the periphery to the nerve centres;\* or if, on the other hand, we suppose that small centres of capillary dilatation, produced by nervous impulses, may provide points of lowered resistance, where a generally diffused virus can settle, or a toxin accentuate a process already initiated. I indicate such possibilities merely to lay emphasis on the wisdom of avoiding the assumption that, because a phenomenon has some obvious relation to innervation, it is of necessity wholly nervous in origin.

Such considerations lead me naturally to a group of phenomena which have been the subject of much study and discussion during recent years. At the risk of a wearisome insistence, I must recall to you again the complex of symptoms which has received its most detailed analysis in the form in which it is produced by histamine. You will

\* For this interesting suggestion I am indebted to Dr. John Brownlee.

remember that it involved a simultaneous stimulation of plain muscle to contraction and of the capillaries to relaxation of their tone. We have considered the effects on the circulation, but have left out of view, up to the present, the equally striking effects produced by contraction of the plain muscle of hollow viscera, and particularly that of the bronchioles. The production of this complex by histamine might excite merely a laboratory curiosity. It becomes of practical interest when we realize that essentially the same combination of plain muscle contraction and loss of capillary tone occurs as the central feature in the action of a large class of protein poisons, and in the so-called anaphylactic shock. In different species, and under different conditions, one or the other feature of the action comes into the forefront of the picture; in the unanaesthetized guinea-pig the conspicuous feature in the action of these poisons, or in the anaphylactic shock, is the constriction of the plain muscle of the bronchioles, causing asphyxial death; in the anaesthetized dog it is relaxation of the capillaries, probably associated with constriction of the hepatic veins, leading to circulatory collapse. But with minor specific and individual variations in the incidence of its component factors, the action produced by this whole group of poisonous agents is fundamentally the same.

The application to human pathology hardly needs indication. It has frequently been discussed in recent years by those more competent than I, and the production, by the same normally or individually toxic agent, of urticaria and subcutaneous oedema in one case, and spasmodic asthma in another, will be very familiar to all of you. There was at one time a tendency, which I hope is dying, to regard the pronouncement of the word "anaphylaxis," whenever this symptom-complex was encountered, as giving absolution from further effort to analyse the condition. Such words are useful when they are used to define, and merely mischievous when they are used to shirk definition. At the same time, it must be admitted that there are points of similarity between the so-called "toxic idiopathies" seen in man, and the acquired specific sensitiveness to a foreign protein, which is properly termed anaphylaxis. I have on several previous occasions maintained, by evidence and arguments which I shall not inflict on you to-day, that the essence of the true anaphylactic condition is the location in the living cells of an antibody of the precipitin type, and that it is the intracellular reaction between this and the antigen which causes the anaphylactic reaction. In the case of the toxic idiopathies, I think it is certain that we have again a cellular sensitiveness, and we must assume that the specifically toxic agent, be it a pollen or an animal epithelium, produces in the sensitive cells changes similar to those which the anaphylactic antigen produces; but we have here but little evidence of the presence of antibodies in the strict sense. Indeed, but few of the substances responsible for these human idiosyncrasies can function experimentally as antigens, and some, such as the simple organic chemicals to which specific sensitiveness occurs—iodoform, antipyrin, etc.—certainly cannot. We cannot assume, then, that whenever a specific reaction of this type occurs an immunity process, involving the presence of an antibody, is at work. All that we can assume is that the protoplasm of an idiosyncratically sensitive cell has some kind of abnormality, whether due to the presence of a separable antibody or not, which causes it to react to its specific poison by the same kind of change as that with which the anaphylactic cell reacts to its specific antigen, or with which the normal cell reacts to histamine or to a naturally poisonous protein cleavage product.

For the main concern of these lectures the point of chief interest is the location of poisoning of this type, however produced, in the walls of the capillaries and in plain muscle fibres. I take this to mean that all these substances produce, either in all individuals or only in those specifically sensitive, the same kind of physical change in cell protoplasm; and that the predominance of visible response to them in the capillary cells, and in the plain muscle, is due to a special physiological sensitiveness of those structures to this type of change.

When a specific sensitiveness is produced to a normally innocuous substance, this is accompanied, apparently, by

a minor degree of enhanced sensitiveness to naturally poisonous substances producing these effects, as shown in some experiments by Dr. Kellaway and myself.<sup>22</sup> This corresponds with the clinical experience that the victim of a toxic idiopathy has capillaries, or bronchial plain muscle, which are to some degree abnormally sensitive to naturally poisonous substances of this class. If this means an enhanced physiological reactivity to a certain type of physical change, it would not be surprising, it would even be expected, that they should also show an abnormal responsiveness to nervous impulses which produce capillary dilatation on the one hand, or constriction of the bronchi on the other. I shall not venture into a discussion of clinical details, which are beyond the scope of an experimental worker. I merely want to emphasize again the fact that there is no experimental warrant for assuming that the two kinds of causation are mutually exclusive. The detection of a neurotic factor does not exclude a toxic one, and vice versa.

I must turn now to conditions in which there is reason to suppose that the whole or a large part of the capillary blood vessels in the body are simultaneously affected by toxic agents. I have given already a brief summary of the conclusions reached, by analysis of the circulatory failure produced by large doses of histamine. Here, again, histamine was chosen simply as a conveniently accessible and accurately measurable representative of a large class of poisons. Sir William Bayliss,<sup>21</sup> in the Oliver-Sharpey lectures a few years ago, gave a full account of the analogous condition of circulatory failure, caused by a general loss of capillary tone, which was studied during the war under the name of secondary wound shock, and attributed to the toxic action of autolytic products from crushed and lacerated tissue. I need only mention, therefore, this special example of what I suspect to be a much larger group of toxæmias resulting in circulatory failure, in which the most serious factor is this loss of capillary tone. A large number of bacterial products exhibit this type of action, including both soluble products and substances liberated only by lysis of the bacteria. In the local, protective, inflammatory reaction to them we probably have a complex of direct dilator action on the capillary walls and reflex dilatation of arterioles through the stimulation of sensory nerve fibres. When poisons like these are formed in such quantities as to be distributed, in effective amounts, through the circulation, so that all or a large proportion of the capillaries simultaneously lose their tonus, there arises the peril of circulatory collapse due to peripheral stagnation of the blood. The most obvious and striking example of such an effect, perhaps, is the cyanotic collapse seen in cholera, where the oligæmia is accentuated by the enormous loss of fluid through the permeable intestinal capillaries. Dr. Esther Harding,<sup>23</sup> who carried out a series of experimental observations in my department, has found evidence of this type of circulatory failure in animals dying rapidly after large doses of diphtheria toxin, and in the early collapse occurring in severe cases of human diphtheria, without respiratory obstruction, and before the toxin had affected the heart muscle. Many years ago Romberg and Pässler<sup>24</sup> put forward the view that the so-called heart failure in septicæmia was not due to defect of the muscular activity of the heart, but to a vasomotor collapse. With the knowledge then available they attributed the result to failure of the vasomotor centre, but, in the light of present knowledge, a direct impairment of capillary tonus suggests itself as a much more probable and sufficient cause of such a condition. Recently Olivecrona<sup>25</sup> has examined this possibility in experimental peritonitis and given definite evidence in favour of a loss of capillary tone as the principal cause of the circulatory defect and of the fatal issue. I believe that the same possibility is well worthy of consideration in the case of all types of acute septicæmia. The condition may be obscured by concomitant poisoning of the heart muscle, but its recognition must have an important influence on scientific treatment. It is obviously useless to stimulate a poisoned and labouring heart if the main cause of its inefficiency is not the weakness of its muscular action, but the failing return of blood by the systemic veins.

One could continue to multiply examples of conditions in which this dangerous complex may arise. Apart from agents directly toxic in themselves, the position is complicated by the fact that, when blood is subjected to injurious influences, as by contact with otherwise inert substances acting as "foreign" surfaces, so that processes are initiated in it which, outside the body, would lead to clotting, it acquires a toxicity of this type. (Cf. Novy and De Kruif,<sup>22</sup> Dale and Kellaway.<sup>23</sup>)

When you also remember that, apart from dilatation and increase of permeability of the capillaries due to loss of their contractile tone, effects at least superficially similar can probably be produced by substances which directly poison the endothelial wall and disorganize its delicate structure, it will be obvious that there may be difficulty in deciding as to the precise nature of a particular effect. Salvarsan, for example, as an arsenical derivative, may, and in some cases probably does, act as a direct endothelial poison. It is also a colloidal substance which, on injection, may be so precipitated in the blood as to initiate precoagulation changes. Both types of effect probably figure among the toxic effects which salvarsan occasionally produces.

Unfortunately methods of dealing effectively with dilated and permeable capillaries are not easy to find. The action of adrenaline, above mentioned, suggests itself; and there are cases in which it seems to have value. As a prophylactic or a remedy for the immediate, so-called vasomotor, reaction sometimes produced by salvarsan, for example, there seems to be no room for doubt that adrenaline is effective; and its effectiveness supports the suggestion, made on other grounds, that this type of reaction is due to capillary dilatation caused by precoagulation changes in the blood, and not to poisoning of the endothelium. Calcium has had a reputation for reducing the tendency to excessive permeability of the capillary walls. Krogh's recent evidence as to the tonic action of pituitary extract should find some therapeutic application. Experience during the war, however, presented as practically insoluble the problem of restoring the volume of blood in effective currency when once the capillaries had become thoroughly lax and permeable. Saline solutions, gum saline, or even blood itself, often produced but a temporary recovery of volume, the fluid escaping from the vessels, or becoming removed from circulation, almost as fast as it was infused into the veins. In some of Dr. Harding's experiments, in the investigation already mentioned, there could be seen what appeared to be a secondary, and rapidly fatal, accentuation of the toxic collapse, when blood which had lain stagnant in toxæmically dilated capillaries was washed back into circulation by an infusion. The therapeutic problem is a peculiarly difficult and complex one; but the first step towards its rational solution is a clear recognition of the nature of the condition calling for treatment.

ENDOCRINES, VITAMINS, AND  
SUBTLETIES.

ABSTRACT OF AN ADDRESS DELIVERED TO THE SUNDERLAND  
DIVISION OF THE BRITISH MEDICAL ASSOCIATION

BY

LEONARD WILLIAMS, M.D.

IN no branch of knowledge is it more difficult, certainly in none is it more necessary, than in ours, to get the spirit of the moment into its right perspective. Between the excited welcome accorded to new therapeutic methods on the one hand, and the obstinate impermeability to fresh ideas on the other, the plain man is apt to be bewildered, and it is well that he should occasionally pause to consider on what sort of ground he is standing and whether the pathway seems to be leading. It is with the hope of affording some help in this direction that I have prepared this paper, and such must be my excuse for the very comprehensive title.

## I.

In the matter of the first subject, endocrinology, I would like to emphasize at the outset the important fact of the interdependence of the glands which constitute the system. I am fond of comparing them to the eight rowers in an out-rigger boat, with the central nervous system as cox. These rowers are all pulling in the same direction; they are, nevertheless, some of them, pulling one against the other. Now, in our clinical dealings with these glands we are much too apt to regard each as an independent entity, instead, as we ought, of considering each as a member of a hierarchy, the whole of which is liable to be deranged when one of the members is seriously affected. As bearing on this generalization, let me indulge in another. It is the evil fashion to speak of "hyper" or "hypo" functioning of certain glands. Such a nomenclature expresses but a part of the truth, and that part a very misleading one. It is no doubt true that in the various degrees of myxoedema, for example, the thyroid is primarily at fault, but the outstanding symptom which brings the patient to the doctor may point insistently to failure of some other gland.

Quite recently a man of 45 came to me complaining of sexual impotence gradually acquired. He turned out to be a case of mild, atypical myxoedema, appropriate treatment for which rapidly restored his sexual capacity. It also restored his domestic peace, which had been seriously impaired by unfounded charges of infidelity.

Now, misleading as it generally is to speak of underaction of a particular gland, it is much more misleading—it is, indeed, generally a misstatement—to speak of overaction of any single gland.

Let us take the thyroid again. It has become a habit with many, who ought by now to know better, to speak of Graves's disease as synonymous with hyperthyroidism. Now, although the thyroid gland may be overactive in Graves's disease, it is so in common with other glands, notably the suprarenal, the pancreas, and the thymus, and the salient symptoms of the disease are due much more to the latter than they are to the thyroid, which, as you know, is frequently not even enlarged. Whatever else it is, or is not, Graves's disease is not a pure hyperthyroidism.

In the matter of underaction it is generally evident that one gland is primarily at fault; in the matter of overaction that is seldom the case, except where there is a definite and local organic irritant, such, for example, as suprarenal and pituitary tumours. The cause of overaction is generally a toxæmia which irritates not one gland only, but many, though in different degrees. In looking for a cause of underaction it is always well to remember the possibility of long-continued toxæmic overaction, leading to exhaustion of the gland or glands in question. This is a frequent cause of thyroid insufficiency, because the thyroid above all others is concerned in combating endogenous toxins. That it is a cause of pituitary insufficiency I hope to show presently. Then again we must always bear in mind that when we have given, say, thyroid extract with success, our good results do not necessarily mean that the patient was lacking in thyroid essence. The good results may mean, and in many cases

I am sure they do mean, that the extract has stimulated an opponent gland—say the suprarenal or the pancreas—to increased effort. So that in giving the extract we are not supporting a flagging thyroid, we are rousing a lazy suprarenal. We are, in fact, restoring the balance by indirect means.

With these preliminary reservations we can proceed to consider a few of the glands individually. First, then, as to the thyroid. Here we are entitled to speak of a primary insufficiency. We know that there are many clinical manifestations of this condition; such are the troubles in the skin and its appendages, the slow pulse, the sensitiveness to cold, the muscular fatigue, the mental hebeticity, the intestinal stasis, the menstrual disturbances, and in children night terrors and nocturnal enuresis. Hertoghe, of Antwerp, long ago pointed out that these and other symptoms might all be reduced to a causal common denominator which is expressed by the word "infiltration." The thyroid is the great activator of metabolism, and when the fires burn too slowly material is deposited in various tissues. We may call this material mucin if we like; its name is less important than the fact that it is a product of inadequate metabolism which is liable to be deposited, capriciously so far as we can see, in any tissue or system, thus giving rise to very diverse findings. Just as a person with a high blood pressure may bleed from anywhere, so a person with thyroid insufficiency may become infiltrated anywhere. The selection of the site of the infiltration is even more difficult of explanation than the selection of the site of the haemorrhage. And when we consider the matter, it is not difficult to realize that a very slight degree of infiltration may bring about serious results. A slightly infiltrated endocardium, an infiltrated intestinal mucosa, an infiltrated endometrium, may very easily produce a train of symptoms sorely baffling to the clinician who fails to remember slight thyroid insufficiency and its powers of depositing unwelcome material in unsuspected and unlikely places. With this general outline in view, it is possible to form a mental picture of the method of production of almost any of the many morbid manifestations which we have come to associate with thyroid inadequacy, but in so doing we must be careful not to forget the possible responsibility of other glands for some, at any rate, of the details of the complete picture. Of the thyroid, more than of any of its congeners, it may be asserted that when it fails to ring true, the others inevitably become jangled and out of tune. It is the leader of the glandular orchestra.

This statement, correct though I believe it to be, seems less so to-day than it used to seem. Some years ago it was thought that the parathyroids were mere accessory or supplementary or immature thyroids, and commercial manufacturers of thyroid extract included in the product thus labelled, not only the thyroid gland itself, but the embedded parathyroids. Since it became evident that the old view was incorrect and that the parathyroids were possessed of functions distinct from, and according to some observers even antagonistic to, the thyroid proper, manufacturers have been careful to separate these glandlets from the thyroid itself, with the result that when we now prescribe thyroid extract we are exhibiting the pure article, whereas in former days we used to exhibit thyroid *plus* parathyroid. This is liable to make a serious difference in our results, and when I now fail with thyroid where I confidently expected to succeed, I generally find that the addition of a small dose of parathyroid—say one-twentieth of a grain—brings about the desired result. There are, of course, still those who deny to the parathyroids any particular part in the endocrine hierarchy. In spite of these, however, clinicians have satisfied themselves that the extract of these despised glandlets, when orally administered, does bring about very satisfactory results in certain cases. Their action may be summed up by saying that they have a very favourable influence upon calcium metabolism and on certain conditions of auto-intoxication; for these glands would seem to have a very definite part to play in the defensive mechanism with which the endocrine system as a whole is endowed. Clinically, parathyroid medication has been found to be exceedingly helpful in the treatment of benign ulcers, both internal and external—that is, gastric and duodenal and varicose ulcers. It is certainly very useful in tetany and in that condition of chronic toxæmia which has been called

latent tetany.<sup>1</sup> Its use in Parkinson's disease may or may not be attended with good results. If it fails to do good in rickets the cause is to be sought in want of skill in guiding the necessary concomitants such as diet, air, sunshine, and the like. The unsightly and painful chilblain will more often than not yield to parathyroid medication where other remedies have failed.

I have said that in looking for a cause of underaction in any gland it is well to remember the possibility of long-continued toxæmic overaction leading to exhaustion of the gland in question. Let me take an illustration from the pituitary, and in so doing say at once that the chronic overaction may own causes other than toxæmia.

There are a fair number of people going about who are so much taller than the normal as to give rise to a suggestion of gigantism, men of over 6 ft. 2 in., and women of 5 ft. 10 in. To careful examination a certain number of these people will reveal present evidences not of pituitary excess but of pituitary insufficiency. They have grown rapidly, outgrown their strength as the saying is, in response to an irritated pituitary. At a given moment the relative pituitary hyperactivity dies down, to be followed by the relative insufficiency of exhaustion, and, although the balance may ultimately become redressed in some degree, that person's pituitary is always lacking in vigour, and without outside help will generally give rise to unpleasant symptoms. The preliminary excess is to be seen in the abnormal height, the spaced incisor teeth, the large hands, and the misshapen lower jaw, which is either receding or underhung, according to the age at which the pituitary excess began to die down. The existing insufficiency is evidenced: by intolerance of extremes of temperature, by late oncoming, irregular and painful menstruation, by absence of half-moons on the nails and other irregularities of pigmentation, especially little black moles, "beauty spots," dotted about the body. These people are as a rule mildly but definitely undersexed, and tend to become obese on and below the waist line. But it is not any of these things which brings them for advice. They come under our notice for indefinable departures from health—headaches, asthenia, lethargy, and the various symptoms which are classified as neurasthenia. They are fortunate if they escape the stuffing of the Strasbourg goose type and the spanking of the anecdotal and too familiar masseuse. In any case they will obtain no real relief until someone recognizes in them the stigmata of their pituitary debauch. Into the various causes of the preliminary pituitary excess it is not possible to enter here. I have already referred to the most important—namely, toxæmia, which is nearly always of intestinal origin, and I shall attempt to show presently that its correction is purely a matter of rational dietetics.

The interrelationship between all the glands of the endocrine system, which it is always so necessary to bear in mind, is nowhere better exemplified than in the association which they all seem to have with the organs of generation—the gonads, as they are conveniently called. Both in the male and in the female the gonads have been shown to have very intimate relationships with the thyroid, the pituitary, the suprarenals, the thymus, and the pineal. Indeed, when one comes to consider each gland separately, its importance, its alliances and ramifications, one is inclined to claim for each in turn the title of leader of the orchestra which I have applied to the thyroid. One is reminded of those detective stories in which the reader is led to believe that each character in turn is surely the real culprit. In the play of the endocrines I am as a rule firmly convinced that the thyroid is the "star turn," but whenever I contemplate the responsibilities of the gonads, this conviction weakens. The ancients who worshipped the phallus as the origin of life were animated by a sound if savage instinct; for latter-day science has taught us that the secretions of the testes come very near to fulfilling that claim.

The researches of Voronoff in testicular grafting,<sup>2</sup> which I have followed with the closest interest,<sup>3</sup> prove to my mind quite conclusively that the internal secretion of the male gonad can accomplish miracles beside which those achieved by thyroid extract in myxoedema pale into insignificance. It has been the fate of most of us to meet with completely negative results from the administration of testicular and ovarian extracts by the mouth, and some people have been moved by these failures to push the negation to the point of denying to the gonads in both sexes any really active internal secretion. Voronoff's researches have taught us this clinically important fact: that though quite inert when administered orally, presumably from destruction of the hormones in the intestinal tract, the internal secretion of the male gonads is extraordinarily active when applied in the form of grafts. These grafts must, however, be applied scientifically to situations in the human body where experience has shown they may be expected to survive.

And when they do survive, their beneficial effects are exercised by no means exclusively, nor even predominantly, upon the sexual capacity, but are displayed to an even greater extent in the muscular and mental and even arterial rejuvenescence of the patient. This chapter in endocrinology is only just opening, but when Voronoff's work has been freed from the salacious wrappings in which the lay press has so far concealed its scientific value, the activities and potentialities of the testicular hormone will go far to justify the primitive adulation lavished by the ancients upon the phallic emblem. The testicular hormone effects rejuvenation and prolongs life. There is here no question of putting new wine into old bottles, because Voronoff's results strongly suggest that the bottles themselves—the blood vessels—partake in the general rejuvenation, and he believes that the application of his methods will eventually result in prolonging the ordinary span of life to 100 or 120 years.

## II.

An inquiry as to why it is that man so conspicuously fails to attain to anything reasonably approaching such an age as 120 brings me to the second item on my programme—the question of vitamins.

There is an old and ugly saying that man digs his grave with his teeth—a very general recognition of the truth of which has impelled medical men for over a hundred years to dabble in the question of diet. Until recently the researches were directed to the discovery of substances in the dietary of civilized man which were responsible for the obviously detrimental effects upon his health. Haig indicted uric acid; Hare accused carbohydrates; other persons have arraigned other substances. The discovery of the vitamins has completely changed all this. It has shown that the real villain in the piece was not an intruder, but an absentee. Food is now seen to be harmful, not from what it embodies, but from what it lacks, and research workers are diligently dissecting the absentee so as to show us his component parts. Now I have no word to say against these researches, still less against the researchers. Nevertheless, I claim that this work, so far as we are concerned for the moment, is purely academic, and that attempts to utilize it in practice are liable to produce a false perspective. Our knowledge of these elusive vitamins is still very meagre. For a long time we admitted three only, as generally necessary to salvation; recently a fourth has been added, and it is as certain as anything can be that there are more to come. For the present, then, we must treat them as a whole, just as we should try and treat endocrines as a whole; for their various members are probably just as interdependent as the various ductless glands. To individualize them, as is now being done, is academically interesting no doubt; but it is dangerous. It is at least possible, it is even very probable, that they only attain to their maximum effect in the presence of one another; that there is in fact a vitamin balance which is just as important to the economy as an endocrine balance. We must therefore so frame our dietaries as to secure the inclusion not only of those already labelled, but also of those which still await isolation. In order to do this we must go back to first principles and ask ourselves what these vitamins really are. The answer is that vitamins are substances which are essential to growth, development, and the maintenance of health, which exist abundantly in raw foods and are relatively absent from cooked foods.

It has been the unfortunate fashion among some of the research workers to try and estimate the minimum amount of each known vitamin which will satisfy the demands of the economy. Now, what we want to arrive at is not the minimum, but the optimum, and I think the optimum in this case will ultimately be found very nearly to coincide with the maximum. Let me remind you that man is the only animal which is unable intuitively to select suitable food. It is obvious that he must at one time have possessed that power, and equally obvious that he lost it through the cooking stove. Whether or not Charles Lamb's *jeu d'esprit* concerning the origin of roast pork represents the real beginnings of cookery I cannot say. In any case it is certain that cookery is an art which, gaining on us gradually through the ages, has long since reached the point of overwhelming us. It is no longer our servant; it is now our tyrannical master. We think and speak and act as though all foods ought to be, must be, and shall be cooked. Cookery has permeated every class in the community, not only as a

practice, but as an article of faith, and has unfortunately succeeded in dragging the medical profession at the tail of its triumphal car. Now if we are to profit by the advent of the vitamins we must modify this attitude, rearrange our outlook, and abjure this molten image. Cooked foods must be placed in the same category with alcoholic drinks—that is, they must be classed as luxuries, moderate indulgence in which is not only permissible, but often even praiseworthy.

Our real foods, that is the foods which are proper to us, are those with which Nature has provided us—namely, raw foods, dairy produce, and uncooked fruits and uncooked vegetables. These should constitute the foundations of our dietetic edifice, our altar, on which the individual may offer up any burnt sacrifice of sheep and oxen, birds and little fishes, which fashion or taste may direct. Up to the present it has been our practice, and for many of us it will remain so until we die, incontinently to forbid our patients to eat raw foods in any form, with the result that we are just as far from the successful treatment of certain general or diathetic diseases, such as gout, rheumatism, and other forms of arthritis, as we have ever been. These maladies rank high amongst the so-called deficiency diseases—diseases, that is, which are directly due to an inadequate supply of vitamins to the economy. Nor do they by any means rank alone. I have satisfied others, and more than satisfied myself, that most of the troubles of the endocrine system are due to a similar deficiency and that hormone medication seldom or never produces its best results unless it is accompanied by an abundant supply of vitaminous foods.

It may be said that vitamins are to the endocrines what the endocrines are to the economy. But it is by no means in the relatively recondite department of endocrinology that you may confidently expect to reap rewards from insisting upon a plentiful supply of vitamins. In this direction the daily round, the common task, will furnish all you need to ask. Let me give two examples.

Arbuthnot Lane has rightly attributed all manner of minor maladies, to say nothing of major, to chronic intestinal stasis. Now anyone who is afflicted with this almost universal disability may very easily convince himself that simple stasis is due directly to vitamin deficiency. I could quote several cases of people who for years—in one case it was as many as thirty years—had never dared to go to bed without taking 2 grains of cascara or its equivalent, since taking to what may be called an intensive vitamin dietary, succeed daily, regularly, and royally in relieving their bowels without any assistance whatever. And there is another feature in this situation, which is supplied by the fact that although such a person never is constipated, he is above all others the one who can afford to be, for stasis in his case does not mean the lethal process of putrefaction; it means the benign function of fermentation. The *Bacillus coli* is like ourselves, he changes his character according to his diet. When stuffed with devitalized flesh foods he becomes quarrelsome and poisons his host, but when fed on live carbohydrates which are enabled by a rational dietary to reach him in an insoluble envelope of cellulose, he becomes lamblike and assists his host in disposing of enemies. The rational outcome, then, of Arbuthnot Lane's teaching is not so much laparotomy as rational dietetics. If the latter is followed out, the former becomes unnecessary.

My other instance refers to the fierce and fantastic fashion of the wholesale extraction of teeth whenever the gums are found to be disordered. The word "pyorrhoea" has become the plaything of the profession and the bane of the public. It ought to be neither, and will not be as soon as it is generally recognized that pyorrhoea is secondary to intestinal stasis, and that intestinal stasis, when it is not structural, is permanently curable by a vitaminous dietary. Several people, mostly youngish women with seemingly good teeth, have come to me asking what they might do to be saved from the dental forceps with which they had been threatened, and all of those who consented to play the dietetic part of Nebuchadnezzar are still wearing the denture with which Nature provided them, surrounded and supported by perfectly healthy gums. Whether the vitamins have any directly beneficial effect upon the gums themselves I cannot say; but I should think it highly probable. They are certainly very powerful in preventing the deposit of tartar.

## III.

There are many subtleties of a biological nature which I would have liked to touch upon, such as climate and environment generally, and their influence upon the physical make-up of individuals and races. But I must confine myself to one or two questions, fraught with difficulties and subtleties, which are forcing themselves upon our attention with ever-increasing insistence.

Of psychology we have heard a great deal during the last ten years. Much of what we have heard has been very illuminating and very helpful, but a great deal of it appears to some of us to be the purest balderdash. In an honest endeavour to sift the wheat from the chaff I have been struck with the responsibilities which have been fastened upon the unconscious or subconscious mind. At first I was inclined to think that the subconscious was a pure assumption, a convenient but rather desperate endeavour to explain the otherwise inexplicable. I have, however, been able to convince myself that the unconscious has a real existence, and that it is therefore legitimate to speculate upon its workings. And not only has it a real existence, but a definite and anatomical local habitation. To appreciate this fact we must once more return to first principles.

On looking back through the ages it is not difficult to realize that mind must have existed in the scale of evolution not only before man was moulded, but even before the vertebrates emerged. The ganglion cells which constituted the nervous system of the invertebrates were the ancestors of our autonomous or sympathetic nervous system. These ganglion cells were the organs of a mind, a very primitive and rudimentary mind no doubt, but quite adequate and effective so far as the needs of its possessor were concerned. The function of these ganglion cells was to control breathing, circulation, feeding, excretion, and reproduction, and the ganglion cells of our sympathetic nervous system are their lineal descendants, performing the same functions for us as the original ganglia performed for our invertebrate ancestors. Now, closely associated with these original ganglia, and practically coeval with them in the scale of evolution, are the endocrine glands. The system thus evolved was the organ of a mind. It received an impression and responded thereto by an act, which, by constant repetition became customary or automatic. If, for example, you inadvertently touch an object which is very hot, you remove your hand with great rapidity, long before the sense of undue heat has reached your consciousness. You perform, in fact, a reflex. The whole of our purely animal physiological life is dominated by these reflexes, situated in the sympathetic or vegetative system. The workings of our viscera, which normally never reach our unconsciousness, are the most orderly and best disciplined things we possess. It is therefore obvious that they must be under the guidance and control of something which for want of a better term we are compelled to call a mind.

Now this unconscious mind is not only automatic, it is also constructive. Arbutnot Lane has shown us how, in order to counteract undue mechanical strain in the adult skeleton, supporting bands of considerable ingenuity in design and complexity in structure are developed. Their manufacture is quite unconscious, but no one who has studied them could for one moment doubt that they are the result of thought. They are not haphazard; they are beautiful illustrations of the laws of mechanics. Moreover, if there be no such thing as an unconscious mind, how are we to explain the hypertrophy of organs in response to a special demand? How else are we to explain the phenomena of intuition, the process by which people, chiefly women, arrive at a correct conclusion by a jump, as it were? Such a person will tell you that she knows; she cannot tell you how she knows; she says she just knows. And, the devil of it, she does know! The reason is, of course, that the primitive, the visceral, the autonomous or unconscious mind gives information to the conscious, but like a wise judge it announces its conclusions but withholds its reasons. I feel that I must in passing emphasize the fact that our vegetative nervous system, this organ of our unconscious mind, includes practically the whole endocrine system. The ganglia of the sympathetic have the closest possible rela-

tionship with the suprarenals and, through these, with each and all the ductless glands.

Now, I am no psychologist, still less am I a psycho-analyst, but events during and since the war have brought home to me the fact that ordinary physicians cannot afford to neglect the operations of the unconscious mind. In my young days our elders spoke gravely of the influence of mind over matter. They did not know what they meant, and our intolerant youthful scepticism convinced us that the words meant nothing at all. Nevertheless, they do mean a great deal, and they are rapidly coming to occupy an honourable place in the domain of therapeutics.

When M. Coué came to London I went to hear him, and subsequently read the book by M. Baudouin which sets forth the principles of the New Nancy School, of which M. Coué is the originator. To the experienced psycho-therapist there is nothing new in this teaching, but to the ordinary physician there is. Or rather should I say that the ordinary physician will find in this teaching the orderly presentation of many facts and considerations of which he was previously cognizant, but so vaguely cognizant as to render his knowledge useless.

We are rapidly passing out of the sector of drug therapeutics in which most of us were brought up, and are being forced to take our bearings in fresh areas. Among these the area of rational psychology is by no means to be neglected. We know something about the anatomy of the unconscious mind; let us study its physiology. Suggestion is a strong living force, and auto-suggestion an even stronger. These forces should not be left to quacks and charlatans to play with. They should be studied, harnessed, and exercised by responsible medical men as a part of the ordinary therapeutic armamentarium. No one has a better opportunity than the general practitioner of utilizing these forces for the public benefit, because no one finds his patients in a more receptive or suggestible condition. Rational psychology should no more belong exclusively to the psychologist than digitalis should be the monopoly of the cardiologist.

## AN OPERATION FOR ATROPHIC RHINITIS (OZAENA).

(Preliminary Note.)

BY

JAMES ADAM, M.A., M.D.,

SURGEON FOR DISEASES OF EAR, NOSE AND THROAT, STOKHILL HOSPITAL, GLASGOW, AND GLASGOW ROYAL INFIRMARY.

THE pathogeny of atrophic rhinitis is still a matter of dispute; this is due possibly to want of attention to classification of cases and need not now be discussed. What is not in dispute is that, apart from epithelial metaplasia, undue width of nostril—that is, of the whole nasal passage from vestibule to choana, whether this width be primary or secondary—is an important factor in stagnation, drying, putrefaction, and fetor of the nasal secretion. Where the disease is unilateral it is in the wider nostril, or worse in it.

To prevent the formation of the stinking crusts characteristic of the disease various operative measures have been devised. Submucous injection of paraffin sometimes succeeds in narrowing the nasal passages sufficiently to enable the patient to cleanse his nose by blowing and so lessens crusting and fetor. But frequently, and especially in extreme cases, the mucosa will not hold much paraffin, even though the paraffin injection is preceded by one of anaesthetic fluid so as to create a pocket; the paraffin perforates the membrane when more than a little has been injected. Moure tries to meet this by prior vibratory massage of the mucosa for months so as to revivify it. In my hands the paraffin method has been on the whole disappointing. Translation of the inner antral wall toward the septum (Halle) seems rather a formidable measure, hardly likely to be generally adopted.

While paraffin may continue to be used for the less

severe cases, for others a more satisfactory method than either of those mentioned was suggested to me by a case in which the crusts were confined to the left nostril. In this girl, aged 14, the right nostril was occluded by a cone-like deviation of the quadrangular cartilage. The left nostril was extremely wide; at least an inch between septum and antral wall below the anterior end of the middle turbinal; turbinal atrophy was marked. The cone was resected through the right nostril with the idea of replacing it with its apex inverted towards the left nostril. Unfortunately the cone broke, but the pieces were pushed under the muco-perichondrium of the left side of the septum. The improvement that resulted was probably due to the freeing of the right nostril, as the left is still too wide, and it has been agreed to do the operation now to be described—transplantation of rib cartilage.

Flakes of cartilage are, with a wide, sharp gouge, taken from the seventh or eighth costal cartilage, and after incision and elevation of the muco-perichondrium of one side of the septum over the greater part of its extent and similar elevation on the inner antral walls between middle and lower turbinates, these flakes are introduced by suitable forceps—the swan-billed septal punch is excellent—into the pockets thus created, which are packed full. The incisions are closed by careful packing with bismuth gauze, which is left for four or five days.

Attention to the following points helps to guard against risks of septic infection, an important consideration in such cases with a closed wound.

Local anaesthesia should, if possible, be used. An intranasal douche with normal saline should be given before the anaesthesia till no trace of pus can be seen. The nose and face must be cleansed with spirit, and the vestibule painted with iodine tincture. The costal wound is closed with an anchor dressing before the nasal operation is begun. If local anaesthesia is used, then, before the costal operation is begun, the nose is anaesthetized with cocaine and an injection, at the vestibule, of eucaine or novocain solution. The pieces of cartilage as removed are laid on

sterile gauze and not touched except with instruments. They may be an inch or more long but neither broad nor thick; for to secure primary union and retention of the grafts the nasal wounds are best not more than 1 cm. long, placed vertically and just posterior to the skin margin, where they can be wiped with iodine.

I have done this operation in three patients, aged 15, 18, and 60 respectively—once under chloroform, twice under local anaesthesia—with primary union and retention of all the grafts in each case. All the patients expressed themselves pleased with the results in respect of comfort and diminution of discharge; but I am not satisfied, as the cavities are still too wide, though the result is better than could be got by any other method known to me. It is surprising how much cartilage can be packed into the pockets; the cubic capacity of the nasal airway is relatively great. To avoid necrosis of the septum the perichondrium can be safely elevated from one side only at one operation; this leaves the other nostril too wide. This defect will be met in future by storing the excess of costal cartilage in a subcutaneous pocket, whence it can be easily taken a month later for transplantation on to the second side of the septum.

Where only one nostril need be narrowed the operation would probably be better done from the other, narrower, nostril; a bevelled incision, longer than that indicated and carried right through septal cartilage but stopping short of perichondrium of the wider nostril, would allow complete elevation of the latter, thorough packing with transplants, and complete closure of the septal window owing to its bevelled edges and elasticity.

Any treatment of atrophic rhinitis, the ciliary brush being gone, can be only palliative. All that is claimed for the method here suggested is that in well developed cases it is more efficient than paraffin injection and less formidable than Halle's operation. The cases are too few and recent to judge results. The method is published that others who have more opportunity than I now have may try it and report.

## ACUTE OTITIS MEDIA WITH JUGULAR BULB THROMBOSIS.

BY

E. WATSON-WILLIAMS, M.C., Ch.M., F.R.C.S.E.,  
REGISTRAR, EAR, NOSE, AND THROAT DEPARTMENT, BRISTOL ROYAL INFIRMARY.

The following case presents some very uncommon features, especially the absence of any of the usual signs of mastoid disease. The notes given explain the main features.

G. G., a girl aged 10, on February 11th, 1923, complained of sore throat, vomiting, and some right earache, beginning suddenly on the previous day. I saw her on the following day; she then had flushed face, dry lips, very furred tongue, and slight tonsillitis; both tympanic membranes were pink but not bulging. There was a little pain in the right ear, and on deep pressure in the postaural sulcus some tenderness, such as an acute myringitis might produce, but no tenderness over the mastoid process, no redness nor swelling there. Constipation was present, the vomiting had ceased. Her appearance was suggestive of scarlet fever. Temperature 102°, pulse 126, respiration 24.

On February 13th, the right ear was discharging. There was epistaxis in the morning and some vomiting; constipation continued. The child looked and felt better. There were no mastoid signs; the tenderness in the post-aural sulcus had disappeared. Temperature 99°.

Left myringitis occurred on February 15th, with rise of temperature to 102.6°. There was discharge from the ear on February 16th; on this day the vomiting ceased.

On February 18th, vomiting began again, with some diarrhoea, general abdominal discomfort, and tenderness, but no distension.

Both ears were discharging; there was occasional slight right earache; no mastoid signs. The tongue and lips were very dirty and dry. The child was not well although the temperature was down to 99°. The case appeared to be possibly abdominal, and enteric was considered.

On February 21st, the temperature, after day, rose again, and the child had a rigor in there were no signs of mastoid abscess; but in the absence of any other reasonable possibilities, I decided to operate on the right mastoid, as there had once or twice been earache on that side. With the patient under ether, I performed the Schwartze operation. The mastoid cells and bone were absolutely normal; the antrum contained a very little mucoid material. I therefore exposed the ascending part of the lateral sinus; it was normal in colour and contained fluid blood; the wound was packed and left open. Lumbar puncture gave perfectly clear fluid

under slightly raised tension; 15 c.cm. were withdrawn. Pathological report: Slight increase of cells and globulin, no organisms, culture sterile.

On February 24th the temperature remained high and another rigor occurred. Ether was therefore again given, and I exposed the internal jugular vein; it was perfectly normal. The lateral sinus, however, was filled with recent clot to a distance of two inches behind the

genu. This was curetted out, as also the jugular bulb; and free bleeding was obtained from both ends. The sinus was packed off, and the jugular vein tied and divided. A small perisinos abscess was found superficial to the sinus, close to the bulb, and was drained. The bone surface was lightly rubbed with "bipp" and the wound packed. The pathological report stated that both clot and abscess contents grew streptococcus. Later that day the patient's condition was good.

Although subsequently the temperature rose again and I feared that the mischief was going to extend, it fell later by lysis, and convalescence was quite uneventful. Hearing was good in both ears. The child was discharged from the infirmary ward on April 3rd.

The course of events is on retrospect fairly clear: the jugular bulb was probably infected through the floor of the middle ear, the disease sparing the mastoid antrum and process. The result was a case very obscure right down to the discovery of the perisinous abscess, which did not exceed a pea in volume. I was not free from anxiety for some days after the second operation. The case well illustrates the necessity for operating sometimes on very slight local indications in the absence of other explanation of a severe infection.

For permission to publish these notes my thanks are due to Mr. J. P. I. Harty, F.R.C.S., who has recorded a somewhat similar case (*Bristol Med.-Chir. Journ.*, 143, September, 1921, p. 78).

## ADRENALINE AS A POTENTIAL FACTOR IN HYPERTHYROIDISM.

BY

D. J. HARRIES, D.Sc., M.D., B.S., F.R.C.S.,  
CONSULTING SURGEON, MOUNTAIN ASH HOSPITAL; SURGEON, CITY LODGE  
HOSPITAL, CARDIFF; ASSISTANT SURGEON, KING EDWARD VII  
HOSPITAL, CARDIFF.

IN a former article (*BRITISH MEDICAL JOURNAL*, March 31st, 1923) I considered the relationship of the putrefactive group of intestinal organisms to the production of thyroxin. My present purpose is to consider the activity of the same group among the intestinal flora as a potential causative factor in regulating the supply of adrenaline. Berthelot isolated from the intestine a bacillus (*B. phenologenus*) which converts a solution of tyrosin into phenol. This represents a considerable advance in our knowledge of the intestinal flora, for although it had been known for many years that there existed in the intestine bacteria capable of converting the aromatic products of digestion into phenol, no specific function had been attributed to any specific and isolated species among these organisms. This observation suggests a concept which may be found to account for the production of adrenaline either from tyrosin, or else (more probably) from some hitherto unidentified aromatic body closely allied to tyrosin, and, like tyrosin, a product of digestion. Can we in the light of our present knowledge conceive of adrenaline as being produced from tyrosin?

### The Amine Producers.

These organisms have the power of removing COO from the COOH group of an amino-acid, converting it into an amine containing one carbon group less than the amino-acid from which it was produced. Apply this to tyrosin. If we limit the function of the amine producers to effecting the change just mentioned, tyrosin becomes, not a body of the adrenaline group, but tyramin, a lower member of the series.

Adrenaline is represented by the formula—

that is, it differs from tyrosin in containing an extra carbon group. If we still regard it as being a derivative of tyrosin, we must attribute an additional function to the amine producers—that of elevating the series by the addition of another carbon group; or else we must postulate a similar synthetic process as being carried out by some other agency, such as the cells of the adrenal glands. Now, as far as the amine producers are concerned, such a view of the question presupposes a type of activity which is, generally speaking, exceptional rather than characteristic among the metabolic processes brought about by micro-organisms. Their function is mainly katabolic; they split up complex into simpler bodies, the building up of complex from simpler bodies being relegated to various types of living body cells. If, then, we are to regard adrenaline as being produced from tyrosin, we

must assume the elaborative activity of some body cell (for example, the cells of the adrenal medulla) to be a factor in its production. On the other hand, if we are to regard adrenalinol as being more directly a product of bacterial activity in the intestine, we must postulate the existence of some precursor other than tyrosin. We must seek for its source in some unidentified amino-acid which is, like tyrosin, a product of digestion, and structurally allied to tyrosin (so closely allied to tyrosin as to escape detection by the analytical processes hitherto employed), but which is higher placed in the series than tyrosin. Such a substance will be represented by the corresponding amino-butyric acid, with the formula—

or, better still,

Both the above could be direct precursors of adrenaline, needing only the intervention of the amine producers to effect the change; but as regards the catechol derivative it is important to note that Ebstein and Müller have demonstrated the presence of catechol sulphate in the urine. Such a concept of the origin of adrenaline traces it to a common source with the other endocrine secretion, thyroxin. As explained in my former article, thyroxin is regarded as being derived from tryptophane. Let us consider what happens if this common source (that is, the products of digestion) is interfered with. Such an interference arises when the putrefactive organisms disappear from the intestine. This state of affairs makes itself manifest biochemically, by the diminution or disappearance of indican and all other organic sulphates from the urine, and, clinically, by the development of the familiar syndrome of hyperthyroidism. But what is significant from the point of view of the present investigation is that hyperthyroidism implies not merely changes attributable to thyroxin, but equally important changes attributable to adrenaline, a state of affairs which we should expect if adrenaline and thyroxin are traceable to a common source—the end products of digestion. The absence of all the organic sulphates shows, in fact, that tryptophane and all the aromatic amino-acids are regulated by bacterial action. We should expect, therefore, a part of the syndrome of hyperthyroidism to be really hyperadrenalism. How far is this the case?

It enunciates no new theory to state that hyperactivity of the thyroid gland is accompanied by a corresponding activity of the adrenals. Hitherto this has been explained on the ground of an interaction between the thyroid and the adrenals, the so-called balancing of endocrine activities. From the foregoing paragraphs, however, the phenomenon is more rationally explained, not by some *recondite* interaction, but by a simple increase in the source of their particular secretions. To emphasize this I would quote the following pregnant paragraph from Professor Swale Vincent's *Internal Secretion and the Ductless Glands*:

"It is doubtful whether a condition strongly resembling Graves's disease has ever been produced by the administration of thyroid substance to animals. But there can be little doubt that definite toxic effects can be produced by thyroid feeding. These are loss of body weight, gastro-enteritis, and diarrhoea, rather than tachycardia, nervousness, and exophthalmos."

A further important question to be considered in relation to hyperthyroidism is that of the increase in the basal metabolic rate, which is now so generally recognized to be an outstanding feature of the condition. There are two main factors affecting this increase. In the first place, it is due to the greater amount of amino-acids rendered available for absorption by the disappearance, or lessened activity, of the putrefactive group of intestinal organisms. In the ordinary course of events a part of the amino-acids would be converted into phenol, indol, and skatol, and would be excreted in the urine as aromatic sulphates. By being

absorbed, instead of being thus excreted, they exercise the typical effect of protein bodies on metabolism—that is, they stimulate metabolism to a degree considerably in excess of their mere calorific value. The same fate also overtakes the fatty amino-acids. The second factor to be noted is this: that if we can assume that the source of adrenaline is to be found among the amino-acids in the intestine produced by the digestive ferments, the failure of the putrefactive organisms still further to split up this precursor into an excretable substance again has a specific bearing upon the increase in the basal metabolic rate, for it is now generally conceded that adrenaline is the sensitizer of the sympathetic nervous system, "the katabolic nerve of the body."

## A CASE OF TORSION OF THE GALL BLADDER.

BY

HERBERT C. JONAS, M.D., B.S.LOND.,

SURGEON TO THE BARNSTAPLE AND NORTH DEVON INFIRMARY.

SINCE torsion of the gall bladder is, and from the nature of the case must always be, an extremely rare accident, every case is worth recording.

A woman, aged 67, under the care of Dr. Seal, of South Molton, was taken suddenly ill at 10 p.m. with acute pain, distributed over the abdomen generally. She vomited and was collapsed, but not with the intensity seen in a case of perforation; there was a slight action of the bowels during the night or the early morning. The pain was not relieved, and from about 8 a.m. she was unable to pass flatus. The vomiting increased, and became green with bile; it was never stercoraceous, and never offensive. Dr. Seal could feel a tumour on the right side of the abdomen on the following morning. There was no rise of temperature.

She was seen in consultation with Dr. Seal at 6.30 p.m., when her expression was anxious but not intensely so; the pulse was just under 100, of fairly good volume and regular. The general condition was such as to give any prospective surgeon a reasonable hope of a favourable result of surgical interference.

The abdomen moved badly with respiration, but still it did move. There was a distinctly visible swelling on the right of the middle line. There was no distension, and no visible peristalsis. The mass on the right side was sausage-shaped, with the lower end blunter and more pronounced than the upper. Its long axis was tilted so that the lower end was slightly to the right of the vertical and the upper to the left. It did not appear to move with respiration, and was freely movable in all directions; the hand could be got between it and the liver above the tumour. Auscultatory percussion gave no indications of any connexion with the liver.

It was obvious that some acute abdominal condition was present, and the history pointed more to an intestinal obstruction than either a perforation or an inflammatory process, and it was thought probable that it was a case of growth in the colon, although the fact that the lower end was the more defined and the upper the less mobile was rather against this.

The physical signs connected with the very obvious tumour were distinctly puzzling. The swelling was exactly in the position of the gall bladder, but it was movable, seemingly in all directions. The liver could be felt moving with respiration and the tumour seemed not to move with it. Auscultatory percussion failed to show any connexion between it and the liver. There was no history of any previous trouble in the gall bladder, and there was no temperature to suggest a cholecystitis. The question of torsion or volvulus was never considered.

### Operation.

The patient was with considerable difficulty persuaded to submit to operation; it was performed the same evening. Before the peritoneum was opened a dark red mass was seen, exactly like one sees when operating for extrauterine gestation. As soon as the peritoneum was opened a very little serous fluid escaped, and it was found that the tumour was a large gall bladder, quite black and nearly gangrenous from strangulation by two half-turns of the neck just at the edge of the liver. The turns were from left to right. After reducing the twist the gall bladder was removed with the greatest ease, since the point of constriction could be readily brought out of the abdomen, and the ligature could be applied to perfectly healthy tissue. The patient made an uneventful recovery.

The organ when removed was about the size and shape of a large pear. The walls were very much thickened, and it was quite black with extravasated blood. It was tightly distended with blood-stained bile, and it contained ten or twelve moderate-sized gall stones. Three of the larger of these were tightly lodged behind a valve or fold of mucous membrane; from their position and the thickness of the wall, they might easily have been overlooked during the course of an ordinary cholecystotomy.

Irwin in recording a case has collected seven previous ones, in only one of which were gall stones found. He also comments on the difficulty of diagnosis. Judging from the case under consideration, the difficulty would seem to lie chiefly in the fact that the possibility of its

occurrence is not taken into account. In spite of the fact that the tumour did not move with respiration, and that it seemed to be free from the liver, there is no doubt that at the time of examination the lower rounded end of the mass and its position were distinctly suggestive of gall bladder, and if the surgeon had in his mind the possibility of this condition being present it is more than likely that he would arrive at a correct diagnosis.

With regard to success of laparotomy, which Irwin also mentions, if all cases were as easy and straightforward as the one under discussion the surgeon could have nothing to fear, so far as mortality is concerned, beyond the ordinary anaesthetic risk.

## ILEO-COLIC INTUSSUSCEPTION CAUSED BY MECKEL'S DIVERTICULUM AND SIMULATING ECTOPIC GESTATION.

BY

H. H. GREENWOOD, B.S.LOND., F.R.C.S.ENG.,

HONORARY SURGEON, VICTORIA HOSPITAL, SWINDON.

THE two features in the following case which seem to warrant placing it on record are, first, the mimicry of ectopic gestation and the absence of the usual signs and symptoms of an ileo-caecal intussusception, and, secondly, the impossibility of reducing the intussusception by the ordinary methods, on account of the tight grip of the ileo-caecal valve.

A woman, aged 30, who had been married for three years, and during that time, and indeed all her life since puberty, had had no menstrual irregularity, ceased to menstruate three months before she was taken ill. As she was in good health at the time, she concluded that she was pregnant.

On June 16th, 1922, she was seized with acute abdominal pain, definitely located in the right iliac region, and occurring in spasms of variable duration; in the intervals she was not entirely free from pain. On that day she vomited once, but not afterwards. On June 18th she called in Dr. Young, who suspected a tuba

FIG. 1.—Diagram of abdominal findings; T=tumour, U=uterus.

FIG. 2.—Diagram of removed ileum.

gestation, threatening rupture; when I saw the patient with him later in the day I concurred in the diagnosis and sent her in to Victoria Hospital, Swindon, for operation.

Her condition then was highly suggestive of a tubal gestation; she was in great pain at intervals, the spasms lasting only a few minutes, and her expression was one of "fear of impending catastrophe." The pulse was not rapid (80), but small and feeble, the temperature 98° F. There was no general distension of the abdomen, and rigidity was confined to the right rectus muscle below the level of the umbilicus.

The bowels had acted normally up to that time; there was no diarrhoea, neither mucus nor blood in the stools, no tenesmus, and no swelling typical of an intussusception. On bimanual examination the uterus, enlarged, but somewhat indefinite in outline, could be felt pushed over to the left by a large elastic swelling which bulged down into the right lateral fornix and was felt to be continuous with a similar swelling in the right iliac fossa. This abdominal swelling reached nearly to the level of the umbilicus, was tender, and did not vary in size. The rigidity of the rectus over it rendered precision of palpation impossible.

### Operation.

With the assistance of my colleague Dr. Young, at 9.30 p.m. a paramedian incision was made below the umbilicus, and the uterus, of the size of a three months' pregnancy, together with the appendages were found lying over to the left and physiologically normal. The appendix, presenting nothing abnormal, was drawn out of the wound. There followed the caecum, so mobile that it was easily pulled completely out of the abdominal wound after being dislodged from the pelvis in which it had lain. After packing off the rest of the abdominal contents the caecum was more closely examined; it was found to be very large and soft, and within its lumen could be felt a harder, more elastic, and slightly movable tumour. The entering ileum was also swollen to double its normal

diameter, its walls thickened and rigid. Realizing the existence of an intussusception, I followed the small gut upwards and came upon the commencement of the lesion some twelve inches from the ileo-caecal valve. Attempts to "milk" back the intussuscepted bowel were ineffectual, and I therefore removed the appendix, enlarged the opening so left in the caecum, and with two fingers inside the caecum reduced the protruding gut through the ileo-caecal valve. It was only by patient and careful manipulation that this could be done, so tightly was the small bowel gripped by the valve. The whole of the intussusception was then, with comparative ease, reduced, and as the last portion emerged a Meckel's diverticulum turned itself inside out, resuming its normal position and appearance. The wound in the caecum was then closed.

The diverticulum was on the antimesenteric border, was short, and its lumen wide. On each side of it the bowel was ecchymosed and of very doubtful vitality. Within the lumen of the gut, at the level of the diverticulum, there could be felt a soft swelling. I removed six inches of ileum, including the diverticulum, performed a lateral anastomosis, and after fixing the mobile caecum in its normal position by catgut sutures, closed the abdomen without drainage.

Recovery was uneventful, and the patient left hospital three weeks later free from symptoms, the pregnancy continuing normally. The pathologist reported: "The intussusception consisted of a portion of bowel in a state of acute congestion and commencing gangrene from strangulation of the blood supply. It contained in its cavity a mass of breaking-down blood clot."

## A CASE OF RAT-BITE FEVER.

BY

J. ODERY SYMES, M.D.,

SENIOR PHYSICIAN TO THE BRISTOL GENERAL HOSPITAL.

RAT-BITE fever is not of common occurrence in this country, and the following case is so typical in character as to merit publication.

T. H., a boy aged 13 years, whilst on holiday in Devonshire was bitten on the left hand by a rat, on August 16th, 1922. The wound was not a severe one, and on the following day it was washed with carbolic lotion and dressed by a surgeon. It did not suppurate, and the doctor who saw the wound on August 23rd said it was doing well. It subsequently healed. About August 30th the wound was red and oedematous, and the temperature rose to 103° F. Two incisions were made near the wound, but no pus was found. During the following week the temperature rose again, but the boy was well enough to make a long journey to his home at Clevedon on September 7th. He was then seen by Dr. Hubert, who dressed the hand and found a little pus escaping. The wound healed rapidly, but from time to time until the date on which I saw him (October 11th) he

was subject to a rise of temperature varying between 102° and 104° F., coming on every three or four days, and lasting for two days. Each return of fever was accompanied by the appearance of a patchy erythematous rash all over the body. There was no lymphangitis. The scar was healthy, and not reddened. There were two small lymphatic glands palpable in the left axilla, and one in the left posterior triangle of the neck. The left hand was cyanosed. During the height of the fever there was a peculiar smell about the patient, reminding one of a hot wet dog. On one occasion there was a trace of albumin in the urine. He was brought to a nursing home under my care on October 12th, and 0.15 gram of novarsenobillon was injected intravenously on October 13th; further doses of 0.3 gram were given on October 18th and 26th, just before the rise of temperature might be expected. The fever which followed each of these injections was brief, and on the first two occasions only was accompanied by a rash which was of both an erythematous and urticarial character. The rash lasted for twelve hours. The blood was examined by Dr. Hadfield on October 14th. His report was as follows:

Red blood cells	...	...	4,100,000 per c.mm.
White blood cells	...	...	7,850 "
Haemoglobin	...	...	78 per cent.

There is no abnormality in the differential leucocyte count. The blood was examined by taking films and a thick drop. No parasites

were seen. There is, however, slight polychromatophilia. This and the anaemia are the only pathological findings.

The patient went home on October 19th and made a quick convalescence. There has been no return of fever. No parasite was found in the blood of this case, but it seems probable that the disease is identical with that seen in India, which is associated with a spirochaete discovered by Futaki in 1915 (*S. morsus muris*). The incubation period is usually two or three weeks. The initial wound heals normally in a few days, but later becomes swollen, painful, and red. Fever recurs every five or six days. The urine is increased in quantity, and contains albumin and casts. In India about 10 per cent. of untreated cases die. In any case convalescence is slow and there is emaciation and anaemia.

## Memoranda:

### MEDICAL, SURGICAL, OBSTETRICAL.

#### RINGWORM AND ITS TREATMENT.

ALL present methods of treating ringworm require prolonged supervision, and even x-ray treatment requires some three months. At the school clinics in Blackburn, in 1920, I experimented with various methods of treatment, and by the end of the year I began to get rapid results with the following method:

The hair is cut short, permitting a good examination of the whole surface, the affected parts are shaved, and then washed with ether soap, dried, and the following lotion applied: Calomel 5 grains, tinct. iodi (B.P.) 1 drachm; stir with glass rod—a reddish precipitate is formed. This lotion is poured upon small pieces of cotton-wool and applied to the ringworm area by gentle rubbing. The piece of wool is then discarded, clean white lint applied and bandaged. The child returns to the clinic the next day, the dressings are removed, the areas are washed well with ether soap, ammoniated mercury ointment (B.P.) applied, and a bandage again used. This process is continued until cure results, generally within fourteen days; the child is ready to return to school during the third week.

During 1921, 61 cases of ringworm of the hairy scalp, 2 involving the whole hairy scalp, forehead, and neck, were treated at the clinics by this method; the average number of days required for cure was eighteen. The shortest period was six days, the longest thirty-seven days; in this case two children at home were being treated for ringworm by the mother; this explained the fresh areas of ringworm on our patient's head which arose during treatment.

The calomel iodine lotion must be applied gently, and must be freshly prepared for each case. If rubbed in instead of gently daubed on, within a few hours' time the child suffers severe pain, due to a burn of the first or even second degree; in the first case a mild erythema, and in the second case erythema and small blisters, simulating erysipelas. I have only had three such cases, and those among my early cases. The best treatment of these early burns is to apply a mixture of olive oil 3 parts and castor oil 1 part. The lotion need be applied only once; it seems to penetrate and destroy the parasites perhaps by the liberation of nascent iodine. The further treatment described keeps the surface clean and rubs out all loose hairs. In several cases a chronic scurfiness continued, but cleared up when the oil application was used. All the 61 cases mentioned have been kept under observation and in no case was there any recurrence.

As the lotion is very active, I considered it necessary to limit the surface of application by dividing the scalp into six equal areas. On the first day the whole scalp is washed with ether soap, and dried. To area 1 freshly prepared calomel iodine lotion is applied gently, and ammoniated-mercury ointment rubbed into the remaining five-sixths; the head is then bandaged. On the second day the five-sixths part is washed with ether soap, and the lotion applied to another sixth part. The part to which the lotion was applied is then washed as a separate area, and ammoniated mercury ointment applied, and so on. On the seventh day the whole head is again treated as one area with ether soap wash, and ammoniated mercury ointment applied.

Ringworm of the body receives similar treatment, the child remaining at school, as the condition is cured within

forty-eight hours. When applying the calomel lotion care must be taken to prevent it running down the scalp.

I have to thank Mr. Holroyd, head of the Chemical Department of the Blackburn Technical College, for giving me the following analysis of the active lotion. He says: "The precipitate is mercuric iodine together with a little calomel. The filtrate from this precipitate contained a mixture of the chlorides and iodides of potassium and mercury. For purposes of convenience the mixture may be said to consist of potassium chloride 0.75 grain and mercuric chloride-iodide 2.95 grains."

JAMES ROBERTSON, M.B., D.P.H.,  
Assistant Medical Officer of Health and Medical  
Officer of Schools, Blackburn.

### FOREIGN BODIES IN THE STOMACH REMOVED BY OPERATION.

THERE have been many cases recorded of foreign bodies being swallowed and removed from the stomach by operation, but the following is perhaps worthy of record, not only on account of the number of articles found, but because of their size and the constancy with which the patient preferred a certain kind of article—namely, iron keys.

A woman, aged 27, who had been the subject of several abdominal operations, again complained of epigastric pain early in January, 1922, but knowing her neurotic nature I was inclined to lay little stress upon her subjective symptoms, and as her objective symptoms

were nil, I temporized. A few weeks later she again came to me, and I found slight tenderness in the right upper quadrant of the abdomen. She was vomiting frequently. I kept her in bed, and on deep palpation a movable mass was felt in the region of the gall bladder. A skiagram was taken, but as the plate was spoiled, and as the pain had become more acute again, I decided not to wait any longer.

I opened the abdomen by a vertical epigastric incision through the right rectus and found the gall bladder to be normal. While passing my hand down over the duodenum I felt a hard irregular mass,

FOREIGN BODIES IN STOMACH.

which proved to be the stomach. I lifted it out of the abdomen, and having opened it anteriorly in the prepyloric area, removed one by one the articles shown in the accompanying photograph. The stomach and abdominal parietes were closed in the usual way, drainage being provided for by means of a small rubber tube, left in the wound for forty-eight hours. The patient made an uninterrupted recovery.

She had not at any time given me the slightest hint as to her peculiar diet, and she must have been swallowing the articles for at least six weeks. The complete list is: 17 keys, the largest of which was  $3\frac{1}{2}$  inches in length; 2 coins (one with a ring through it); 3 safety pins (one open); 1 button; 1 engineer's split pin; and 1 pencil sharpener.

A. GEORGE BRAND, M.B., Ch.B.

Ayr County Hospital.

THE late Mr. Arthur Leaman Crossfield, of Oxtou, Birkenhead, who left personal property valued at £44,898, has bequeathed one-fourth of his estate to the Hospital for Women, Liverpool; one-eighth to the Hospital for Cancer and Skin Diseases, Liverpool; and one-sixteenth to the Liverpool Sanatorium, Delamere Forest.

IN a recent communication to the Royal Society Drs. Leonard Hill and Eidinow state that the biological action of light is accelerated by warmth, retarded by cold. This was found to be true for bacteria, infusoria, and human skin. By adequate exposure to cool air overaction of the sun on the skin can be prevented. The success of heliotherapy applied to children with surgical tuberculosis, depending as it does on exposure to sun and cool air, can probably, the authors think, be secured for cases of phthisis if they are no longer exposed in hot sun boxes, but suitably stripped and exposed in cool air.

## British Medical Association.

### CLINICAL AND SCIENTIFIC PROCEEDINGS.

#### CAPE OF GOOD HOPE (WESTERN PROVINCE) BRANCH.

THE Cape of Good Hope (Western Province) Branch was entertained by the medical superintendent and visiting staff of the New Somerset Hospital, Cape Town, on April 13th, when a clinical evening was held. Two sections were organized—one, surgical, in charge of Mr. C. C. ELLIOTT, and the other, medical, in charge of Professor A. W. FALCONER.

Mr. C. C. ELLIOTT showed cases of depressed fracture of the skull, depressed fracture of the supraorbital ridge, and, for diagnosis, a case of tumour in the right inguinal region in a male European. He also exhibited an excellent specimen of an excised Gasserian ganglion. Mr. H. A. MOFFAT demonstrated an old dislocation of the head of the radius, a fracture of the head of the radius, a fracture of the carpal scaphoid, and a tuberculous shoulder-joint. Mr. C. F. M. SAINT exhibited an interesting and unusual case of psoas abscess, with superimposed pneumococcal infection. He also showed a case for diagnosis, probably duodenal ulcer, and a tuberculous shoulder-joint. Dr. A. REITH FRASER exhibited a case of digital chancre in a coloured midwife, and one of granuloma inguinale in a Kaffir which had failed to respond to intravenous tartar emetic and intramine. Professor E. C. CRICHTON showed an interesting collection of pathological specimens. A series of radiograms exhibited by Dr. H. W. REYNOLDS included cervical ribs, fractured skull, fractured spine, bone graft, talipes calcaneo-cavus, and perforating gastric ulcer. Professor A. W. FALCONER conducted the medical section to his wards, where cases of amoebiasis, cerebellar tumour, and gummatous meningitis were demonstrated. Dr. D. P. MARAIS showed a specimen of a cerebellar growth *post mortem*; he also demonstrated a case of Addison's disease, and several cases of children indicating the value of heliotherapy in strumous conditions. Mr. D. J. WOOD's collection of eye cases included a rare example of glaucoma in a child 7 years of age. This was believed to be a record in the matter of age incidence, and tended to upset preconceived speculative theories regarding the etiology of glaucoma—a condition which had been taught to be unknown in childhood. Other cases included chalazion, tuberculosis of the conjunctiva, trachoma, and spring catarrh. There were sixty-nine members present.

On April 27th Dr. O. M. GERICKE read a paper entitled "In the days of Van Riebeeck." He outlined Van Riebeeck's medical and political career, and gave an interesting account of the establishment of a hospital at the fort in Table Valley in 1652, the nature of the various sicknesses in the valley, and the need for such an establishment. Van Riebeeck's contemporaries in Europe, the state of public health and sanitation in England, France, and Holland at that period, the universities, the teaching methods, the first London Pharmacopoeia, and the materia medica of the times generally were passed under review. The paper stimulated a keen discussion, in which Dr. DARLEY-HARTLEY, Dr. A. REITH FRASER, Dr. DE BEER, Dr. D. P. MARAIS, and Dr. R. SHARP took part.

Dr. R. A. BARLOW then read a paper on "Some surgical complications of influenza." He laid emphasis on the extremely large proportion of cases of influenzal bronchopneumonia which were followed by empyema, met with in the Royal Navy during the pandemic of 1918-19. The difficulty of making a diagnosis in this condition was due to lack of conformity with the usual textbook symptomatology. The advantages to be gained from delaying open operation until repeated aspiration had been fully tried out were clearly stated; in this connexion a certain measure of success had followed the use of intravenous eusol in septicæmic cases. Other complications discussed included appendicitis, perinephric abscess, surgical emphysema, and otitis media. Mr. C. C. ELLIOTT and Dr. D. P. MARAIS discussed the paper, and the President, Dr. C. M. MURRAY, thanked Dr. GERICKE and Dr. BARLOW for their interesting contributions.

## ULSTER BRANCH.

A CLINICAL meeting of the Ulster Branch was held in the King Edward Memorial Hall of the Royal Victoria Hospital, Belfast, on May 31st, with Mr. ANDREW FULLERTON, President, in the chair. The following cases and specimens were shown:

Drs. DARLING and PEDLOW (Lurgan): The specimens of an ovarian pregnancy, and a patient on whom Rammstedt's operation had been successfully performed.

Mr. MITCHELL: A case of grafting of sarcoma of tibia four years after operation, with x-ray photographs showing the progress of the case; and two cases of plating for fractured femur, with x-ray photographs.

Mr. IRWIN: A case of tibial bone graft for spondylolisthesis, and Mr. CRYMBLE a testicular tumour.

Dr. R. MARSHALL: A case of dystrophia adiposo genitalis, in a boy who was losing weight at the rate of about a pound a week under 2 grains of pituitary gland.

Dr. MCKISACK: A case of gumma of brain, where the symptoms had disappeared under treatment.

Dr. SMITH showed charts of the effect of insulin, and gave a demonstration of some experiments.

Dr. ALLISON exhibited charts showing results of fractional examination of stomach contents; the curves of duodenal ulcer and chronic appendix, as confirmed by operation, were often closely similar, and even x-ray photographs of opaque meals did not always differentiate. The two together formed a most valuable help.

Dr. CALWELL: A case of a young lad with mental deficiency, subject to petit mal, who was admitted with an attack closely resembling hystero-epilepsy, but which cleared up in a couple of weeks; and a case of a young girl, under-developed, who was admitted with sudden clouding of consciousness, from which, in about three weeks, she has suddenly recovered; also specimens from a case of hypernephroma of kidney with secondary deposits in brain, lungs, intestines, etc.

Mr. KIRK: A case of advanced scirrhus of breast treated with vaccines, colloids, and operation; two specimens of tuberculous ulceration of ileum successfully resected; recent case of excision of knee-joint; recent intertrochanteric fracture of femur, following accident, with x-ray photographs; a case of traumatic paraplegia.

Professor MACILWAINE: Some abnormal electro-cardiograms indicating lesions in the conducting system of the heart.

Dr. BOYD CAMPBELL: A case of subacute bacterial endocarditis, with the now classical signs of paleness, clubbing of finger-ends, petechiae, enlarged spleen; a non-haemolytic streptococcus was found in the blood.

Mr. HOWARD STEVENSON: A specimen of a brain with a large endothelioma of the right frontal sinus; a decompression had been performed three years before for headache, and a meningeocele had formed over the site, from which large quantities of clear cerebro-spinal fluid were taken from time to time, up to 300 c.cm. in a week; epileptic turns developed, in one of which the patient seriously injured his arm, and died. Microscopic slides showed the whorled arrangement of the tumour, and some typical psammoma bodies.

The PRESIDENT (Mr. Fullerton) showed the following among other cases: Subtotal cystectomy for malignant disease of bladder with implanting of ureter; hour-glass contraction of stomach treated by gastro-enterostomy; an obscure case of urinary obstruction; decortication of lung in a child 2 years old who had suffered from empyema for eighteen months; after-result of laminectomy for gunshot wound of spine—the hole in theca was covered by a thin layer of muscle; and chronic colitis treated by appendicostomy and vaccine.

THE seventeenth French Congress of Medicine will be held at Bordeaux from September 27th to the 29th. The subjects to be discussed include: Remote sequelae of meningitis (Professor Le Dantec of Bordeaux), relations between the sympathetic and the endocrine glands in pathology (Professor Pachon of Bordeaux and Dr. Perrin of Nancy), treatment of meningococcal infections (Dr. Dopter of Paris and Dr. Boidin).

THE Medical Congress held annually at Brussels under the name of "Les Journées médicales de Bruxelles" will take place this year from June 24th to the 27th. The following addresses will be given: Our knowledge of prehistoric man, by Professor Pittard of Geneva; the high traditions of army surgery in France, by Professor Forgue of Montpellier; ileocolic stasis, by Professor de Beule of Ghent; French medicine and social laws, by Professor Balhazard of Paris; new discoveries in the prophylaxis and treatment of syphilis, by Professor Levaditi; the fight against cancer in France, by Professor Bergonié of Bordeaux; and the medical profession and hygiene, by Dr. Rolot of the League of Nations.

## Reports of Societies.

## PRIMARY CANCER OF THE LIVER.

A MEETING of the Pathological Section of the Royal Academy of Medicine in Ireland was held on May 25th, with the President, Dr. W. D. O'KELLY, in the chair, when Dr. G. E. NESBITT described a case of primary cancer of the liver. The patient, aged 21, had a history of some injury to the back, from which he dated his illness. The only marked symptom at first was a large mass which could be felt in the liver. The patient died of haemorrhage into the abdominal cavity ten days after admission to hospital. Dr. J. H. POLLOCK described the pathological conditions. The point of haemorrhage could not be determined, but there appeared to have been a general oozing. The tumour was bile-stained, and there were metastases in the lung and mediastinum. The tumour also penetrated into the vena cava. Dr. V. M. SYNGE described another case of primary cancer of the liver, in a boy aged 17. When admitted to hospital the patient was suffering from vomiting and wasting. On examination it was found that he had considerable ascites, and a hard mass felt in the abdomen was thought to be a matted mass of tuberculous glands. At operation a number of small nodules were found studded over the peritoneum, while a larger obviously cancerous mass was attached to the liver; cancer developed in the operation wound. The boy lived for six months in hospital. At the *post-mortem* examination a large tumour attached to the splenic flexure was found to occupy the left lobe of the liver, and a great number of nodules were scattered over the peritoneum. The diaphragm was thick and leathery. No metastases were found in the lung. No primary focus was found elsewhere. The cell masses were mostly diffuse, solid collections of cells, and showed no lumen. The PRESIDENT recommended a careful search of the pancreas in these cases of liver cancer, as a small primary focus might possibly be found there. Professor A. C. O'SULLIVAN said that the second case was undoubtedly a genuine liver cell cancer, and he felt inclined to classify the other as also derived from the liver cells rather than from the bile ducts. Dr. Syngé's case resembled one which he had shown some years ago, in which the liver cells over a considerable area could be traced through a transition first into small abnormal cells like those of the bile ducts, and then into the diffuse masses of the tumour.

Dr. G. E. NESBITT described a case of sarcoma in an ex-soldier aged 30; it seemed to be a typical case of advanced pulmonary tuberculosis, except that the patient suffered from great pain in the right side of his chest. At the autopsy the primary growth was situated in the front wall of the thorax, probably arising from one of the bones, and there were metastases in the heart as well as elsewhere.

Dr. A. R. PARSONS described a case of pneumococcal meningitis, which was first diagnosed as tuberculous meningitis on account of a mistaken report on an enlarged gland of the neck which was incised. On lumbar puncture the turbid cerebro-spinal fluid was found to contain pneumococci. There was some improvement after lumbar puncture, but death eventually ensued.

Dr. B. H. MICKS gave notes on a case of encephalitis lethargica.

There was a sudden onset with vomiting, followed by severe neuralgic pain on both sides of the head and both upper extremities. Pain lasted for a week, accompanied by insomnia, and then the patient, a man aged 56, began to suffer from illusions and delusions, by which he was never dominated completely. A generalized persistent muscular twitching was observed, with slight lethargy, but no marked tendency to somnolence. There were no signs of meningeal irritation, no marked motor disturbances, and the optic discs were normal. Slight continuous fever was present, the highest recorded temperature being 102° F. on the day of death. There was slight leucocytosis, 10,500 per c.mm.; Wassermann and Sigma reactions were negative. On *post-mortem* examination round-cell infiltration was found around the vessels in the cerebral substance, but not around those in the meninges. There were well marked round nuclei in floor of the fourth ventricle and upper portion of the spinal cord. Death had occurred with all the signs of respiratory and cardiac failure.

The case was discussed by Dr. ABRAHAMSON, Dr. MACPETRIDGE, Dr. NESBITT, Dr. WIGHAM, and the PRESIDENT.

## Reviews.

### PROBLEMS IN TUBERCULOSIS.

*In Problems in Tuberculosis* Sir JAMES FOWLER follows up the success of his larger work on *Pulmonary Tuberculosis*, reviewed in our columns at the time (1921, ii, 599), by a consideration of some questions connected with the administrative side of the tuberculosis problem, and with the gracious courtesy of a senior dedicates it to Dr. P. C. Varrier-Jones of the Papworth Hall Colony and Village Settlement, in appreciation of his work. The solution of some of the great difficulties of the tuberculosis problem is shown to be the gradual transformation of the existing sanatoriums into settlements on the lines adopted at Papworth; this will require endowment, State or other; "The country has to maintain small-pox hospitals because it will not enforce vaccination, and it will have to maintain tuberculosis settlements until it rebuilds its slums." This is an aphorism which it would perhaps be unkind to commend to the attention of the Minister of Health. The organization of such a settlement is described with much wise advice as to the nature of employment that should be arranged for the convalescents.

On the all-important subject of diagnosis Sir James makes some very important observations; while there is no trustworthy evidence that pulmonary tuberculosis is now detected at an earlier stage than it was formerly, it is often (in from 60 to 75 per cent. of the cases) diagnosed erroneously. Here he is supported by Dr. E. Rist's statistics from France (vide *BRITISH MEDICAL JOURNAL*, 1922, ii, 733), chronic bronchitis very commonly being the real disease. Among the reasons for this vast error are the absence of cases of pulmonary tuberculosis from the wards of general hospitals, and the increasing tendency to transfer the responsibility of diagnosis to radiographers who have not always the training in morbid anatomy necessary to enable them to correlate rightly the x-ray appearances with the structural changes. He advocates a school for the training of the future directors of sanatoriums, and considers a diploma in tuberculosis just as necessary for those who are to treat that disease as is a diploma in tropical medicine for those responsible for the care of tropical diseases. Throughout this attractively written book there are scattered *obiter dicta* which, as those in his last work appeared to him to be useful to the reviewers, have now been considerably collected at the end of the volume. His numerous readers will be glad to learn that they may look forward to a further volume from Sir James Fowler, dealing with bovine tuberculosis in man, or, as he prefers to call it, para-tuberculosis.

### UREA.

*The Chemistry of Urea*,<sup>2</sup> by Professor EMIL WERNER, is the latest addition to the well known series of biochemical monographs edited by Professors Plimmer and Hopkins. These little grey books have won a high place in the esteem of all those interested in biological problems, and any addition to their number is received with interest. Most of these—each from the pen of a master of research in some particular field—present a critical analysis of the trend of work in a large subject and are books of inestimable value; but there are monographs of another sort, of more limited scope but none the less valuable and having a charm of their own. These are those in which the author is concerned with some restricted subject that he has made his own and in which he presents a measured verdict of his own work and relates the story of the steady march of his researches. Such a monograph is the one under review.

We have all been taught that urea is the amide of carbonic acid. We call it carbamide. The natural fermentation of urea and its artificial hydrolysis agree to produce carbon dioxide and ammonia, do they not? What could be simpler?

And from the synthetic side much confirmatory evidence is surely available? Of course, the reactions of urea never quite fitted in with those of an amide but we were content to put these among the many "exceptions" in organic chemistry. Not so Professor Werner: in 1913 he challenged the conventional formula and suggested instead the cyclic structure:

This formula lacked the pleasing symmetry of carbamide, and it was not taken too seriously. But he set to work to reinvestigate the syntheses and the main decompositions of urea from the basis of the new structure. In this monograph we are given the history of this research and watch the results grow steadily into what must be conceded to be a very formidable argument. We would direct the attention of the compilers of textbooks to his book that they may make a few notes for their next edition. We might be content to leave the problem to the organic chemist satisfied with the knowledge that physiologically urea means ammonia and carbon dioxide minus a molecule of water. But the author will not have this at all. He finds that all the syntheses of urea, including Wohler's historical reaction, may be expressed as the union of ammonia with cyanic acid in its keto form:

This immediately brings urea into relation with ammonium salts in general and makes cyanic acid the most significant decomposition product. Serious consideration must, therefore, be given to the latter in relation to protein anabolism and katabolism. The researches of Fosse and others have shown that urea has a very wide natural distribution, even down to the lowest plant forms, so that a larger place may yet have to be ceded to it in any general plan of nitrogen metabolism, and we must be prepared to study therefore the claims of cyanic acid also.

A series of simple lecture experiments to demonstrate his views have been included in this fascinating monograph, which is completed by two appendices and an extensive bibliography. The first appendix is a critical survey of the proved methods for the detection and estimation of urea and full details are given, the second includes a brief discussion of the fixation of nitrogen as urea. Atmospheric nitrogen can now be economically converted into ammonia and the latter is at present fixed as ammonium sulphate. The possibility of fixing it instead as urea is attractive, for the latter contains nearly 50 per cent. of nitrogen and is an ideal source of this element for all plant life. The chemist would then have achieved one more step in the economic reversal of the cycle of nature.

### A NATIONAL HEALTH POLICY.

DR. HARRY ROBERTS of Stepney, before the advent of the Insurance Act, practised medicine in East London. Under the Act he and his partners have, he believes, one of the largest insurance practices in England, and it is matter for congratulation that such a man has had the inclination and possesses the literary skill to set forth his views on a *National Health Policy*.<sup>3</sup>

Dr. Roberts emphasizes his agreement with the report of the Consultative Council of the Scottish Board of Health, especially, we take it, because of its recommendation that "the organization of the health service of the nation should be based upon the family as the normal unit and on the family doctor as the normal medical attendant and guardian." As regards allegations of medical carelessness, he makes no attempt to defend the indefensible, but remarks: "After all, panel doctors are the same individuals as those known as general practitioners before the Insurance Act came into being. Those who neglect their duties now neglected their duties then, but no political

<sup>1</sup> *Problems in Tuberculosis: Administration, Diagnosis, Employment, Settlements.* By Sir James Kingston Fowler, K.C.V.O., C.M.G., M.D. Oxford Medical Publications. London: Henry Frowde, and Hodder and Stoughton. 1923. (Demy 8vo, pp. ix + 54. 5s. net.)

<sup>2</sup> *The Chemistry of Urea.* By E. A. Werner, M.A., Sc.D., F.I.C. Monographs on Biochemistry. London: Longmans, Green and Co. 1923. (Roy. 8vo; pp. xii + 212. 14s. net.)

<sup>3</sup> *A National Health Policy.* By Harry Roberts. The Labour Publishing Company, 38, Great Ormond Street. 1923. (Crown 8vo, pp. 123. 3s. 6d.)

question being involved we heard less about it." Further, he holds that "the greatest fault of 'panel doctoring' lies in a quality which it shares with 'private' medical practice—the necessity which the doctor feels of pandering to the ignorance and superstition of his patients." This, Dr. Roberts says, is specially illustrated in the prescribing of drugs. He believes that "nine out of every ten bottles of medicine prescribed are entirely useless to the persons taking them, and are known to be useless by the doctors who prescribe them," but "patients, almost without exception, . . . insist on their bottle of medicine, and if one doctor will not give it they go to one who will." This, he urges, "is the dilemma which usually confronts the doctor," but after all he can "console himself with the knowledge that his medicine need be nothing more than a harmless placebo," and "he can accompany it with some good advice which without it would fall on deaf ears." No doubt the demand for and prescribing of drugs varies in different parts of the country, and while the problem is a general one it is probably most acute in an area like the east of London. Dr. Roberts ends his chapter on the panel system by declaring his objection to a State-controlled medical service. He also criticizes the attitude of Mr. and Mrs. Sidney Webb, who, "whilst recognizing the advantages of a free choice of doctors, propose to limit the privilege to the 'well-to-do'"; he expresses the hope that if ever the Labour party gets into power "it will tolerate no official medical service that is not the best available and equally for the use of every citizen of the country."

In a brief chapter on "Doctoring the Healthy" he records approval of "regular periodic examination of every man, woman, and child in the country who has no 'conscientious objection' to being seen by his doctor." That was a recommendation made to the Royal Commission on the Poor Law by its medical investigator, but objected to by that body lest it should result in hypochondriasis among those so examined. Dr. Roberts points out that in America there is now a rapidly growing movement in favour of such a system.

We have called attention only to parts of the essay which are of special interest at the present time, but the whole book is well worth perusal. Obviously the views expressed have a controversial aspect, but even where they may be found most open to dissent the vigour and frankness with which they are stated make the book interesting from beginning to end.

#### MICROSCOPICAL EXAMINATION OF FOODS AND DRUGS.

VEGETABLE microscopy applied to the recognition of materials for dietetic and medicinal use is a field in which among English workers Mr. GREENISH stands almost alone. Textbooks on the examination of foods usually give illustrations of the microscopic appearances of a few articles, such as pepper, coffee, and arrowroot, but the number of substances so noticed is seldom adequate, and little or no attention is given to methods of preparation or to the botanical relationships of the constituents. Work in this branch of technology has had a tendency to become individualistic, each worker exploring for himself to find suitable schemes of preparatory treatment. A volume such as *The Microscopical Examination of Foods and Drugs*, now in its third edition,<sup>4</sup> meets a real need: it is exceptional, if not unique, in providing systematic tuition in methods of preparation and guidance to the recognition of distinctive features.

The volume deals more especially with the methods applicable to the types covered by such headings as roots, stems, barks, leaves, seeds, etc. The fact that it gives under this system of treatment complete descriptions of important officinal products from seventy different plants will serve to indicate that it is a worker's as well as a learner's manual. In every instance the methods recommended have survived the test of experience. The subjects are very well illustrated by drawings which give views of prepared sections of tissues and also of the appearances

in the powdered state. The illustrations do not form a complete atlas of vegetable histology; that requisite is furnished in another work by the same author. A useful chapter on adulterants completes a very satisfactory volume.

#### AN AMERICAN TEXTBOOK OF PSYCHOLOGY.

PROFESSOR KNIGHT DUNLAP, who is one of the leading experimental psychologists in America, has written an introductory textbook for college students entitled *The Elements of Scientific Psychology*.<sup>5</sup> The author departs from many of the traditional formulae and conceptions of the older psychology, and insists on the necessity of submitting all working hypotheses to experimental tests and of rigidly defining psychological terms. He is an opponent of introspection as the term is generally understood, and considers that "it should be exclusively used to indicate alterations of one's own body through the visceral and somatic senses" (p. 28). It is difficult to understand how all the data discovered by introspection can be included under this definition. A visual hallucination, for instance, would appear to include purely mental content in addition to the kinaesthetic sensations which, no doubt, comprise part of the total experience. Professor Dunlap's treatment of thought and thought content contains much of interest to psychologists, but he tends somewhat unconvincingly to "explain away" the existence of the image by emphasizing the kinaesthetic processes or muscular content of thought. A considerable section of the book is devoted to sense perception, and a chapter is reserved for an account of the anatomical and physiological mechanisms involved in behaviour.

The book is not elementary and it will be found most serviceable by the advanced student of psychology. The publishers are to be congratulated on producing a volume which it is a pleasure to read and handle.

#### THE WORKMEN'S COMPENSATION ACT.

REVISION of the Workmen's Compensation Act appears likely at no very distant date. In May, 1919, the Home Office appointed a committee to inquire into the working of the present Act, to consider the question of establishing a national system of insurance against accidents, and to report what alterations in the law appear desirable. The report of the Committee was issued in July, 1920, and in May, 1922, a motion was made in the House of Commons calling upon the Government to introduce a bill to amend the Workmen's Compensation Act, 1906. The Home Secretary promised to discuss the possible lines of an agreed measure with representatives of employers and trade unions. In view of these facts the appearance of a work which sets forth as simply as possible a statement of the existing laws, an account of their working, and the problems they give rise to, is opportune. Mr. Joseph Cohen's *Workmen's Compensation in Great Britain*<sup>6</sup> is such a book. Of handy size, it should be of service to employers, trade union officials, law students, and those interested in social problems. Perhaps of most interest to medical men is the chapter dealing with reduction of accidents. We learn that in recent years the British Industrial "Safety First" Association has proved a valuable adjunct to the Factory Acts, by making and considering suggestions for reducing risk, and impressing upon workers the need for care and attention. Tables show that accidents have been reduced by 16 to 75 per cent. in different industries. In 1907, the number of accidents at Port Sunlight reported to the Home Office was 25 per 1,000 employees; in 1920 the figure had fallen to 7.8. Mr. Cohen does not discuss the proposal which has been so frequently advocated by medical men who have had much experience of the working of the Act—namely, that steps should be taken to settle more cases by reference to medical authority, and that greater use should be made of medical referees sitting as assessors. Neverthe-

<sup>4</sup>*The Microscopical Examination of Foods and Drugs*. By H. G. Greenish, F.I.C., F.L.S. Third edition. London: J. and A. Churchill. 1923. (Demy 8vo, pp. 385; 209 figures. 18s. net.)

<sup>5</sup>*The Elements of Scientific Psychology*. By Knight Dunlap, Professor of Experimental Psychology in the Johns Hopkins University, Baltimore. London: Henry Kimpton. 1922. (Sup. royal 8vo, pp. 358; 31 illustrations. 18s. net.)

<sup>6</sup>*Workmen's Compensation in Great Britain*. By J. L. Cohen, M.A. Cantab. F.S.S. London: *Post Magazine*, 9, St. Andrew Street, E.C.4. 1923. (Cr. 8vo, pp. 222. 6s.; post free 6s. 4d.)

less, the chapter on suggested reforms will be read with interest, and the book can be cordially recommended as a useful synopsis of the Workmen's Compensation Act and its working.

### ZOOLOGY.

BUT a short time ago the student and teacher of elementary zoology were alike confronted with the difficulty of finding a textbook suitable to their requirements. Now the difficulty is to select one, out of very many, which most nearly meets their requirements. Professor MEEK's *Essentials of Zoology*<sup>7</sup> caters for the medical and science student who is beginning the study of zoology. It seems remarkable that there should be a sufficient demand for so many elementary books on the subject, for while each may incorporate descriptions of "types" not included in others, still of necessity the anatomy of many—for example, frog and rabbit among vertebrates—is common to them all.

The distinctive character of Professor Meek's book is the inclusion of such forms as *Blatta*, *Taenia*, and *Distoma*; this is useful. A classification of the phylum is given at the commencement of each chapter dealing with a particular "type." This is a doubtful advantage. Schemes of classification differ, often widely, from one another, and are the cause of much confusion to the beginner. Moreover, to make the classification even moderately complete the author is compelled to introduce a number of terms like *Eurypteridae*, *Prototracheata*, etc., without any mention of the kind of animals to which they refer; to do so would too greatly enlarge the scope of the book. The anatomical descriptions are clear, and the book is both reliable and readable; there are numerous illustrations, though they are not always very good.

### NOTES ON BOOKS.

DR. A. W. FULLER, in his small book on *Anaemia*,<sup>8</sup> insists on the frequency of simple anaemia among countless numbers who are neither aware of it themselves nor are informed of what is really the matter by those whom they consult for other complaints. The treatment recommended is hypodermic injection of iron, arsenic, and strychnine in isotonic serum, the last addition rendering the injection painless. During the last two years the author has given 2,000 such injections. Stress is laid on the importance of rheumatism in the causation of this simple anaemia, and on the advisability of commencing the treatment of such cases with salicylate of sodium. The medical reader will not, we fear, get much information of value from this elementary work.

Dr. WALTER LIBBY's pleasantly written *History of Medicine in its Salient Features*<sup>9</sup> is based on his lectures to third-year students in one of the American schools of medicine, and is therefore not an exhaustive so much as a general introduction to the history of medical science and art. In twenty chapters the ground from the dawn of medicine in Egypt and Babylonia to medical science and modern warfare, as illustrated by the world war of 1914-18, is covered, and there is a pleasant biographical flavour conveyed by the short sketches of the makers of medical milestones; for example, in the chapter on "Harvey and the Revival of Physiology" and in that entitled "Science and Practice," in which the question where the physician's attention should be focused is illustrated by the lives of Sydenham and Boerhaave. For renal disease the British Hippocrates recommended various mineral springs, and among them those of the London suburb now known by his name. The chapter on the cell theory rightly contains an analysis of Virchow's achievements, and attention is directed to his doctrine of embolism, which is described as perhaps his greatest triumph. In the account of "the founders of bacteriology" Spallanzani's experiments in connexion with spontaneous generation are summarized, and lead on to Pasteur's work, and so to the chapter on antiseptic surgery, which contains a portrait of Lister and W. E. Henley's fine lines to "The Chief."

<sup>7</sup> *Essentials of Zoology for Students and First Year Students of Science.* By A. Meek, D.Sc. London: Longmans, Green and Co. 1922. (Demy 8vo, pp. xii + 325; 145 figures. 10s. 6d. net.)

<sup>8</sup> *Anaemia, its Causes and Modern Treatment, with a chapter on Neurasthenia.* By Arthur W. Fuller, M.D. Edin. London: H. K. Lewis and Co., Ltd. 1923. (Cr. 8vo, pp. vi + 64. 3s. 6d.)

<sup>9</sup> *The History of Medicine in its Salient Features.* By Walter Libby, M.A., Ph.D. London, Bombay, and Sydney: Constable and Co., Ltd. 1923. (Demy 8vo, pp. xi + 427; 9 plates. 15s.)

The volume entitled *The New Constitution of India*<sup>10</sup> contains two courses of Rhodes lectures; one of three, by Sir COURTENAY ILBERT, deals with the general principles which guided the framers of the constitution; the other, also of three, by Lord MESTON, is more particularly devoted to the workings of the new constitution, and traces the growth of the movement which preceded the change. In appendices are given lists of central and transferred subjects, and the text of the instructions from the Crown to the governors of provinces. Neither writer seems to have given any attention to the preservation of health and the prevention of disease.

The new number of *Brain*,<sup>11</sup> which is the first part of vol. xlvi, contains papers by Dr. F. M. R. Walshe, neurologist to the medical unit, University College Hospital, on postural reflexes in hemiplegia and associated movements, by Drs. Adie and Greenfield on dystrophia myotonia, and on iron in the brain by Dr. A. Gans, from the laboratory of a provincial hospital in Holland.

The International Labour Office at Geneva has published the first number of a *Bibliography of Industrial Hygiene*, which is intended to be a quarterly publication. Most of the writing on industrial medicine appears in current medical and industrial periodical literature, and such a bibliography of the scattered references to the subject should prove very valuable. The references are grouped under the headings of industrial hygiene, industries, hygiene of the worker, physiology, and pathology, and each group has many subdivisions. The subject headings are given in English, French, and German, and the titles of the articles in the original language.

*C.M.B. Examination Questions and Model Answers*<sup>12</sup> is a handbook which, in addition to giving model answers (reprinted from the *Nursing Mirror*) to questions set at recent examinations of the Central Midwives Board, includes a note on how to become a certified midwife, a list of institutions, homes, and midwives by whom pupil midwives may be trained, and an abridged list of the rules of the Central Midwives Board.

The Michelin Guide to Great Britain, 1923, retains all the well known and most useful features of previous issues. There is a section on the numbering of roads recently introduced into this country. The maps are retained, as also the plans of towns. On the back of one of the plans there are some striking illustrations of experiments made in France which prove to how great an extent solid tyres ruin the roads.

<sup>10</sup> *The New Constitution of India.* Being three Rhodes Lectures by Sir C. Ilbert and three by Right Hon. Lord Meston. Delivered at University of London, University College, session 1921-22. 1923. London: University of London Press, Ltd. (Cr. 8vo, pp. 212. 5s. net.)

<sup>11</sup> London: Macmillan and Co. (6s. a part; 24s. a year.)

<sup>12</sup> *C.M.B. Examination Questions and Model Answers.* London: The Scientific Press, Ltd. 1922. (Fcap. 16mo, pp. 125. 1s. 6d. net, 1s. 8d. post free.)

### THE STUDY OF VENEREAL DISEASE IN SCANDINAVIA.

THE transactions of the fifth meeting of the Northern Dermatological Society in Stockholm in June, 1922, have now been published in English, French, or German in *Acta Dermato-Venereologica* (vol. iii, fasc. 3-4). Of the twenty-eight original papers about half deal exclusively or principally with venereal disease. The standard of most of these papers is remarkably high, and they give a useful summary of the observations and opinions of the leading Scandinavian specialists in venereal disease.

#### GONORRHOEA.

##### *In Female Children.*

Dr. H. I. Schlasberg reports the results on 146 girls between the ages of 1 and 11 years, treated in hospital for gonorrhoea during the period 1912-20. In 106 cases the vagina and urethra were infected, in 11 only the vagina, and in 29 the vagina, urethra, and rectum. It is often said that gonorrhoea relapses in young girls because of neglected gonorrhoeal Bartholinitis, but though Dr. Schlasberg saw many relapses he could not trace one to this cause. Another reason why relapses are so common is said to be extension of infection from the rectum to the vagina and adjacent parts. But though Dr. Schlasberg found gonorrhoea of the rectum required longer treatment than gonorrhoea of the neighbouring structures, he saw only three cases of relapsing gonorrhoeal proctitis out of

the 29 cases in which the rectum was involved. Among the 135 patients with gonorrhoea of the vagina and urethra, 81 relapsed after the completion of treatment. In many cases there was more than one relapse, and the site of the reappearance of the gonococci was always the same. Not until twenty successive bacteriological examinations had been made should success of any given treatment be claimed; a lower standard is bound to bring many disappointments. The cervix was found to be infected in several cases, but Dr. Schlasberg considered it inadvisable to attempt local treatment of the cervix; when gonorrhoea of the vagina is cured the disease of the cervix usually clears up.

#### *Certification of Cure in Men.*

Dr. Björling, who discussed the question, When can gonorrhoea in the male be certified as cured? maintained that a negative bacteriological examination is of little value when there is a persistent discharge from the male urethra. In 16 instances he has known the husband to infect his wife after being certified, on the strength of a negative bacteriological examination, as no longer infectious. Though a man suffering from so-called "sterile post-gonorrhoeal catarrh" may marry and his wife may not have acute gonorrhoea, yet many such women develop signs of chronic gonorrhoea months or years later. Dr. Björling considers that as long as there is a urethral discharge, with leucocyte threads in the urine, the patient cannot be certified as non-infectious even when provocative treatment has failed to produce gonococci. Only when the urine has been perfectly normal for a month after completion of treatment are there reasonable grounds for assuming recovery from the infection.

#### SYPHILIS.

##### *Mercury and Salvarsan.*

Dr. O. Jersild has made an interesting comparison of his salvarsan with his pre-salvarsan era patients. In his private practice he treated 200 patients with mercury alone before the salvarsan era, and only in 40 of these cases was there no sign of secondary eruptions during the first two years; the majority of the eruptions occurred during the first year. The second group of patients, numbering 169, were given salvarsan and mercury, and in only 19.5 per cent. of these cases did clinical relapses occur during the first two years. Dr. Jersild considers that syphilis may ultimately be extinguished by the suppression of the infectious stages of the disease by salvarsan.

##### *Salvarsan Jaundice and Dermatoses.*

The statistics given by Dr. W. Holland with regard to salvarsan jaundice and by Dr. N. Nander with regard to salvarsan dermatoses have one important point in common. Both authors state that they have observed these complications more frequently of late, and suggest that the fault may lie with the recent consignments of salvarsan they have used. As Dr. Nander found, the solubility of different samples varied greatly, and while some were greenish others were dark yellow. At the University Dermatological Hospital in Copenhagen in 1914 only one case of skin disorder was traced to salvarsan; in 1915 and 1916 there was not one and in 1917 and 1918 there were only 3 such cases. But in 1919 their number rose to 10, in 1920 and 1921 there were 10 such cases, and in 1922 there were 11. Dr. Holland's paper on salvarsan jaundice tells the same tale. The first case was not seen till November, 1919, whereas during 1920 and the first ten months of 1921 he saw as many as 14 cases. In 4 of these cases the salvarsan was given for primary syphilis with a negative Wassermann reaction, and it is held that in these cases, at any rate, the syphilis could not be responsible for the jaundice.

##### *Abortive Treatment.*

Another brace of papers deals with the abortive treatment of syphilis. The paper by Dr. U. Müllern-Aspegren (Sweden) is more optimistic than the paper by Dr. H. Boas (Denmark). The former has come to the conclusion that when patients have been clinically and serologically free for two years after the completion of a course of abortive treatment with salvarsan and mercury, they may,

as a rule, be regarded as cured. Of 165 first-stage Wassermann-negative cases 141 were subsequently traced, and only 4 were found to have relapsed. In all 4 cases only two injections of salvarsan had been given. Of the 89 cases of syphilis in the first stage, in which the Wassermann reaction was positive, 81 were subsequently traced, and 8 were found to have relapsed. The inadequacy of the dose was thought to be chiefly to blame. This author has known only one case of relapse to occur more than a year after the completion of a full course of abortive treatment, and in this the reappearance of the disease may have been due to reinfection and not to relapse. Dr. Boas, on the other hand, states that even when a course of abortive treatment has been carried out under apparently ideal conditions, a relapse may occur even after as long an interval as seven years or more. A comparison of these papers suggests that the best system of dosage of salvarsan and mercury may not yet have been ascertained, and it is worth noting that Dr. Müllern-Aspegren gave as many injections of salvarsan after the Wassermann reaction had become definitely negative as he gave before. He advocates a minimum of eight injections of salvarsan, to be supplemented by fifteen to twenty injections of mercury. He has not had a serious salvarsan accident.

##### *Syphilis and Marriage.*

Dr. J. Strandberg deals with 250 marriages or equivalent unions in which one or both parties suffered from syphilis. His paper is so full of statistical tables representing various methods of grouping his material that it is rather difficult to see the wood for the trees. A point which he emphasizes is the great danger to the progeny when the mother, and not the father, was the first to contract syphilis. Of 19 women who were the first to be infected, as many as 18 passed the disease on to their progeny. On the other hand, among 18 marriages in which the husband was the first to be infected, only one yielded syphilitic progeny. In view of this and similar experiences, Dr. Strandberg insists that, in the matter of giving consent to marriage, doctors should enforce a more rigorous standard for women than for men. Provided the husband does not infect the wife there may be little danger to the progeny. But the wife may have long ceased to be infectious to the husband, and yet be capable of bearing syphilitic progeny. Another of Dr. Strandberg's conclusions is that many of the 250 unions were sterile owing largely to the use of contraceptive devices, the original object of which was to prevent transmission of the disease from one partner to the other.

##### *Prevention by Salvarsan.*

Dr. Karl Heden has treated with salvarsan twenty persons cohabiting with patients suffering from syphilis in an infectious stage; in none did signs of syphilis appear in spite of exposure to infection. In two cases this prophylactic treatment was instituted three weeks after coitus with a syphilitic patient; in the remaining cases the interval was two to thirteen days. In another series of thirty-six persons exposed to infection in the same manner, but not given prophylactic treatment, only six persons escaped infection.

##### *The Bismuth Treatment.*

Dr. Karl Marcus, of the St. Göran Hospital (Sweden), has treated 35 cases of syphilis with bismuth according to the method described in this JOURNAL (vol. i, 1922, p. 443). Marcus used the French proprietary trepol or a 10 per cent. emulsion of bismuth salicylate prepared by the hospital's chemist. Both preparations were given by intragluteal injection, seven to eight doses being given in each case. The clinical results were, on the whole, very satisfactory, and in the comparatively short observation period there were no relapses. Dr. Marcus concludes that intramuscular injections of bismuth are at least as effective as the mercurial and arsenical preparations, and bismuth seems to have the advantage of being comparatively non-toxic. Among 11 cases of recent syphilis the average interval required to make the Wassermann reaction negative was thirty-seven days, whereas for the 17 cases of secondary syphilis it was, on the average, as long as sixty-two days.

# British Medical Journal.

SATURDAY, JUNE 16TH, 1923.

## THE VENEREAL DISEASE REPORT.

IN presenting to our readers last week the report of the Committee on Venereal Disease, over which Lord Trevethin, lately Lord Chief Justice of England, presided, we transposed the signatures to the beginning, thereby emphasizing the fact that it was signed by all those who served on it. The Committee owed its existence to the initiative of Lord Dawson of Penn. By the publication of this report an unedifying wrangle between two bodies, upon both of which the medical profession was largely represented, ought to be brought to an end. The *Times* has called it "a treaty of peace between the two factions"; the word "faction" is severe, but we are not prepared to say that it is too severe. Any individual or organization that seeks to revive the squabble will deserve, and will, we believe, receive, the reprobation both of the public and of the medical profession. The National Council for Combating Venereal Diseases has accepted the report "as a document that can bring together all persons of good will in efforts to reduce venereal diseases," and we observe that the honorary secretary of the Society for the Prevention of Venereal Disease considers that the report should make co-operation between the two societies possible.

To assert that the moral and ethical questions have not been judged differently by individual members of the profession, as by members of the community in general, would imply blindness to obvious facts, but one good result of Lord Dawson's action has been to separate out an aspect of the matter with which members of the medical profession, by the nature of their calling, are specially concerned.

The great body of the medical profession has held aloof from the controversy, not because it was indifferent to the urgency of the problem, but for various good reasons. As we had to say in another connexion only a week or two ago, certain promises were being made in its name which it was not convinced could be fulfilled. It is one thing to bring evidence, as Metchnikoff did, that calomel cream, if thoroughly applied within a certain time after exposure, would prevent syphilis, and quite another, even if the evidence were accepted as conclusive, to be confident that in the actual conditions of promiscuous sexual intercourse the method would be efficacious. The instruction to the Committee "to consider and report upon the best medical measures for preventing venereal disease in the civil community" covered this, and the opinions it expresses are clear, though necessarily subject to several important qualifications. The Committee begins its consideration of this part of the subject with the statement that in the laboratory disinfectants will destroy the specific organism of both syphilis and gonorrhoea, and that a man who is thoroughly disinfected by disinfectants of appropriate strength and nature runs little risk of infection if this thorough disinfection is carried out within a short time after exposure. The Committee is also of opinion that though the chances

in favour of success are greater in the case of skilled disinfection (by a "trained person"), yet "an intelligent man, if furnished with reasonable instructions, could in favourable conditions effectively disinfect himself." The Committee points out that in the opposite sex it is not possible to speak with so much confidence, and frankly states that "it is extremely difficult for a woman to disinfect herself, and that the prospects of success for disinfection by another person, however skilful, are in the case of a woman less than in the case of a man."

These conclusions will, we believe, be accepted as medically sound, but, as the Committee admits, they do not carry us very far in determining the other question which nearly concerns the medical profession—the question whether it is advisable to introduce any system or measures for affording to the general public facilities for disinfection. The evidence before the Committee has led it to the opinion that the success of any such general facilities is likely to be small, but in view of its earlier conclusion—that disinfection in an individual, if properly and promptly effected, will in all probability be successful—it expresses the view that there is no "justification for putting obstacles in the way of individuals who desire to procure the necessary disinfectants." This leads it to recommend that the Venereal Diseases Act, 1917, should be amended so as to permit "properly qualified chemists to sell *ad hoc* disinfectants, provided such disinfectants are sold in a form approved and with instructions for use approved by some competent authority." The suggestion that such disinfectants should be freely sold by pharmaceutical chemists follows naturally, but the consequences of this relaxation of the law will have to be carefully considered. The proposed alteration would maintain the prohibition of commercial advertisements, and this condition seems to us to be essential if the other suggestion is to be approved by the medical profession. Granted so much, the difficulty arises of finding an authority to approve the disinfectant and the instructions to be issued with it. The Committee suggests the Medical Research Council. At first sight, at any rate, we find it difficult to see how such work comes within the scope of the Council; it might properly be invited to advise on the efficacy of disinfectants now in use or of others which may be introduced; it is, however, not a laboratory standardization that is wanted, but a practical method which will work in real life. Failing the Medical Research Council it is not easy to think of any existing official body which could draft a prescription and the instructions by which the disinfectant is to be accompanied, unless it be the Consultative Council on Medical and Allied Services; but the Ministry of Health might well hesitate before taking the responsibility involved, more especially as such official approval—however cautious and qualified its terms—would almost certainly be interpreted by the uneducated public as an official guarantee. The difficulty is very real, and is one on which the medical profession may properly have something to say.

The Committee expresses a feeling very widely shared in the medical profession when it decides against any system of general notification of venereal disease. But in the two following paragraphs dealing with "modified" notification, the Committee has not set out a complete scheme for conditional notification which has a certain amount of support. Any measures taken under this scheme would not be confined to patients at clinics only, but would be applicable also to every person who comes under treatment; it would provide that no notification what-

soever should take place unless the infected person had ceased attendance for treatment, and had neglected warnings given by his doctor, and that then, and then only, should he be notified to the medical officer of health, who should again warn him, and only resort to prosecution in the case of recalcitrants. This is the form of "conditional" notification which, we understand, is in force in the Dominions, and which the Committee of the New Zealand Board of Health has unanimously recommended for introduction into New Zealand. Whether any form of notification would cause concealment and a diminution in the number of those coming for treatment is a matter of opinion. The almost unanimous belief of the health officers in Canada and Australia is that it in no way diminishes the number of those who come for treatment. There is no doubt, however, that no form of notification can be introduced into Great Britain until both public opinion and the opinion of the medical profession are in its favour. The replies to the questions sent down to the Divisions by the Council of the British Medical Association<sup>1</sup> show plainly that in the general view of the profession notification is impracticable under present-day conditions.

The recommendations in paragraph 23 and succeeding paragraphs speak for themselves; in particular we note the recommendations for ante-natal treatment. With regard to the instruction of nurses and midwives in venereal disease, a letter appears this week in our correspondence columns from the secretary of the Central Midwives Board for England and Wales.

The Committee does not recommend the establishment at the public expense, save in exceptional cases, such as seaport towns, of a system either for self-disinfection or skilled disinfection, but considers that where public money is available it may be better expended on the treatment of disease and the education of the community, and on the elimination of those conditions of life which tend to foster spread of the disease. It is to be hoped that this strong expression in favour of continuous education will aid the strenuous campaign to impart knowledge and give instruction which has been carried on for the last seven years.

The conclusions arrived at in this report will be read with deep interest by everyone concerned in the problem of combating venereal disease. It seems to provide a starting point for work towards the common goal of reducing the incidence of this disease to negligible proportions, and should it, as it ought, be the means of ending unfortunate controversies which have so prejudicially affected the campaign against this disease in the near past, the Committee will indeed have earned the gratitude not only of the medical profession, but of all those interested in the welfare of the individual, the community, and the State.

## THE PHYSIOLOGY OF THE ADRENAL SECRETION.

THE suprarenal medulla has for long been generally considered the typical example of an organ of internal secretion, and it is frequently adduced as the endocrine gland concerning whose functions our knowledge is most complete. In recent years, however, an acute controversy has been proceeding in physiological journals concerning the importance of adrenaline

secretion, and numerous workers have denied that it is of any importance in normal physiology.

Professor E. Gley<sup>1</sup> has recently written a most interesting summary of the history of our knowledge of the functions of the suprarenal glands. He recognizes three periods: in the first the importance of the suprarenal glands was established; in the second adrenaline was discovered and its pharmacology was fully worked out; during this period the pharmacological action of adrenaline was rather rashly assumed to give an indication of the physiological action of the suprarenal glands—but we are now in a third period, which is one of doubt and uncertainty.

Brown-Séquard, as early as 1855, demonstrated the lethal effects of adrenalectomy, but the possibility of sepsis was held to render his results doubtful. Between 1893 and 1897 Langlois, however, conclusively proved that extirpation of the suprarenals rapidly caused death, but showed at the same time that administration of extracts of the suprarenals did not prevent death. As Gley says, "twenty-five years have passed since then, in the course of which many similar therapeutic attempts have been made, but there is not much to alter in the conclusions of Langlois." At about the same time, in 1895, Oliver and Schafer demonstrated the potent pharmacological action of suprarenal extracts, and this discovery was followed by the isolation of adrenaline, and thereafter all the wonderful pharmacological actions of this substance were explored. Gley suggests that these striking properties allured the investigators away from true physiology into pharmacology. It was generally assumed that the adrenaline secreted by the suprarenal glands produced the same effects in the body as those observed to follow the injection of adrenaline. The secretion of adrenaline was supposed to maintain normal arterial tonus, and Cannon elaborated the attractive theory that visceral changes attending emotions were produced, or at any rate reinforced, by the liberation of adrenaline. The third period, in which we now are, is one of criticism and doubt, and it has come to be realized that we have very little certain evidence as to the part played by the suprarenal medulla in normal physiology.

Gley's first conclusion is that adrenaline is not necessary for the normal functioning of the sympathetic nervous system; it has been shown that in animals from whom the adrenals have been removed the principal functions of the splanchnic nerve are manifested normally, and that asphyxia, which excites all the vaso-constrictor apparatus, produces its normal effects. His second conclusion is that adrenaline is not necessary for the maintenance of normal life. If one suprarenal be excised and the other denervated, though the animal is either deprived of adrenaline secretion or only minimal quantities pass into the blood, yet it remains alive and in perfect health, and presents all normal nervous reactions. These conclusions appear to be supported by the majority of recent investigators in this subject; furthermore, it is agreed that if the splanchnics are stimulated the suprarenal glands can excrete into the blood sufficient adrenaline to produce definite physiological effects, but it is also agreed by most workers that there is little evidence that the adrenaline secreted by an animal in a tranquil condition is sufficient to produce any definite physiological effect. Controversy at present centres chiefly round the question as to what stimuli are adequate to produce an adrenaline secretion sufficient to produce any effect in the body.

<sup>1</sup> SUPPLEMENT, April 28th, 1923, p. 160.

<sup>1</sup> *Revue de Médecine*, xl, 193 (1923).

Gley's conclusions do not meet with universal acceptance, and in the same issue of the journal that contains his article is a paper by Tournade and Chabrol<sup>2</sup> giving an account of elaborate and ingenious experiments upon animals with crossed circulations. They consider that they have proved that the adrenaline liberated by the suprarenal medulla, even without splanchnic stimulation, is sufficient to produce definite effects upon the blood pressure of an animal deprived of its adrenal glands. This experiment appears, however, a little inconclusive, for the fall of blood pressure after adrenalectomy is supposed to be due to lack of the adrenal cortex, and the effects might well be due to some internal secretion of the cortex. If this were so it would if anything increase the importance of the result, for our knowledge of the suprarenal cortex is even in a more unsatisfactory state than our knowledge of the medulla. We do not really know what is the function of the adrenal medulla, although we have a full knowledge of the nature of its internal secretion; as regards the cortex, we know that it is absolutely essential to life, but nevertheless do not know for certain whether it produces any internal secretion, for it is quite conceivable that it acts solely as a detoxicating organ.

### THE CONFERENCE OF PANEL COMMITTEES.

THE Special Conference of Local Medical and Panel Committees which was held last week, and a full report of which appears in the SUPPLEMENT to this issue, was of great importance because, although by the nature of the circumstances it could not come to any final decisions upon the terms of service for insurance practitioners from the end of this year, it affirmed the general policy which was to be pursued, and settled the lines on which the necessary negotiations are to proceed. This was the main purpose for which the Special Conference was called. The Insurance Acts Committee can now pursue its conversations with the Government with a clear indication as to how far the representatives of insurance practitioners are prepared to accept certain alterations of the terms of service that have been suggested. The results of these conversations, together with the proposals as to remuneration, will be presented to the Annual Conference, which should be held late in September or in October, and a final decision upon them will then be taken. Meanwhile, the Annual Representative Meeting at Portsmouth will have an opportunity, if desired, of considering such of the proposals as may be held to affect the profession outside the insurance service.

The important memorandum on the National Health Insurance Fund, which was published in the SUPPLEMENT of May 26th last, and upon which we commented at that time, was received by the Conference. Its bearing upon the question of remuneration was fully appreciated, but there was no detailed discussion upon the capitation rate of payment. Such discussion would have been premature and not helpful at this stage. It was significantly resolved, however, "that the full cost of remuneration of insurance practitioners, determined on the merits of the case, should be borne by the Fund, and that practitioners should not be placed in regard to any portion of their remuneration in the position of residuary beneficiaries after all other charges have been met"; and "that any rate of remuneration lower than that given as the result of the

1920 arbitration is less than adequate for the service rendered." A capitation rate of eleven shillings was then awarded as a result of a full and impartial skilled investigation. Any changes which have since occurred, such as the somewhat lessened devaluation of money, tending to justify any lower rate, may clearly be held to be counterbalanced by other circumstances, such as some of the improvements and widenings of the service now suggested.

The Insurance Acts Committee has undoubtedly acted wisely in trying to meet all the criticisms that have honestly, though sometimes on mistaken premisses, been levelled at the present service, even though in doing so it has gone beyond the official requests from the Ministry of Health; and the Conference showed equal wisdom in endorsing this action. Apart from some minor but important suggestions for dealing with inadequate surgery accommodation and for improving facilities for consultation, the three main proposals are that insured persons should be free to change from one doctor to another at any time; that there should be some further limitation in the number of persons for whom a doctor carrying on practice single-handed may accept liability, save in exceptional circumstances already proved to exist; and that there should be a restatement of the range of service contracted for, together with some alteration of the machinery for determining that a particular form of treatment is outside that range and so may legitimately be charged for. None of these things is free from difficulty—logical, administrative, technical, or practical—but the conditions which they are designed to remedy have been the subject of frequent and sometimes justifiable complaint, and may in particular circumstances bring considerable discredit upon the service. It is eminently desirable that no unnecessary restriction should be placed upon the free choice of doctor by patient, but care will have to be taken to prevent undue or improper influence being used to affect such choice. It is desirable, too, to minimize any temptation for a practitioner to assume liabilities which he is unable properly to meet, and to discourage practitioners from becoming wholly insurance practitioners without the wider experience of more general professional work; but in districts where the proportion of insured persons to the total population is very large there may be a danger of placing too severe a limit on a doctor's opportunities. Further, it is not in the interest either of the profession or of the public to narrow the scope of treatment described as "such as can consistently with the best interests of the patient be properly undertaken by a general practitioner of ordinary competence and skill." This scope is nowadays very wide; and it will be an advantage if there can be such a restatement of the insurance practitioner's duties as will secure for insured persons free of charge in every area all that ought to be included within the above description, while at the same time definitely excluding such services, and such services only, as should not be undertaken, except in case of urgent necessity, by practitioners without special training and experience. Whatever may be the exact form in which all these proposals emerge from the negotiations with the Ministry, they must be recognized as a sincere and generous offer on the part of the profession, and they ought to silence some of the commoner allegations made against the insurance medical service.

Apart from these very important suggestions to meet criticisms of the service from outside, the principal requests made by the Insurance Acts Committee and endorsed by the Conference on behalf of insurance

<sup>2</sup> Tournade and Chabrol: *Revue de Médecine*, xl, 222.

practitioners are: that the certification system shall be made more simple, especially by reducing the number of certification forms, and by a removal of the obligation to give certificates to insured persons not under the practitioner's own treatment; that special provision shall be made for rural practitioners in sparsely populated districts; that any terms agreed upon shall be secured for at least five years; and that increased diagnostic facilities of a special character shall be provided for insured persons, the method of provision and administration of such an extension of service and of the present "additional benefits" being made the subject of careful consideration. All these are of very considerable importance, and the last of them is obviously of great interest to the whole profession.

Another subject to which the Conference gave attention was the much misused phrase "unity of the profession." This was dealt with in the resolutions put forward by the Insurance Acts Committee and agreed to almost unanimously by the Conference. These resolutions expressed a strong desire for as great a degree of common action by the profession as possible in relation to National Health Insurance matters, and requested the Committee, within its constitution and powers, to co-operate as far as it effectively could with other medical organizations. They urged that the Committee should be made thoroughly representative of insurance practitioners in the way now recommended by the Council to the Representative Body, and asked for the fullest support for the National Insurance Defence Trust from all Panel Committees and practitioners. An amendment avowedly moved in the interest of a particular organization was defeated. It is to be hoped that the Conference will not be asked to go over this ground again. There probably always will be—and perhaps it is not altogether undesirable that there should be—a number of different organizations within the profession. They need not necessarily be antagonistic to one another. Even where their professional interests are not identical their actions can be harmonious, and in certain cases the British Medical Association has shown that amicable co-operation is possible over a long series of years. If certain practitioners prefer to organize themselves on technically trade union lines it is, of course, open to them to do so, though this does not differentiate them in any professional respect from other practitioners, and it is impossible to discover any basis for their claim that their particular political or economic views should secure for them special privileges in other organizations of the profession, or any reason for taking up the attitude that if such privileges are not granted they must maintain a continuous opposition. Common aims should ensure goodwill, and the Conference has indicated a line of policy in connexion with the revision of the terms of service for insurance practitioners upon which it should be possible for the whole profession to unite.

#### CO-OPERATION AMONG VOLUNTARY HOSPITALS.

SHEFFIELD has recently been filled with discussion on various aspects of the hospital question. Not only has the British Hospitals Association held its annual meeting in that city; reports have also reached us of meetings of the Sheffield and District Association of Hospital Contributors (otherwise the Sheffield hospitals' penny in the £ scheme), and of the Grand Lodge of the Sheffield Equalized Independent Druids. There seems to have been a general desire at all these meetings to retain the voluntary system of hospital

management, while increasing the sources of financial support. Lord Onslow, chairman of the Voluntary Hospitals Commission, expressed the opinion that the problem of making ends meet, and that of extending hospital construction which had been in abeyance for the last ten years, would be met in part by co-operation between the hospitals and other organizations interested in the matter. He disliked subsidies; but spoke highly of the success of the efforts of the Joint Hospital Council in Sheffield in finding a new source of income. Apparently about £60,000 a year is contributed by employees under what is called the penny in the £ system; 1,879 firms in Sheffield co-operate in the scheme, the number of contributors being 154,000, with an additional 35,000 in outlying districts. The contributions of the employees are supplemented up to the amount of one-third by the employers. There seems to be some fear that the system may lessen charitable contributions, and in some cases large employers of labour, such as the City Corporation, have not yet seen their way to pay their contribution as employers. Mr. Bedford, chairman of the Board of Management of the Royal Infirmary, pointed out that the penny in the £ system did not do away with the need for charitable subscriptions. According to the Master Cutler, Mr. R. W. Matthews, the work of the Joint Hospitals Council is leading to the growth of the "hospital conscience" in Sheffield, and the Council appears to be a very active body. There are said to be 3,000 patients on the hospital waiting lists in Sheffield; and to help in meeting the deficiency in beds the Council has set up a method for providing convalescent treatment, nursing facilities, and after-care. A list of suitable convalescent homes has been compiled; firms contributing to the hospitals appear to be charged 10 per cent. on their contributions as convalescent payment; and not only patients from hospitals, but also persons in whom illness can be prevented by a stay in a convalescent home are sent to these institutions. For nursing there is an arrangement with the Queen Victoria Nursing Association, and efforts are made to follow up patients when they leave the hospital. At the British Hospitals Association meetings much was said about the middle-class patient and his need for hospital help, which it was said could be met only by extension of the present accommodation. It was thought that it would pay hospitals to make provision for paying patients. According to Mrs. Wilkinson, a Councillor of Sheffield, the system of payment would lead to a tendency to public control. But with regard to the contributory schemes in Sheffield, very little evidence as to the representation of contributors seems to have been given. Professor Arthur Hall, while emphasizing the necessity for equality of treatment in the wards, whether patients paid or not, expressed the opinion that payment had not as yet affected the spirit of hospitals, because the staff did not know who were paying. Professor Hall made the interesting remark that the British patient does not want to go into hospital; he would rather be treated at home; consequently an extension of district nursing would be of great help in relieving the pressure on hospitals. Mrs. Wilkinson, while admitting the need for more maternity beds, explained the reluctance of women to go into maternity hospitals by the necessity they have of keeping supervision over their homes. Many women, even when seriously ill, kept their purses under their pillows—and with good reason! An effort was made at a meeting of the British Hospitals Association to obtain a vote in favour of the establishment of a central fund for provincial hospitals, to be administered on the lines of King Edward's Fund in London. The proposal was defeated; and there were several indications that even if some measure of co-operation is ultimately brought about, the provincial hospitals will maintain their autonomy and cultivate individualism for the reason given by Dr. H. L. Eason, that the problems of each hospital differ from

those of its neighbours. How this will affect Viscount Hambleden's vision of the possibility of voluntary hospitals taking a definite and permanent part in the scheme of National Health Insurance is not yet clear.

#### BRITISH ORTHOPAEDIC ASSOCIATION IN HOLLAND.

A MEETING of the British Orthopaedic Association was held at Leyden on May 24th, when twenty-four members from England and Ireland, with several Dutch visitors and one Austrian, were present. The programme of scientific work was provided entirely by Dutch orthopaedic surgeons, and included short papers and demonstrations by Dr. Alvares Correa, Dr. J. van Assen, Dr. W. F. Wassink, Dr. J. W. P. Fransen, and Dr. Murk Jansen. In the evening most of the members went to Amsterdam to attend the congress commemorating the twenty-fifth anniversary of the Dutch Orthopaedic Association. It was held under the presidency of Dr. Murk Jansen, and was of an international character. On May 25th Dr. Adolf Lorenz, of Vienna, gave a demonstration of his method of operating upon untreated congenital or acquired dislocation of the hip, illustrated by cinematograph films; this method was recently described by Dr. Lorenz in the *New York Medical Journal and Record*, and an abstract of the article appeared in our *Epitome* on May 19th, 1923 (para. 410). Sir Robert Jones gave an address on orthopaedic experiences during the war, Dr. F. Calot, of Berck-Plage, spoke on the nature of arthritis deformans of the hip, and Dr. F. H. Albee, of New York, read a paper on bone transplantation, based on 3,000 operations. The physiological treatment of infantile paralysis was discussed by Professor Biesalski of Vienna, the surgery of joints by Professor H. Spitzzy of Vienna, and plastic operations on joints by Dr. Putti of Bologna, in addition to eight papers by Dutch orthopaedic surgeons. Next morning, May 26th, the meeting discussed the social care of cripples and the methods of organization in Great Britain, Germany, Vienna, the United States, and Holland, the methods being described by Sir Robert Jones, Professor Biesalski, Professor Spitzzy, Dr. Albee, and Dr. van Assen respectively. The orthopaedic work of Holland is chiefly carried on in three centres—Amsterdam, where Dr. Correa is in charge; Leyden, where Dr. Murk Jansen has made a world-wide reputation; and Rotterdam, where Dr. van Assen is mainly responsible. At the Hague, while a certain amount of orthopaedic work is done, there is apparently no surgeon who devotes himself exclusively to this branch of surgery. The British visitors were most generously entertained; a largely attended dinner of the combined British and Dutch Associations was held at Amsterdam on May 25th, when one of the features of the evening was a lengthy humorous poem, read by one of the Dutch surgeons, wittily hitting off, in half a dozen languages, the characteristics of orthopaedic surgeons all over the world. On Saturday, May 26th, the party was taken for a trip on the Zuyder Zee, visiting Marken and Vollenham. As the dam that will enclose a large section of the Zuyder Zee will shortly be finished, this trip, which is very well known to visitors to Holland, will probably be impossible after the present year.

#### THE DIFFERENTIAL ACTION OF X RAYS.

AN account of experimental researches upon the effects of  $x$  rays of different wave-lengths when directed upon animal tissues was given by Professor Sidney Russ, D.Sc., at the Royal Society on May 31st and again at the Röntgen Society on June 5th. The object of the experiments was to decide whether, when equal amounts of  $x$ -ray energy of different wave-lengths are absorbed by animal tissues, equal effects are produced. If this is not the case, obviously it would constitute a proof of differential action—an effect to be clearly distinguished from the selective action of the rays themselves. A matter of outstanding

importance was to devise some method which would serve to measure the intensity of different beams of  $x$  rays used. The ionization method was chosen for this purpose, the ionization in an air-gap giving a measure of the  $x$ -ray energy absorbed in the tissues. One of the sets of wave-lengths selected for the purpose of the test ranged from about 0.45 to 0.3 of an Angström unit, the other was about 0.17 of an Angström unit. It was found that on replacing the air-gap by an ionization chamber in which it was possible for secondary rays to be excited by the primary beam, the basis of quantitative comparison was completely upset, and Professor Russ believed that this fact might account for some of the statements of other observers to the effect that a differential action did not exist. The animal tissues employed were the normal skin of the rat and Jensen's rat sarcoma. When the tumour cells are given a sufficient dose of  $x$  rays of the longer of the two wave-lengths, the subsequent inoculations of small pieces of irradiated tumour fail to grow, and this dose is called the lethal dose. When this same dose is given in the form of the shorter wave-lengths it is found that the dose is no longer sufficient to prevent subsequent proliferation of the sarcoma cells. By gradually increasing the dose the lethal effect is obtained, and in this case about 2.6 times as much energy has to be absorbed by the tissue as when the longer wave-lengths are used. When the skin of the rat is exposed in somewhat similar fashion it is again found that more of the short wave-length energy has to be absorbed by the skin in order to provoke the same kind and degree of reaction as that produced by the longer wave-lengths. In this case it was found that about six times as much had to be absorbed. Professor Russ considered that these numbers might perhaps be looked upon as therapeutic factors, and he went on to discuss the bearing of these observations upon the selection of the most suitable kind of  $x$  rays in the treatment of various forms of malignant disease. In the discussion at the Röntgen Society Dr. N. S. Finzi remarked that he could confirm from another method of measurement the same type of effect. On using the now despised Sabouraud pastille for measurement, he found that the dose to produce epilation of the scalp with unfiltered rays was 5 H, which was just sufficient to cause erythema, whereas if a filter of 0.8 mm. of copper were used the necessary dose rose to 15 H. Major C. E. S. Phillips said that the German school of radiologists had held generally that the therapeutic effects of radiations were simply a function of the amount of energy absorbed by the tissues, and this work by Professor Russ appeared not to be in agreement with that. He thought the feeling of most English physicists was that there must be some specific action, and it should not be exceedingly difficult, certainly not impossible, to suggest some physical basis for such an idea. Professor Russ, in replying on the discussion, agreed with the remark of one speaker that the reaction of the normal tissues was probably as important as the reaction of the cell the operator was trying to affect. But while the reaction of the contiguous normal structure which the malignant cell might be invading was of such great importance, it was very difficult to say anything definite on that subject at the present time. The fact was that the people who were entitled to speak on the subject held rather opposing views, and decisive experiments to establish the reaction of the normal tissues were not easy to devise.

#### PHYSIOLOGY AT HIGH ALTITUDES.

THE Research Institute for Alpine Physiology and Tuberculosis at Davos will be formally opened in the autumn. The building has been completed and the laboratory equipped; work has, indeed, been going on since the beginning of the year. Professor Loewy, who for many years worked with Professor Zuntz, is the director of the

institute, and is head also of its physiology section. The promises of financial assistance for establishing a bacteriological and physiological section warrant the hope that it also will soon be in working order. The laboratory is ready and the principal equipment installed. This section will be independent of the rest of the institute, both scientifically and financially. Twenty rooms have been provided for scientific work. There is a platform on the roof for irradiation, and a well appointed stable for animals. Rooms are provided for the study of respiration and for blood and gas analyses. There are also chemical laboratories, a dark room for spectral measurements and another for microphotography, an operating room for animals, a sterilizing room, and two large rooms for the library. The institute has been established by the members of the medical profession and the community of Davos, the Grison Association of Physicians, the Canton of the Grisons, the Swiss Association of Naturalists, the Swiss Red Cross, and the Swiss Association for Balneology and Climatology. Among those who have made gifts are the Arosa and the Engadine Associations of Physicians, and it is confidently expected that when the discussion on the tuberculosis bill has been concluded the institute will receive help from the Confederation. The board of directors consists of nine members, of whom five are physicians or naturalists. There is also a scientific advisory council consisting of professors in Swiss universities, and scientific workers recommended by them to undertake researches connected with tuberculosis and high altitudes, and the climate of high altitudes will be considered first in the assignment of working places in the institute. Scientific men of all nationalities, however, will be readily admitted to work under the directors of the several sections. The board of directors will decide whether papers founded on work done in the institute shall be published in scientific periodicals or in a separate volume. The physico-meteorological observatory at Davos, conducted for some time by Professor Dorno, will work in association with the new institute, but will retain its independence. The chief object of this observatory is to investigate the effects of the high mountain climate of Davos on the healthy and the sick, thus continuing the physico-meteorological researches already undertaken. The special character of the Davos Institute is that it will ensure close collaboration among workers in meteorology, physics, physiology, and pathology in a place where climatic conditions are favourable, where material for investigation is ample, and where the medical profession has had special experience in the matter. Dr. Mitchell Bruce, to whom we are indebted for this information, expresses the opinion that the institute deserves the support of scientific workers and medical men in this country, and the hope that some young workers in science, particularly in physiology, will take advantage of the offer to provide working places. Further information can, we understand, be obtained from Dr. Buol of Davos Platz.

#### MEDICAL HYDROLOGY.

THE course of lectures and demonstrations on medical hydrology—said to be the first of its kind in England—which was announced in our columns (April 28th, p. 735) has recently been concluded in London and Harrogate, and, although it was arranged at short notice, twenty-two medical men and women took part in it. Many efforts have previously been made to organize some systematic teaching in England on the actions and uses of waters and baths in medicine, and shortly before the war a memorial was presented to the Senate of the University of London. Last April a committee was formed representing the International Society of Medical Hydrology and the Section of Balneology and Climatology of the Royal Society of Medicine. A memorandum favouring the inclusion of some form of teaching on the subject at the University of London

was signed by seventy-nine medical practitioners at the different spas in England and by fifty-eight other practitioners, and was presented to the University Extension Board. The course which has just been concluded was arranged by the Extension Board in co-operation with this joint committee. The lectures were delivered at the University of London by Drs. Buckley, Edgecombe, Fortescue Fox, Leonard Hill, and Waterhouse. A demonstration on the applications of heat and cold was given at the laboratories of the National Institute for Medical Research, Hampstead, and short lectures on methods of treatment employed in military cases were given at the Ministry of Pensions Special Surgical Hospital, Shepherd's Bush, where a demonstration was given by Dr. Arthur Herbert on the preparation and uses of radio-active mud from New Zealand, and on hyperthermal baths. A very comprehensive and interesting programme was arranged at Harrogate, in which Drs. W. Bain, W. Brown, G. Holmes, Liddell, Miller, Pringle, Saberton, Solly, and others took part. The visitors were conducted by Dr. Campbell McClure. The various forms of treatment given at the Royal Baths were demonstrated and discussed, such as the uses of the different waters internally, sulphur baths, douches of all kinds, peat baths, local vapour baths, colon lavage, etc. The chemical and biochemical investigations and research work carried on at the pathological laboratory were explained, and an x-ray demonstration and discussion of cases took place at the Royal Bath Hospital. In the concluding lecture of the course in London, Dr. Fortescue Fox dealt with the applications of hydrology to incipient and chronic disease at different periods of life, and described the characters of British spas as compared with those of other countries. He pointed out that the climatic character of a spa affected the action of every kind of bath. At Strathpeffer the mean summer temperature was 12° less than in the valley of the Rhine, and equal to that of Leukerbad, at 4,600 feet. Harrogate and Buxton were 8° cooler than Nauheim or Aix-les-Bains, and had the same temperature as Bormio, near the Stelvio Pass, at 4,500 feet. Owing to their northern latitude the climate of some British spas had many of the qualities of high altitudes, as might be seen from the flora of the Highlands. The position of Britain on the north-westerly fringe of Europe, and its incomparable coasts, gave to the constantly changing atmosphere of these islands a stimulating quality, analogous in its effects to those of the effervescing bath. All these conditions were different on the Continent. The British spas were the most tonic in the world, and, if suitably utilized for preventive and curative treatment, were well adapted to the chronic ailments and infections of our own country, such as catarrh, tuberculosis, and rheumatism. If it were sometimes necessary for British invalids to be heated up, they might go to the Continent. On the other hand, Continental invalids, who often required the cooling and invigorating phase of treatment, could obtain it best in the British Islands. A third large class of invalids and convalescents for which the British health resorts should cater were those who had lost their health in tropical countries. Among the modern methods which required development at home Dr. Fox specified the utilization of the British eliminative waters, the employment of various forms of effervescing baths, and the external treatment of young subjects by salt waters.

#### THE RETREAT, YORK.

THE annual report of the Retreat for 1922 is the first presented by Dr. Henry Yellowlees, who succeeded Dr. Bedford Pierce as medical superintendent. The number of patients resident on January 1st, 1922, was 175, and 174 in December, 1922. Since the admissions numbered 109, of whom no fewer than 50 were voluntary boarders, it is

evident that the hospital has an influx of new patients large in proportion to the average number resident. It is fortunate in this respect, because a large number of admissions and discharges does much to create an atmosphere of hope and enthusiasm, which can only be maintained with difficulty in an institution containing chiefly chronic cases. The large proportion of chronic cases is a noteworthy and satisfactory feature. The recoveries were in the proportion of 24 per cent. of the number of cases admitted, or 22 per cent. if voluntary cases are included; 21 cases were discharged recovered, 37 relieved, and 28 not improved. Unfortunately Millfield House, a separate establishment intended for uncertified "borderland" cases, involves a financial loss at present, but the committee has decided not to withdraw from this lead it has given in the development of treatment. Dr. Yellowlees thinks it would be hard to overestimate the value of the work at Millfield; though he feels bound to utter a warning against the optimistic view that all, or even most, cases of mental disease are curable in their incipient stages, yet he is of opinion that treatment in these stages certainly increases the patient's chances, and records with satisfaction and thankfulness that in many cases early treatment at Millfield, so far as he could judge, definitely saved some patients from drifting into chronic mental illness. It is certainly to be hoped that this new scheme will meet with success, so that other institutions may be encouraged to develop along similar lines. It is greatly to the advantage of patients suffering from mild and curable forms of mental disorder that they should be treated entirely apart from the chronic insane.

#### THE ETIOLOGY OF BLACKWATER FEVER.

Of diseases which affect Europeans in the tropics, blackwater fever is to-day probably that which most urgently calls for investigation. It is a disease the knowledge of which has not progressed in proportion to that of other diseases in tropical countries; yet it takes annually a steady toll of Europeans in these places. Residents in so many districts are exposed to its incidence and so many interests are detrimentally affected by its prevalence that it seems that some concerted action towards the complete elucidation of the causes of it should be undertaken. The best means of approaching the problem of discovering how blackwater is to be eliminated from our tropical possessions, whether by the method of a travelling commission, or by the establishment in a blackwater area of a laboratory for its special study, or by endowing research work in already existing laboratories, has to be determined. Whatever method is adopted, it must be carried out in such a manner that all available modern means of investigation can be utilized, and the work should be organized on co-operative and progressive and, as far as necessary, permanent lines. Such an effort will involve considerable expenditure, but if the problem can be solved the cost will prove to be trifling in comparison with the result achieved. The study of the etiology of blackwater fever has lately received an impetus from the investigations of Blanchard and Lefrou, who discovered in the blood a spirochaete (*S. biliohaemoglobinuriae*) which they assign as a cause. So far, no one has been able to confirm the findings of the workers in the Congo, and we noted last week that Dr. J. Gordon Thomson also had had negative results. An experiment which has a bearing on the important question whether blackwater fever is due to a specific parasite is that carried out by Dr. Blacklock, Director of the Liverpool School Laboratory in Sierra Leone. He injected into a healthy adult European blood taken from the vein of a patient who was suffering from blackwater fever. The injection was made into the deltoid muscle on the fourth day of the disease; the amount of blood used was 1.5 c.cm.

The temperature of the patient at the time the blood was taken was 102.5° F., and it remained high until death five days later. Blacklock notes the following sources of fallacy: (1) the possibility that the parasite of blackwater fever is never present in the blood at all; (2) that it is present in such small numbers that the amount injected did not include the organism; (3) that it is present only for one or two days at the commencement of the disease; (4) that it has an unusually long incubation period; and (5) that the subject of inoculation was immune. With regard to the fourth possible source of fallacy it is to be noted that the inoculation was performed on December 4th, 1922, and no ill effects have occurred down to the present date, a period of over six months. Blacklock's experiment shows, therefore, that if there is a parasite of blackwater fever it may be very rare in the peripheral blood, even when the blood is taken on the fourth day of the disease and when the patient's temperature is high. It is evidence against a spirochaetal or other specific organismal origin of blackwater fever.

#### MILK UNDER SPECIAL DESIGNATIONS.

THE Milk and Dairies (Amendment) Act, 1922, empowered the Minister of Health to make regulations under which milk can be produced and sold under special designations, such as "certified," "Grade A (tuberculin tested)," "Grade A," and "pasteurized," thus ensuring to the purchaser certain degrees of purity. On December 9th, 1922, the Minister made an order embodying these regulations, and ten days later, having ascertained that there were difficulties connected with that part of the order relating to the pasteurization of milk, an amending order was made. We endeavoured to epitomize these orders in the JOURNAL of March 10th, 1923 (p. 433), but without making any comment on some of the difficulties which seemed to be connected with their administration. In other quarters criticism was not so sparing, and in a circular (408) issued from the Ministry on May 29th we are informed that representations have been made to the Minister as to the working of these orders, and that "after consideration it appears to him that certain amendments of the detailed provisions of the orders are desirable." A new order (No. 601, 1923) has accordingly been issued embodying these amendments and revoking the existing orders as from July 1st next. The original order required that every animal of the herds concerned should be subjected to periodical veterinary examination. It is now required that the milch cows only should be so examined, and a "milch cow" is defined as "a cow kept for milking purposes." Further, if a cow is found to be suffering from a disease which is not of a permanent nature it will be sufficient for the cow to be isolated, but in the case of a disease the injurious effect of which is likely to be of a permanent character the cow must, as at present, be removed from the herd. To meet the difficulties which have arisen as to the economical disposal of dry cows the provision as to separation of the herd has been altered so as to require that only the cows in milk belonging to the herd shall be kept separate from all other cows in milk. A very important alteration has been made in connexion with "pasteurized milk." The original order required that after pasteurization there must not be in the milk *B. coli* in one-tenth of a cubic centimetre or more than 30,000 bacteria per cubic centimetre, subject to the provision that, until January 1st, 1924, no test for *B. coli* would be imposed, and the maximum bacterial content might reach 50,000 per cubic centimetre. The day of pasteurization was required to be indicated on the vessel containing the milk. In the new order the bacteriological condition has been relaxed so as to remove the test for coliform bacillus altogether, and to provide that

the number of bacteria shall not exceed 100,000 per cubic centimetre; until the end of this year this limit is to be 200,000 per cubic centimetre. There is no longer any obligation to state the day of pasteurization on the milk vessel. Amongst what are described by the Ministry as "minor alterations" are some which will be welcomed by those who are called upon to administer the order. It is now made quite clear that a county borough council is an administering authority, and that a veterinary surgeon who makes the tuberculin test of an animal need only be approved by the Minister of Health and not nominated as required by the original order. In a circular (356) addressed to local authorities in December, 1922, the Minister expressed the opinion that samples of "certified" milk should be taken on the average at the rate of about one sample a month for each producer, the samples generally being taken from all the distributors concerned. It appears that a scheme has now been drawn up by the Ministry by which the sampling of the milk of each producer is divided between two or three authorities, the samples being taken more frequently in the summer than in the winter months.

#### AN AMERICAN PSYCHOPATHIC HOSPITAL.

THE first annual report of the Boston Psychopathic Hospital is a document of considerable interest to psychiatrists in view of the fact that hospitals with similar aims are now being developed in this country. Formerly a department of the Boston State Hospital for the Insane, the Boston Psychopathic Hospital was established as an independent institution "for the first care and observation of mental patients and the treatment of acute and curable mental disease" in 1920. In presenting his first report Dr. C. Macfie Campbell, the medical director, who was a pupil of the late Sir Thomas Clouston at Edinburgh, formulates the principles involved in the work of the hospital, and restates some of the main problems which it has to deal with, and the function it plays in the general health activities of the community. The main tasks, when the new status was instituted, were to build up the medical staff, to put the various laboratories into commission, to develop occupational opportunities for the patients, and to co-ordinate the social service department with the other activities of the hospital. It would appear to be somewhat to the disadvantage of the hospital that, to a certain extent, it has to be utilized as a clearing house for the disposal of a large number of patients. During the year under review the number of patients received in the wards was 1,937, and there has been a tendency on the part of the medical profession and of the community in general to regard the hospital as an institution in which patients only remain for a few days. As Dr. Campbell observes, it would be unfortunate if this mistaken opinion should become firmly fixed, for, if the hospital is going to undertake the treatment of acute and curable diseases, as well as the study of the nature, causes, and results of insanity, it is obvious that it must be prepared to care for the individual patient during a period of weeks or even months. If a hospital of this type with only 100 beds is utilized as a clearing house we cannot but feel that its usefulness must be diminished, as mental disorders, perhaps more than any other form of illness, cannot be either satisfactorily studied or treated in a few days. One of the problems of the medical work has been to make such arrangements with the other hospitals in the vicinity and with visiting consultants that the patient may be examined as carefully as if he had been admitted to a general hospital. It has fortunately been possible to make very elastic arrangements with the staffs of the hospitals in the adjoining area, so that these principles have been carried out. An endeavour is also being made to improve the nursing

personnel by introducing pupil nurses from general hospitals, and graduate nurses who may require special training in mental disorders. A social service department has been organized, as it is realized that in mental disorders environmental factors are of considerable importance. The work of this department has been closely co-ordinated with the work of the individual physicians, and the hospital keeps in close touch with the great number of social organizations which have problems cropping up from time to time requiring some psychiatric review. The account given of this psychiatric social work is most interesting, and its importance can scarcely be overestimated. The out-patient department, in which 1,075 patients were treated during the year, is the subject of a special report by Dr. Douglas Thom, the chief physician. He writes hopefully of his work, and is convinced of its social value. His experience leads him to express the view that in no way can the State do more for the mental health of its citizens than by a well organized out-patient clinic. "More and more we are finding," he writes, "that the out-patient clinic is becoming the pivot point from which preventive medicine, so far as it relates to the mental health of the community, is radiating. Ministers, teachers, judges, probation officers, physicians, and lawyers are daily turning to the psychiatrist for advice pertaining to the problems of human conduct. Not only are they coming to us, but they are permitting us to become part of their organizations." The hospital is discovering a wide sphere of usefulness in respect to nervous children, and it is satisfactory to observe that an increasing number of cases are being referred to it by the police or by the courts. Dr. Campbell indicates very clearly the attitude of the psychiatrist towards the delinquent—a matter which is apt to be unnecessarily complicated by metaphysical discussions—when he writes: "Some judges feel it is something of an intrusion on their territory for the psychiatrist to formulate an opinion as to the responsibility of the accused, and upon the soundest method of dealing with the accused. In some cases the individual psychiatrist may go beyond the proper limits of a purely medical opinion; this is not necessary. The psychiatrist has to state his opinion of the causes of the behaviour which he investigates, and he can state his opinion in perfectly objective medical or biological terms which involve no reference to such a complex and evasive conception as that of responsibility. He may also state the medical factors to be kept in view in the management of the case without neglecting the importance of other aspects of the case, such as the social and the legal, and without seeking to make the medical management of the case the dominant aspect." Reports of the out-patient department, the biochemical laboratory, the psychological laboratory, the neuropathological laboratory, the department of therapeutic research, and the nursing, social service, occupational therapy, and executive departments are given by those who are responsible for these various spheres of work. Altogether it is evident that the Boston Psychopathic Hospital is filling a definite need, and carrying out medico-social work of great value to the community.

#### MEDICAL RESEARCH COUNCIL.

DR. GEORGES DREYER, C.B.E., F.R.S., Professor of Pathology in the University of Oxford, has been appointed a member of the Medical Research Council in the vacancy caused by the resignation of Major-General Sir William Leishman, K.C.M.G., F.R.S., consequent on his appointment to be Director-General, Army Medical Services. The appointment of Professor Dreyer was made by the Committee of Privy Council for Medical Research, after consultation with the Medical Research Council and with the President of the Royal Society, by Order of Council dated June 11th, 1923.

## THE OCTOCENTENARY OF ST. BARTHOLOMEW'S HOSPITAL.

THE celebration of the eight hundredth anniversary of the Foundation of St. Bartholomew's Hospital was carried out from June 5th to 8th in a most satisfactory manner and on the whole under fairly good conditions of weather. In a large institution like St. Bartholomew's there is always abundance of talent available for every purpose; age was able to temper the exuberance of youth and young blood to stimulate the sluggishness of age. The tradition of centuries has resulted in an *esprit de corps* which proved of the greatest value. Everyone worked in harmony with his neighbour and did that part which was assigned to him without thought of fatigue and to the very best of his ability. It may be said in the words of the herald who used to proclaim the results of the tournaments in Smithfield, "The Treasurer has done well and the Clerk has done well, but to Sir Ernest Flower, Mr. Girling Ball, and Mr. Roth must be awarded the prize."

The celebrations divided themselves into several sections, some serious and formal, marking the real significance of an event without parallel in the history of English medicine; others appealing to the higher instincts of the aesthetic; and yet others for the baser sort. Former students, nurses, and friends of the hospital came in their thousands from all parts of the world and entered into the proceedings as members of one large and contented family.

### *Service at St. Bartholomew-the-Great.*

The formal celebrations began on Tuesday, June 5th, in the magnificent choir of the contemporary church of St. Bartholomew-the-Great, founded, like the hospital, by Rahere, Augustinian Canon and first Prior. The service had throughout the note of joy and rejoicing befitting the occasion: a processional hymn, a psalm, the lesson from Ecclesiasticus, the *Te Deum*, a few introits and the Lord's Prayer. The Collect in commemoration of founders and benefactors was adapted from that in the 1560 Latin book of Common Prayer. It was followed by an address given by the Bishop of Chester on the parable of the Good Samaritan. In a few words he paid tribute to the memory of his father, Sir James Paget, and, recalling the story of Rahere, he told how few institutions could show to their founders a record so wholly for good as that of the hospital. A charity which for eight centuries had continued uninterrupted to carry on the work designed by the founder, enlarged only in scope and improved by experience. A hymn, the Blessing, and the Nunc Dimittis concluded the service.

### *Solemnity in the Hospital Square.*

The large congregation then proceeded to the Hospital Square and witnessed a still more ancient ritual peculiarly consonant to the occasion. A procession of Augustinian Canons—to which order Rahere belonged—from the four houses now established in England, preceded by a thurifer, a cross bearer, two bearers of lighted candles, and some singing-men, came slowly round the square singing a hymn in honour of St. Augustine, the music of which is said traditionally to have been written by Rahere himself, for he was a skilled musician. The procession halted in front of the fountain, offered up a prayer, commemorated St. Bartholomew, and retired singing the psalm "*Deus misereatur nobis*." The rear of the procession was brought up by the two Abbots of the Order wearing black capes and gold pectoral crosses, the thirteen Canons themselves having short white surplices over their white habits and wearing birettas. The procession on the same spot which had presented a similar procession on the hospital on March 17th, 1123, celebrated the opening of the hospital on March 17th, 1123, when the staff consisted of eight Canons and four sisters. Eight hundred years later sisters, nurses, and staff had increased a hundredfold.

As the clock struck twelve a fanfare of trumpets and the roll of drums high up on the roof of the Great Hall was followed by the announcement of a herald who proclaimed in a loud and commanding voice that the ceremonial observances were about to begin. Immediately two little

processions of the sick and poor of London in the dress of King Henry I's days appeared in the square asking charity of two haughty nobles. They asked in vain, but at the very instant Rahere, just returned from a pilgrimage, passed by and the piteous little crowd appealed to him and were clinging round him when Richard Beaumais, the Bishop, came by, stopped, listened to Rahere whilst he drew in the dust a plan for the hospital, gained his consent to proceed with the undertaking, and received a blessing. Two centuries passed and the square was filled with a cheering crowd of citizens—who really did cheer *con amore*—with watermen, beefeaters, courtiers, and a jester. In the middle was the burly, bearded King Henry VIII, who gave to the kneeling Mayor and citizens a charter restoring some of the lands and revenues which he had taken into his hand a few years previously. As he was assuming to himself all the merit of his action, Rahere stepped forward and pointing solemnly upwards reminded him to give honour where honour is due. The bluff King—admirably impersonated by Mr. Arthur Boucher—fortunately took the reproof in good part and the whole assemblage did homage. The King retired, his court dispersed, and the scene was replaced by nurses and the wounded soldiers in hospital blue who have been only too familiar to the present generation, and to the singing of the hymn, "O God, our help in ages past," the solemnities ended. They were brightened by the brilliant academic costumes of the audience, who wore the gowns and hoods of their degree.

The delegates and staff to the number of 250 lunched with the Lord Mayor at the Mansion House, who, in spite of his recent accident, was present in a wheeled chair to receive them, the assembly being honoured by the attendance of the Prince of Wales, President of the hospital.

### *The Guildhall Ceremony.*

At three o'clock the President, H.R.H. the Prince of Wales, attended at the Guildhall to receive addresses from the delegates who had been chosen to offer good wishes from institutions in many parts of the English-speaking world. The delegates represented the Church of England, Universities of Great Britain and Ireland, Universities of the Dominions and India, Universities of the United States of America, and the Learned Societies of Great Britain and Ireland and the United States of America.

In the absence of the Lord Mayor, Alderman Lord Bearsted welcomed the Prince. Lord Stanmore, treasurer of the hospital, presented His Royal Highness with a gold medal which had been struck in memory of the anniversary from a design made by Mr. Charles L. Hartwell, A.R.A., and a copy of the *Short History of Bartholomew's Hospital*, which had been specially bound by Mrs. Loosely, a daughter of Mr. Henry Power, the first ophthalmic surgeon to the hospital. The delegates then came forward in single file, bowed, presented the address with which they were charged, and retired. Sir Archibald Garrod, Regius Professor of Medicine in the University of Oxford; Dr. Alexander Primrose, representing the University of Toronto; Dr. William Henry Welch, President of the Board of Scientific Directors of the Rockefeller Institute; Sir Walter Fletcher, F.R.S., secretary of the Medical Research Council; and the Right Reverend E. H. Pearce, Bishop of Worcester (and an "Old Blue"), made commendably short speeches of congratulation. His Royal Highness acknowledged the addresses, and in doing so took occasion to review briefly the history of the hospital and to express his satisfaction with the manner in which it had progressed.

The band of the Welsh Guards, under the direction of Lieutenant Andrew Harris, L.R.A.M., played selections of music both at the hospital and in the Guildhall. The formal proceedings being thus brought to a conclusion, the following days were devoted to various social and spectacular functions.

### *The Tableaux.*

A committee, of which Sir Aston Webb, P.R.A., was chairman and Mr. Richard Jack, R.A., honorary secretary, arranged a series of tableaux in the Great Hall of the hospital to illustrate notable events in the history of the

<sup>1</sup> See Review, BRITISH MEDICAL JOURNAL, June 2nd, 1923, p. 911.

ancient foundation. The subjects presented were: Rahere as a courtier; the crowning of the victor at a tournament in Smithfield, arranged by Mr. Charles Ricketts, R.A.; Rahere's dream; the building of the hospital by Rahere and the delivery of the Charter by King Henry VIII, arranged by Mr. Charles Sims, R.A.; a miracle at Rahere's tomb, and Harvey demonstrating the circulation of the blood to King Charles I, by Mr. Solomon J. Solomon, R.A.; Hogarth painting the pool of Bethesda, and war work by Mr. George Harcourt, A.R.A., were beautiful examples of colour and grouping. Where all were excellent it was hard to say whether one excelled the rest, but as a mere personal feeling, Mr. Solomon's tableau of a girl cured at the tomb of Rahere appealed most to the writer. Each tableau was revealed three times to the audience. Mr. C. S. C. Prance gave a short explanation of each situation before the curtain was drawn, and the music played by students of the Royal Academy of Music was selected by Sir Alexander Mackenzie.

At the conclusion of the first display of the tableaux the delegates were received at the Royal College of Surgeons of England by the President, Sir Anthony Bowlby, and a Vice-President, Sir D'Arcy Power, and were afterwards shown round the Hunterian Museum by Sir Arthur Keith, the Conservator, and Professor Shattock. In the evening, as mentioned below, an old students' dinner was held at Merchant Taylors' Hall; the delegates were invited and the hall was filled to its utmost capacity.

#### Exhibits.

Numerous valuable and interesting exhibits were to be seen in the Museum and Library of the Medical College, as might be expected in so ancient an institution. Foremost, perhaps, was the actual grant by Rahere of the Church of St. Sepulchre to Hagno, who succeeded him as Master of the hospital. The deed is dated 1137, and the seals were affixed in the presence of Rahere himself. There was also on view the Charter granted by King Henry VIII in 1544 and the Deed of Covenant between Henry VIII and the Mayor and citizens of London dated December 27th, 1546, as well as the Letters Patent of 1547. The beautifully illuminated Cartulary written by John Cok between 1456 and 1468, the Repertory Book, ledgers and journals were amongst the manuscripts shown, as well as a vellum MS. which once belonged to Reginald Colier, Prior of the Convent from 1435 to 1471; this was lent by the Right Hon. John Burns, who also lent a copy of the 1552 edition of *The Order of St. Bartholomew's Hospital*. There was also the indenture of apprenticeship of William Lawrence to John Abernethy dated April 30th, 1799, and a gold snuffbox presented to Sir William Lawrence by Sir William Blizard in gratitude for a successful operation for cataract "in the ninety-second year of his age." There was also a fine display of the plate belonging to the hospital, including a loving cup and the Renter's Mug, in which the tenants of the hospital were given refreshment when they came to pay their rents, whilst in the same case were the Renter's Pistols, which he carried when he journeyed to collect the rents. The Library also displayed a fine collection of portraits, prints, pictures, and other objects of interest connected with the hospital gathered by the pious care of Mr. Morrant Baker, Mr. Walter Jessop, Dr. Arnold Chaplin, Dr. Leonard Mark, and arranged by Mr. G. P. Baker, Sir D'Arcy Power, and Mr. Geoffrey Keynes. In addition to the specimens recently added to the Museum by Dr. T. H. G. Shore, the Curator, there was a remarkable exhibition of surgical instruments, either invented or used by former members of the medical staff from the time of Percivall Pott in 1745 to Mr. G. H. Colt in 1903. The instruments were selected and described by Mr. Alban Doran. Amongst the books the most notable was a copy of the first edition of Harvey's *De Motu Cordis*, lent by the Royal College of Physicians. There was also a copy of the original edition of the *Carmen de Sanguinis Circuitu* which was written by Robert Grove, afterwards Bishop of Chichester. It describes in elegant Latin hexameters Harvey's demonstration of the circulation of the blood on the dog "Senior." The description is so minute and life-like that Grove must have been present. It was lent by Mr. Sidney H. Badcock, who also showed the original copper-plate portrait of William Harvey engraved by

Faithorne to illustrate the first English edition of the *De Generatione* published in 1653. Mr. Badcock was able to trace the subsequent history of the plate.

#### Bartholomew Fair.

It was a happy thought to revive the ancient Bartholomew Fair as part of the octocentenary celebrations; and it was wise as well as happy to hand to the students of the hospital the duty of making the undertaking a success. Even before Rahere founded the Priory in 1123, a fair, then called the King's Market, was held regularly in the Smooth- or Smith-field, and every year from that time till 1855 a fair was held in the same place. This year once again the Lord Mayor proceeded in state through the city and proclaimed the fair, as so many of his predecessors had done before him. He did not, however, stop at Newgate Gaol for "a cool tankard of wine, nutmeg, and sugar." Nor did the City Treasurer pay a fee of three shillings and sixpence to the rector of St. Bartholomew-the-Great for making the proclamation in his parish. June 6th, the day chosen for the opening of the fair, was unfortunately wet, but this did not deter the Lord Mayor, still crippled by his accident, from opening the proceedings, nor did it prevent a very large attendance.

After the proclamation had been made the following address was read by Mr. W. Holdsworth, senior honorary secretary of the Students' Union:

My Lord Mayor,

We, the Students of the Medical College of St. Bartholomew's Hospital, in the City of London, desire to thank you most heartily in our own name and in that of the present assembly for your courtesy in coming amongst us to-day to open the mimic representation of that Fair which was held for so many years in the immediate neighbourhood of the place where we now stand, a Fair of much value to us as Students because, under the eye of our Masters, we learnt to treat many injuries and divers wounds which we might otherwise never have had the opportunity of seeing. "We feel, Sir, that your presence to-day is an additional proof of the interest which the Citizens of London have always shown in the welfare of their Hospital during the eight hundred years it has served them, an interest which has increased, were it possible, with the lapse of years. "We remember with gratitude that when in the past the fortunes of the Hospital were at their lowest ebb, the Citizens of London interceded for this their Hospital, and did establish it on so firm a foundation that it has been enabled, in the fulness of time, to obtain a foremost position amongst the great charities, not only of this metropolis, but of the world itself.

Sir,—We are grateful to you, and we know that so long as we are true to the great traditions we have inherited from the long line of our illustrious predecessors, we shall merit your esteem and continued confidence.

After hippocras had been drunk from a loving cup the Lord Mayor made a round of the fair, ordering the release of certain malefactors who happened to be incarcerated in the stocks. The fair itself was a very great success. The stalls were quaintly named and did good business. "Here is sold Sac and Petum of Virginia" had the identity of a tobacco stall; flowers were sold from "Sir Ernest's own Beaupot and Posy Booth." The side-shows were arranged with skill and enterprise. Magicians, astrologers, stilt-walkers, soothsayers, boxers, and "makers of sweet music" were very evident. Here was the representative of quackery through all the ages. Gowned in fur and chalk in hand, he described the growth of a corn in a manner entirely unauthorized by his professor of pathology, Sir Frederick Andrewes. His cure was marvellous. A learned man in Egypt had given him the secret with the hand of his daughter. "The remedy is here. The lady I left on the banks of the Nile." Here, too, was the palmer fresh from the shrine of St. James of Compostella, staff in hand and shell in hat, telling his tale to all and sundry, averring that he had gone bare-foot all the way when it was plain from the look of his feet that he had been shod and had had peas, and boiled peas at that, in his boots. And so the fun continued till seven o'clock on the evening of June 8th, when the fair terminated with the singing of the National Anthem. About £4,000 was raised by fair and tableaux, sufficient to cover the cost of the enterprise. The students, under the leadership of Mr. W. Holdsworth, are to be congratulated on managing the fair with the utmost success and dignity. High-spirited fun was everywhere at all times apparent; never was there any suggestion of rowdiness. Sir Ernest

Flower, whose was the older brain behind the show, must feel mightily pleased at the success of his efforts.

### *The Conversazione.*

On Thursday, June 7th, at 8.30 p.m., a conversazione was held at St. Bartholomew's Hospital. More than 3,000 guests were received by Lord Stanmore, treasurer of the hospital and president of the medical college; Miss McIntosh, C.B.E., R.R.C., matron of the hospital; Dr. T. W. Shore, dean of the medical college; and the Rev. W. F. G. Sandwith, rector of St. Bartholomew-the-Great. The old square of the hospital and the fountain, so essentially the centre of the life of St. Bartholomew's, had been gaily decorated with fairy lamps. Each department vied with the others in making its own branch of medical science interesting to the lay as well as to the medical mind. In the chemical laboratory Dr. W. H. Hurtley had hit upon the happy plan of allowing his students themselves to demonstrate striking chemical experiments, and remarkably well and enthusiastically did these youngsters do their work. The dispensary, with its demonstration of the making of drugs, was immensely popular. So varied and remarkable were the displays that it is not possible to do more than suggest their nature, but one side-show must not be forgotten. In a small room off the surgery was a representation of a Sairey Gamp: the comfortable figure, the poke bonnet, the hot and flushed face, the patient lying uncared for in the corner, the mug of gin and water, together with much histrionic skill, made a Dickensian picture which will never be forgotten by those who saw it. Miss Birch, affectionately known to generations of Bart's men as "Sister Scrubbing-Ladies," must be complimented on her demonstration of "ancient nursing." The heads of departments deserve congratulations on the value and interest of their exhibits, and the warden of the college, Mr. Reginald M. Vick, on his excellent staff work.

### *Rahere Lodge.*

The Masonic Lodge founded in 1895 for the convenience of Freemasons belonging to St. Bartholomew's Hospital held an especial meeting in the Freemasons' Hall on Friday, June 8th, in the presence of the Grand Master, H.R.H. the Duke of Connaught, and the Pro-Grand Master, Lord Amptill. Mr. W. Girling Ball was installed as Master of the Lodge by Dr. Harold Pritchard, his predecessor in the chair. Upon the nomination of Dr. R. J. Reece, seconded by Sir D'Arcy Power, the Duke of Connaught was elected an honorary member of the Lodge. In returning thanks, His Royal Highness recalled the fact that his brother, King Edward, when Prince of Wales, had personally constituted the Lodge twenty-eight years previously, and had honoured it by becoming an honorary member. Immediately afterwards H.R.H. the Prince of Wales was elected an honorary member upon the proposition of Dr. H. Morley Fletcher, seconded by Dr. Harold Pritchard. In the course of the proceedings, Mr. Ernest Clarke read a brilliant but short address on the history of the Lodge, pointing out that ten of the twenty-six founders survived and seven of the ten were then present in the Lodge. The Rahere Lodge, he said, was the first of the long line of hospital Lodges which had drawn into Freemasonry a large number of earnest men who had diffused the principles and tenets of the craft throughout the world. Upwards of three hundred and fifty brethren afterwards attended the banquet in the Connaught Rooms, where eloquent speeches were made by Lord Amptill and by Dr. George E. McLean, the delegate from the State University of Iowa, U.S.A.

### *THE OLD STUDENTS' DINNER.*

The annual Old Students' Dinner usually takes place at the beginning of the winter session, but the date was advanced, this year in order to coincide with the octocentenary celebrations. The dinner was accordingly held on Wednesday, June 6th, in Merchant Taylors' Hall, Threadneedle Street, lent for the purpose by the Master and Wardens of the Merchant Taylors' Company. The chair was taken by Mr. H. J. Waring, senior surgeon to the hospital and Vice-Chancellor of the University of London, who was supported by a company which numbered some 315, filling

the large chamber and overflowing into the gallery. Among those present were most of the consulting and active staffs. The guests included many of the delegates from the universities and learned societies of Great Britain and Ireland, the Dominions, and the United States, who had presented congratulatory addresses to the President, H.R.H. the Prince of Wales, on the previous afternoon during the Guildhall ceremony. Of these a considerable proportion are old students of the hospital, like the Presidents of the two English Royal Colleges and the Regius Professor of Medicine at Oxford; Sir Walter Fletcher, representing the Royal Society; Sir Joseph Verco, University of Adelaide; Professor A. J. Hall, University of Sheffield; Dr. Howard Tooth, University of Malta; and Professor A. J. Clark, University of Cape Town. Other delegates besides those mentioned among the after-dinner speakers were the Presidents of the Royal Colleges of Surgeons of Edinburgh and Dublin, and of the Royal Society of Medicine; the Vice-President of the Royal College of Physicians of Ireland; Sir David Drummond, representing the University of Durham; Mr. G. P. Newbolt, University of Liverpool; Professor Edward Fawcett, University of Bristol; Professor T. Sinclair, the Acting Vice-Chancellor of the Queen's University of Belfast; Professor J. Read, University of Sydney; Dr. D. J. Coffey, National University of Ireland; Dr. W. C. Quinby, Harvard University; Dr. A. Primrose, University of Toronto.

After the loyal toasts had been honoured, the Chairman proposed "Prosperity to the Hospital." He said that the history of the hospital might be divided into three epochs: the first beginning with its foundation by Rahere in 1123; the second in 1544 with Henry VIII's charter; and the third in 1901 when the momentous decision was taken to keep it on its ancient site in the City and to adapt it to modern requirements. Much had been done already in the past twenty-two years to carry out this intention, but much still remained to do; in particular, the question arose of how best to modernize the wards. The toast was replied to by Lord Stanmore, treasurer of the hospital and president of the medical college, who welcomed the great number of honoured guests now assembled to pay honour to St. Bartholomew's. The financial position, he said, was already much more secure, and this year the hospital would make both ends meet; but more money was needed in order to keep it in the front rank of the hospitals of the world. A reconstruction committee of five had been set up, consisting of two governors, two members of the medical college, with the treasurer as chairman. The toast of the Medical College was proposed in a witty speech by Sir William Lawrence, Bt., Senior Almoner, who took pride in the excellent relations between the governors, the staff, and the students. He coupled the toast with the name of the Dean, Dr. T. W. Shore, who on rising to reply was received with great enthusiasm. Dr. Shore began by remarking that Bart's was a blend of the very ancient and the extremely modern. Records of the attendances of students went back to 1662, but the real beginning of the school was about a century ago, when Abernethy was asked to take over the educational arrangements. Dr. Shore was proud to feel that throughout his own association with Bart's, a mere matter of 44 years, the keynote of the school had been progress. To quote one instance, it was the first to accept the offer of the Board of Education to assist in the establishment of clinical professorial units. The health of the guests had been wisely entrusted to Dr. Herbert Williamson, who has the gift of paying compliments in sparkling phrases; and the responses to this toast were entrusted to Field-Marshal Lord Methuen (delegate of the Bishop of Salisbury), Professor T. Kirkpatrick Monro (Delegate of the University of Glasgow), and Professor William Henry Welch (Delegate of the Rockefeller Institute and the Johns Hopkins University). As an ecclesiastical representative (Dr. Williamson had included him among the "guests spiritual") Lord Methuen spoke of the happy relations between the Church of to-day and modern Medicine; as a soldier he expressed admiration for the medical services, mentioning in particular his debt to Sir Archibald Garrod and Dr. Tooth at Malta during the late war. Professor Monro, in offering

the congratulations of Scottish Medicine to St. Bartholomew's, reminded his hearers that the Principal and Vice-Chancellor of his own University, Sir Donald MacAlister, had been a student and teacher at Bart's. Professor Welch, in an eloquent speech, said that Bart's in its octocentenary year was proud of the glories of the past, but its face was towards the future. He declared that the backbone of American Medicine was British, and America was now beginning to pay something of her debt to British Medicine.

## Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

### The Mental Treatment Bill.

THIS bill was considered on report in the House of Lords, and a few formal amendments having been agreed to, the bill was ordered for third reading.

### Insurance Medical Service.

Sir Kingsley Wood asked, on June 6th, whether the Minister of Health proposed to make any independent inquiry into the panel system. Lord E. Percy said the Minister was independent and was always inquiring. Dr. Watts asked of what use were the records kept by panel doctors, either from scientific or other point of view, and what was the cost of the insurance fund; and whether the Minister was aware that the fact that these records had to be kept stopped many insured persons, especially when suffering from certain diseases, from consulting their panel doctors, and so allow these diseases to become much more serious owing to the lack of proper treatment. Lord E. Percy referred the honourable member to the report of Sir Humphry Rolleston's committee which was presented to Parliament (Cmd. 836 of 1920). The keeping of records was part of the terms of service of insurance practitioners, and was not separately paid for. Great care was taken to preserve their confidential character, and the Minister had no evidence in support of the suggestion contained in the last part of the question. In reply to Mr. Hurd, Lord E. Percy said that certain proposals for the revision of the terms of service of insurance practitioners, based mainly on recommendations of the Insurance Consultative Council, had been discussed with the Insurance Acts Committee of the British Medical Association, and that Committee had put forward certain suggestions. All the proposals would be discussed at a conference of representatives of panel committees throughout the country. Lord E. Percy has also stated that the desirability of revising medical certificate forms. Minister of Health has promised to be utilized to give Insurance questions.

**Insurance Dental Treatment.**—In answer to Mr. Scrymgeour, on June 6th, Lord E. Percy said that the payment of the whole or part of the cost of dental treatment was included among the additional benefits which an approved society was entitled to provide for its members out of a disposable surplus declared on its value. Several societies, with a total membership of nearly 7,000,000 insured persons, had already made such provision. The Minister of Health hoped that under the scheme arising out of the second valuation, which was about to take place, it would be made available for an even larger number of insured persons than at present.

**Cancer Research.**—Dr. Chapple asked, on June 6th, whether the Minister of Health would take steps to ensure that the scientific research effort now being made in Britain in the direction of discovering the cause and cure of cancer were not hindered by lack of funds, and Major Molloy inquired whether the Minister would endeavour to procure a large increase in the present inadequate subsidy granted by the Treasury for research, so that it might be co-ordinated so far as notification and clinical information as to incidence were concerned. Lord E. Percy referred members to the answer he gave on June 4th to Mr. Alfred T. Davies, which has been published in these notes.

**Infectious Diseases.**—Sir W. Preston asked, on June 6th, whether the Ministry of Health had any control over arrangements which county medical authorities made when dealing with epidemics and infectious diseases; and whether, if a county medical officer made improper or inadequate provision for handling cases, the Ministry of Health had powers to compel such officer to take proper steps. Lord E. Percy said that the duty of dealing with infectious diseases was imposed by law on the local authorities and district medical officers of health. The Minister of Health was, however, empowered to make regulations enabling the county council to provide hospitals for the isolation and treatment of the diseases. Such regulations, where made, placed on the district medical officer of health, subject to any directions which might be given to him by the county medical officer, the duty of securing the isolation and treatment of patients in hospitals and to take all the necessary steps for preventing the spread of the disease. The answer to the last part of the question was in the negative.

**Miners' Nystagmus.**—Mr. Mardy Jones asked, on June 11th, whether the attention of the Secretary for Mines had been drawn

to Mr. Frederick Robson's paper read before the South Wales Institute of Engineers, in which he advanced evidence in support of his theory that miners' nystagmus is caused by the inhalation of noxious gases given off in a coal face and not to the defective illumination of miners' lamps; and whether, in view of the character of the evidence submitted, the Minister would institute further inquiries into the whole matter. Lieut.-Colonel Lane Fox of his theory had been considered. Medical Committee concerned, able to accept that theory. He appreciated that Mr. Robson had devoted much time and care to the study of nystagmus, and every theory supported by evidence should be considered.

**Metropolitan Asylums Board Hospitals.**—Lord E. Percy informed Mr. Gilbert, on June 6th, that fifteen hospitals for infectious diseases, other than tuberculosis and venereal diseases, were maintained by the Metropolitan Asylums Board and the number of beds therein was 8,779. The total numbers of patients treated during the years 1920, 1921, and 1922 were 40,705, 55,324, and 41,819 respectively. The total net expenditure of the Board during the years ended March 31st, 1920, March 31st, 1921, and March 31st, 1922, was £1,872,013, £2,748,872, and £2,565,233 respectively. A rate of 9½d. in the £ had been levied to meet the expenses of the Board during the current financial year. The provision and maintenance of hospitals for infectious diseases formed only a part, though an important one, of the work of the Board.

**A Medical Officer's Salary.**—Lord E. Percy informed Sir R. Winfrey, on June 6th, that the reason why the Minister of Health refused to agree to a reduction in the salary of the medical officer of health for the Nutford and Launditch Union was that efficient service could not reasonably be expected from the medical officer of health in this extensive rural district for less than his present salary of £150 per annum, which was inclusive of traveling and clerical expenses.

**Disability Pensions.**—Major Tryon informed Mr. F. Roberts, on June 11th, that in the case of men invalidated from service it was an express rule of the Pensions Department that there was a prima facie presumption that the invaliding disability was due to, or aggravated by, the man's service. In the case of demobilized men he had, in accordance with the advice of the highest independent medical authorities in the kingdom, directed, in the case of certain diseases, in which the first overt symptom might not appear for some time after the original causation of the disability, that even though such symptoms did not manifest themselves until a year (in the case of tuberculosis), or, in the case of certain other diseases, even two years after the man's discharge from service, the disease might, subject to the proper diagnosis of the man's condition, be accepted as having originated in, or existed during, service without further evidence on the point. He was advised, however, that these principles could not apply to any and every complaint from which an ex-service man might suffer for the rest of his life, for the reason he had given in a previous answer on April 19th to Mr. Bennett.

**Tuberculous Milk.**—Mr. Adams asked, on May 30th, whether the corporation of Newcastle-upon-Tyne, in their weekly examinations for tuberculosis in samples of milk sold for use in that city, found that the highest proportion of positive samples was 10.4 per cent. in 1912, and the general control by the 3.6 in 1919, but that it stood at the relative high figure of 7 per cent.; and whether the Minister would take or propose measures for dealing more efficiently with herds in rural areas by transferring the duties in connexion therewith from the small local authorities to combinations of these, or to county councils. Mr. Chamberlain said he understood that the facts were as stated. The duty of taking measures to prevent the sale of tuberculous milk was placed on county and county borough councils by the Milk and Dairies (Consolidation) Act, 1915, but the commencement of that Act had been postponed till September 1st, 1925, by the Milk and Dairies (Amendment) Act, 1922. Section 11 of the Act of 1922 provided for the transfer to the county council of the powers and duties of a district council under that Act or any other enactments, orders, or regulations relating to milk and dairies, if the county council resolved that the district council had failed to exercise or perform any of those powers or duties and made complaint to his department.

**Answers in Brief.**  
The total amount paid from the Exchequer in respect of the tuberculosis schemes in Scotland during the year ended March 31st last was £339,509.

Lord E. Percy states that particulars are not yet available regarding vaccination in Leicester during 1922, but in the previous five years only 3.5 per cent. of the newly born children were vaccinated, the bulk of the remainder being exempted on account of statutory declarations by parents or guardians. No cases of small-pox had been notified in Leicester and there had been no deaths from that disease during the past five years.

During the past six months (four years after the armistice) 1,600 first claims on account of tuberculosis have been rejected on the grounds that the disability was neither due to nor aggravated by service, and 1,100 have been admitted.

The British Government is sending a delegation to the International Congress on Alcoholism the Danish Government has arranged to hold in Copenhagen in August.

Mr. Neville Chamberlain states that the average amount devoted by the Medical Research Council to direct cancer research has been approximately £5,000 during the last three years.

## England and Wales.

### VITAL STATISTICS OF ENGLAND AND WALES.

WE have received from the Ministry of Health a copy of a publication bearing the somewhat cumbersome title *The Registrar-General's Statistical Review of England and Wales for 1921. (New Annual Series, No. 1.) Tables, Part II, Civil.*<sup>1</sup> This volume, we learn, forms part of the annual series of statistical publications which, under the style of the Registrar-General's Statistical Review, will henceforth take the place of the Registrar-General's Annual Report. The change in form and name is governed by the provisions of Section 5 of the Census Act, 1920, which requires the Registrar-General from time to time to collect and publish statistical information regarding the number and condition of the population in the interval between one census and another. The tables for 1921 have been divided into two groups—medical statistics and civil statistics—and the whole Statistical Review will, from now onwards, be issued in three sections at different prices, entitled respectively: Text; Tables, Part I, Medical; Tables, Part II, Civil. The intention is to issue each section as soon as it is ready, instead of, as formerly, holding back the publication of the tables until the text based upon them has been prepared. The present volume consists primarily of those tables contained in the old series which have a general demographic interest. It includes also tables showing populations, births, deaths, infant mortality, and marriages in British Dominions, and other administrative statistics of various kinds relating to the social and civil condition of the population. The companion volume of medical tables has already appeared,<sup>2</sup> and the series will be completed for the year 1921 by the volume of explanatory text shortly to be issued. From the tabular matter now published it appears that the birth rate for 1921—22.4 per 1,000 persons living—was the lowest recorded since the beginning of civil registration in 1837, except for the war years 1915-19 inclusive. The 848,814 births consisted of 454,895 males and 413,919 females—that is, 1,051 males to every 1,000 females. Illegitimate births numbered 38,618, or 45 in every 1,000 births. The excess of births over deaths ("natural increase") was 390,185, or approximately 10 per cent. of the population. Marriages numbered 320,852, representing 16.9 persons married per 1,000 living. The figures for divorce were the highest ever recorded; the number of decrees *nisi* made absolute for "dissolution" were 3,458, and for "annulment" 64, making a total of 3,522. Divorced men to the number of 1,592, and 1,286 divorced women, remarried in 1921; 28,627 widowers and 29,141 widows remarried.

### ROYAL ALBERT EDWARD INFIRMARY, WIGAN.

The fiftieth anniversary of the opening of the Royal Albert Edward Infirmary, Wigan, was celebrated on June 4th, when Lady Mary Lindsay, daughter of the Earl of Crawford, acting for her mother, unveiled a commemoration tablet in connexion with the new operating theatre now in course of construction. The new building, which is to commemorate the jubilee of the Infirmary, forms a complete operating unit with all the conveniences of modern surgery. Around a small octagonal hall are arranged the operating theatre, with an annexe containing sterilizers, sinks, etc., an anaesthetizing room, surgeons' cloak room and dressing room, and a separate room for the large sterilizers. The heating will be partly by hot water and partly by steam, and the ventilation is taken by flues to a duct over the roof with an electric exhaust fan, and fresh air is admitted behind the radiators through filters so that it is cleaned and warmed as it passes into the theatre. Lord Crawford, president of the Infirmary, who presided at the opening ceremony, said that in the first completed year of the institution, fifty years ago, twenty major operations were performed, whereas during the last completed year the number of operations had risen to 1,335. The financial status of the Infirmary was remarkable; and was mainly based upon the system of weekly contributions; last year the income from these contributions amounted to

£17,000. This meant much confidence in the Board of Management and in the medical and nursing staffs. That confidence had been maintained ever since the Infirmary was founded, by the knowledge that its door was ever open, that its authorities were alive to the progress of science, anxious to keep the equipment up to date, and ready to serve the interests and comfort of the patients. The people of to-day ought to be proud to belong to an age which had devised marvels for the relief of human suffering. In an age which had produced Simpson, Lister, and Pasteur the tide must indeed be at flood which might lead forward to further victories. Colonel W. M. Roocroft, C.M.G., honorary consulting surgeon to the Infirmary, said that he first joined the surgical staff of the Infirmary in May, 1883, and he served until he had to relinquish his duties, owing to the war, on August 4th, 1914. The hospital had doubled the number of beds, and the number of operations was multiplied ten times as compared with when he was first on the staff. Many constructional alterations had taken place in the operating theatre and the question of a new theatre had previously been brought forward from time to time, but was frustrated by lack of funds. The improved facilities now available for the carrying out of modern surgical technique would be for the benefit of the institution and the well-being of the patients.

## Scotland.

### THE GIBSON MEMORIAL LECTURE.

The George Alexander Gibson Memorial Lecture will be delivered before the Royal College of Physicians of Edinburgh by Dr. W. T. Ritchie on Wednesday and Thursday, June 27th and 28th, at 5 p.m. on each day. The subject of the lecture is the response of the heart in health and disease.

### PUERPERAL MORBIDITY AND MORTALITY.

The Scottish Board of Health has appointed a Departmental Committee to inquire into the incidence of puerperal morbidity and mortality, with special reference to the causes contributing thereto, and to suggest any remedial measures. The composition of the Committee is as follows: The Right Hon. Lord Salvesen (chairman); Mrs. Mary Barbour, a member of Glasgow Town Council; Dr. R. C. Buist, honorary secretary Dundee Branch of the British Medical Association; Miss M. E. Cairns, Glasgow, vice-president Scottish Midwives' Association; Dr. T. F. Dewar, C.B., Scottish Board of Health; Miss A. M. Fraser, Assistant Inspector of Midwives and Chief Health Visitor, Motherwell and Wishaw Burgh, and Superintendent of the District Nursing Association; Dr. Matthew Hay, Professor of Forensic Medicine, University of Aberdeen, late Medical Officer of Health of Aberdeen Burgh, a Director of Aberdeen Maternity Hospital; Dr. B. P. Watson, Professor of Midwifery and Gynaecology, University of Edinburgh; with Mr. C. L. Farmer, Scottish Board of Health, as Secretary.

### EDINBURGH SURGICAL APPLIANCE SOCIETY.

An important Edinburgh war medical charity held its final meeting last week when Sir Montagu Cotterill, C.M.G., F.R.C.S.E., presided over the last annual meeting of the Edinburgh Surgical Appliance Society. The honorary superintendent, Miss Malcolm, reported on the activity of the Society since its inception in 1917, by the Scottish Women's First Aid Corps, for the purpose of supplying splints, drop-foot boots, and similar requisites to wounded men. Altogether in the six years of its existence some two thousand orthopaedic appliances had been manufactured and sent out. During the war the staff numbered 70; the work had been entirely voluntary. The chairman expressed the regret which the Society felt that the work now had to cease, and said that the medical charities in Edinburgh were losing an important adjunct to their work, and ample testimony to its value had been forthcoming from those who had benefited by it. A vote of thanks to the honorary superintendent was adopted with cordial unanimity.

### CONFERENCE OF HEALTH VISITORS.

The fourth annual conference of the Scottish National Association of Health Visitors, Women Sanitary Inspectors, and School Nurses was held recently in the City Chambers,

<sup>1</sup> London: Printed and published by H.M. Stationery Office, or to be purchased through any bookseller, 1923. Price 5s. net.  
<sup>2</sup> British Medical Journal, February 17th, 1923, p. 299.

Glasgow, under the presidency of Lady Leslie Mackenzie, the president of the association. Dr. A. K. Chalmers, M.O.H. Glasgow, gave an address on the causes of the decrease in the infant mortality rate during the last twenty years. He said that at the beginning of the present century there were no maternity and child welfare schemes as at present known, little organized effort to control tuberculosis, and none at all to deal on a large scale with venereal disease in the expectant mother and her offspring. It was a curious and significant coincidence that the awakening and afterwards the extension of effort on behalf of infancy and childhood had both been very definitely related to periods of war. The co-ordination of effort for the reduction of infant mortality began after the revelations of physical inefficiency at the time of the South African war, and the inclusion of a much larger field of child welfare was the work of recent years. He thought that in the future of social reconstruction the welfare of the child would fill an important place.

Professor B. P. Watson, professor of midwifery, Edinburgh University, read a paper on the value of ante-natal work, in the course of which he said that no branch of medicine was so encumbered and hampered by superstitions born of ignorance as that which was concerned with the care of the expectant mother. The social worker possessing the requisite knowledge could do much to overcome the prejudice against modern means of prophylaxis and treatment. In no department was preventive medicine more important than in midwifery, for practically all the disasters which resulted in the disability or death of the pregnant or parturient woman could be anticipated and prevented. In England and Wales there was an average of 3,500 deaths each year from childbirth, and in Scotland between 600 and 700. Then there was an enormous wastage of life in miscarriages and the birth of stillborn children. On an average, one pregnancy in every eight terminated in abortion, and under modern conditions that proportion was constantly tending to become higher. Three children out of every hundred were stillborn, and a considerable number born alive were so feeble that a further 4.5 per cent. died within the first four weeks of life. It was therefore very important that the pregnant woman should seek medical advice early. In the well-to-do and working classes this supervision should be exercised by the family doctor or the obstetrician, and for the poorer classes maternity centres should be established in every city and every district. These centres, where possible, should be in direct contact with an obstetrical hospital and should be staffed by physicians and by nurses who would follow up the patients in their own homes.

## Ireland.

### ANNUAL MEETING OF THE IRISH MEDICAL ASSOCIATION.

The annual meeting of the Irish Medical Association was held on June 6th in the Royal College of Surgeons, Dublin, when Senator W. J. O'Sullivan, M.D., occupied the chair. A warm vote of thanks was passed to Dr. Edward Magennis, the outgoing president. The report stated that the council of the Association decided to invite the Irish Medical Committee, as constituted in July, 1913, to be attached to the Irish Medical Association as one of its standing committees. The adoption of the scheme would not in any way prejudice the question of amalgamation with the British Medical Association, nor would it alter the broad lines on which the Committee was formed. The matter will be brought before a delegates' meeting to be held at a future date. Owing to the unrest in the country the Association has been greatly hampered in its work. It is hoped, however, that the activities of the Association may be renewed. Efforts were made to have the motor tax on doctors' cars considerably reduced, and while some slight change has been made in the method of rating, yet it affords no material advantage.

In his presidential address Dr. O'Sullivan said that, short as was the time for which the Irish Government had existed, it had already given solid assurance of its will and ability to grapple with the several economic questions

affecting the Irish people. There was, however, to be noticed an almost total absence on the part of the Irish Government of any disposition to request, or accept when given, the advice of the Irish medical profession on purely medical affairs. In the Free State were commissions dealing with most questions of national importance, with the one notable exception, the health of the people. It was, of course, true that, under the new régime, far-reaching changes in the Poor Law administration had been seen, and many of the changes had a great deal to recommend them, but so far as they included the medical services they had been decidedly for the worse. At the time these changes were being first contemplated their more serious defects were pointed out on behalf of the profession, but the warnings were unheeded, with the result that at the moment the efficiency of the medical services which were considered to meet the requirements of the less well-to-do classes were at a lower standard than they had been for the past twenty-five years. It could not be said that there was in the modern sense any live public health service. The prevention of the spread of infectious disease was altogether dependent on the medical attendant, who, in a large percentage of cases, might be the dispensary doctor, and who also was medical officer of health for his district. For the latter office he received generally about £20 a year, which seemed to suggest that he was not expected to knock up a very great row about public health. It must be admitted, Dr. O'Sullivan said, that the reputation of Irish sanitation was very bad; that, from the commercial point of view for a food-exporting country, was not reassuring.

### GRADUATES OF DUBLIN UNIVERSITY.

We have received the following letter, which is of interest to graduates of the University of Dublin. It points out that though resident elsewhere they retain their right to vote for representatives of the University of Dail Eireann.

Trinity College, Dublin,  
June 7th, 1923.

SIR,—All scholars, ex-scholars and graduates of Dublin University, whether resident in the Irish Free State or not, who desire to retain their Irish citizenship and their privilege of voting for representatives of their University in Dail Eireann, are earnestly requested to fill up and return to the Registrar of University Electors the forms of claim to vote which were recently sent out.

It is not the case that residence in the Free State is essential to entitle an elector to be placed upon the Register of University Electors, nor is an elector who happens to have a vote in a constituency in Great Britain or in Northern Ireland prohibited from retaining it. No University elector may be upon the register of any other constituency in the Saorstát, but an elector in Great Britain or Northern Ireland may also be upon the university register, provided he claims the rights of citizenship, of which one is the right to vote for the representatives of his university in the Saorstát and has the qualifications prescribed by the constitution.

It must be remembered that domicile is not tantamount to residence, as some persons appear to suppose.—We are, etc.,

E. H. ALTON,  
JAMES CRAIG,  
GERALD FITZGIBBON,  
WM. E. THRIFT.

The position with regard to the National University is the same. Graduates who have not yet received forms, or mislaid those sent them, should apply at once to the Registration Officer, Trinity College, Dublin, or to the Registration Officer, National University of Ireland, 49, Merrion Square, Dublin.

### NEW CANCER HOSPITAL, BELFAST.

The foundation stone of the new Cancer Hospital, Belfast, to be erected by the Belfast Board of Guardians, was laid by the Duchess of Abercorn on May 24th. Numerous speeches were delivered congratulating the board on its forward policy and its determination to do the best for those under its charge. The building will be of great help to the staff in their work, and will carry out the principle of the board as previously shown in the Consumptive Sanatorium at Whiteabbey, in the recently erected Children's Block, and in other improvements. The wards will face south, and there will be a flat garden roof.

AN examination of 445,000 school children in St. Gallen, Switzerland, for goitre showed that the thyroid was not palpable in 6.4 per cent., 31.7 per cent. had a palpable thyroid but no goitre, while 39.8 per cent. had a soft goitre and 22.1 per cent. a nodular goitre.

## Correspondence.

### PREVENTION OF HEART DISEASE.

SIR,—“The ravages of rheumatic heart disease deserve our close attention in London, and wherever there seems to be any ray of light that direction is worth exploring.” This sentence from the concluding paragraph of Dr. Poynton's admirable lecture on the prevention of heart disease (June 2nd, p. 919) encourages me to remark that light may, perhaps, be found in the unpromising atmosphere of this rather grimy city, for it is now nearly two years since the Birmingham Education Committee, on my advice, began an experiment to this end which has proved, I think, successful.

As Dr. Poynton points out, no physician can avoid noticing the frequent incidence of serious sequelae of rheumatism in children of the hospital class, and their comparative rarity in the children of the well-to-do. It seemed clear to me that this difference resulted almost entirely from the lack of adequate provision for the convalescence of the poorer child. Here in Birmingham we suffer in the same way as Dr. Poynton suffers at Great Ormond Street—we are torn between the desire to keep our rheumatic children in hospital and the constant urgent necessity for the admission of acute cases.

The experiment to which I refer began shortly after the opening of the Baskerville Residential School for Cripples at Harborne, within a few miles of the centre of the city. At that time I certified a few rheumatic children among my out-patients at the General and Children's Hospitals as “physically defective within the meaning of the Act,” and took them into Baskerville for periods of six or twelve months.

The considerations which induced me to choose a residential cripple school for the purpose were the following:

(1) Life in a cripple school is lived at a slow pace, which seemed peculiarly suitable for rheumatic children.

(2) One of the difficulties in an ordinary convalescent home is to ensure rest for the nervy rheumatic child. Example outweighs precept in the treatment of children, and I hoped that the unruly rheumatic girl might be induced to rest more willingly if next to her were placed a child totally immobilized for months in a plaster case or box-splint. This, indeed, proved to be the case.

(3) I was satisfied that rheumatic children do not do well while living a vegetable life—“of blind unreasoning rest,” as Dr. Poynton puts it. They are frequently unusually intelligent and tend to become neurotic if left without mental occupation. For this reason a school is preferable to a hospital. In passing, I may say that Miss Smith, the head mistress, to whom so much of the success of the school is due, has been engaged for some time on an inquiry to determine the best methods of education—very much in the way suggested by Dr. Poynton. At some future date, indeed, in collaboration with Miss Bridie, we hope to publish a report on the investigation of the changes of mentality in children resulting from various diseases.

(4) For obvious administrative reasons it is a great advantage to dilute the population of a cripple school with a number of children who can to a certain extent look after themselves.

So remarkable was the improvement of these rheumatic children at Baskerville (even of those who had shown none after long periods of treatment in hospitals and convalescent homes) that we have now decided to allot half the available beds to them. In all probability we shall have fifty places for them before long. We shall most certainly need more. I cannot discuss all the points raised by Dr. Poynton. We have not found elaborate control of exercise by graded walks and slopes necessary: simple dancing is very valuable.

It would ill become me to discuss imperfections of medical education, but I cannot forbear remarking that a curiously large number of rheumatic children have passed some time in sanatoriums and other places for the tuberculous, and that about 15 per cent. of the children sent to me for admission to the open-air schools are rheumatic.

My letter is already too long; my aim in writing it is

to indicate what can be done by a local education authority of courage and vision. It would be ungrateful of me not to acknowledge the support of Councillor Miss Martineau in this undertaking; only those who know what is involved in the defence of estimates at council meetings in hard times can appreciate how much of the realization of Baskerville is due to her.—I am, etc.,

Birmingham, June 8th.

A. P. THOMSON.

### DISEASED TONSILS AND HEART DISEASE.

SIR,—In your issue of June 9th (p. 995) Mr. Carruthers asks, “What is a ‘diseased’ tonsil?” It is a question which many of us must often have asked ourselves, but without arriving at a more satisfactory answer than if we had faced the old queries “What is truth?” or “What is fame?” Whatever replies we make must be influenced by “relativities.” In any discussion on disease of the tonsils few will dissent from the following statements:

1. It is impossible by mere inspection to say whether a tonsil is healthy or diseased.

2. A large tonsil may produce no other effects than those brought about by mechanical obstruction of the upper air passages, the middle-ear clefts, etc.

3. A small but buried and septic tonsil may be the cause of a number of local and constitutional symptoms, which vary in their situation as well as in their gravity.

In his second paragraph Mr. Carruthers says, with reference to the definition of an “unhealthy” or “diseased” tonsil, “that this is a question of real practical value which has never been satisfactorily answered.” I would venture to say that a practical solution is more easily given than any verbal definition which would include all the points at issue.

When a tonsil is “unhealthy” or “diseased” it will nearly always produce, sooner or later and in greater or less degree, local or constitutional symptoms.

In a child two of the common symptoms are enlarged glands behind the angle of the jaw—an evidence of infection from the tonsils—and mild bouts of pyrexia for which there may be no apparent cause—that is, the patient's general health is fairly good, and the fever lasts for only one, two, or three days.

In adults “diseased” tonsils are often small and buried between the faucial pillars, so that they do not arouse suspicion, but if the outer area of the tonsil be pressed upon foul-smelling purulent debris can often be expressed from the crypts. As a general rule adults are more liable than children to suffer from the more chronic constitutional symptoms of septic absorption, such as “muscular rheumatism,” “rheumatoid arthritis,” neuritis, various skin eruptions, and such diseases of the eye as keratitis punctata, irido-cyclitis, etc.

Such facts must be common knowledge to those who have given much attention to diseases of the throat, and I venture to state them because the practical answer to Mr. Carruthers's question is “the only thing that matters.”—

I am, etc.,

London, W., June 9th.

HERBERT TILLEY.

SIR,—In his very interesting lecture on this subject published in your issue of June 2nd, Dr. Poynton says, “It would be in my opinion a mistake to suggest the wholesale removal of tonsils in rheumatic children and those suspected of rheumatism, when there is no evidence that they are diseased.”

We have recently analysed the subsequent history of 144 patients admitted to Guy's Hospital for acute rheumatism; some of them had their tonsils removed, the others had no operation. Rheumatic infection recurred quite as frequently among the former as among the latter. The exact figures will be published in the next issue of the *Guy's Hospital Reports*, and they certainly do not support the belief that tonsillectomy is likely to prevent the recurrence of acute rheumatism. While we think that tonsils which are definitely septic ought generally to be removed, we entirely agree with Dr. Poynton that there is no justification whatever for the enucleation of tonsils as a routine measure in every rheumatic child.—We are, etc.,

G. H. HUNT,  
A. A. OSMAN.

London, W., June 8th.

## THE COMMITTEE ON VENEREAL DISEASE.

SIR,—In the Report of the Trevethin Committee, paragraph 25 (referred to on page 978 of your issue of June 9th), a recommendation is made that

"Increased facilities for medical supervision of women during pregnancy is desirable, and may in part be obtained by an extension of the system of ante-natal clinics, and by the instruction of midwives, who would refer suspicious cases to a doctor. In this connexion we would also call attention to the importance of including instruction on venereal diseases in the general training of midwives and nurses." (The italics are mine.)

I would point out that the Rules of the Central Midwives Board provide for both these desiderata. All pupil midwives are bound to receive instruction in venereal diseases, as Rule C, which prescribes the subjects of examination, includes amongst such subjects, the venereal diseases (syphilis and gonorrhoea) in relation to their signs, symptoms, and dangers in women and children and to the risks of contagion to others.

As to referring suspicious cases to a doctor, Rule E 20 requires a midwife in all cases of illness of the patient or child, or of any abnormality occurring during pregnancy, labour, or lying-in, as soon as she becomes aware thereof, to call in to her assistance a registered medical practitioner. Rule E 21 (2) (3) makes Rule E 20 particularly applicable in the case of a patient suffering from a purulent discharge or sores of the genitals. In fact, no midwife can fail to call in medical help and to notify to the Local Supervising Authority without rendering herself liable to have her name removed from the roll.

In addition, I would point out that all midwives on their enrolment receive, together with the Rules which regulate their practice, a copy of two leaflets drawn up at the request of the Board by the Chairman, Sir Francis Champneys, in 1916, setting forth in detail the signs and symptoms of these diseases, their dangers both to mother and child, and the necessity for prompt medical help. Copies of these leaflets I enclose.

The Board's Rules do not seem to be known to some of those who deal with matters of public health. It might be well, before making recommendations for the improvement of the training and practice of midwives, to ascertain what such training and practice include as a matter of fact. A few weeks ago I had to draw attention to advice of a similar nature given at a meeting of the Royal Society of Medicine with regard to cancer.—I am, etc.,

London, S.W., June 11th.

H. G. WESTLEY.

## DIPHTHERIA ANTITOXIN ON SUSPICION.

SIR,—I have read Dr. F. Foord Caiger's letter in your columns (June 9th, p. 996) with interest, more particularly as I have recently been dealing with a case, in which it was desired that all contacts should receive a prophylactic dose of antidiphtherial serum.

These I administered to seven persons; but I should like to know what the chances of anaphylaxis are, should any of these patients develop diphtheria, say, in two or three weeks, or later, and require a further dosage.

I am in the same quandary when I have to deal with a motor or other accident, complicated with much road dirt, in an ex-soldier who, wounded during the war, received the usual antitetanic injections. Up to a limit of eight days, I take it, there is very little fear of anaphylaxis with a succeeding injection of serum. After that there is, of course, a danger—but for how long does this danger persist? Exceptionally a case of anaphylactic reaction occurs with even a first administration of serum.—I am, etc.,

Sevensoaks, June 11th.

GERALD SICHEL.

## THE NATURE OF BLOOD SUGAR.

SIR,—We have read Dr. Hewitt's letter in the BRITISH MEDICAL JOURNAL, June 9th (p. 994), and find that there are two points which require explanation.

In our article of May 26th we wrote "figures 1 and 2." It should have been "figures 2 and 3." We tender our apologies for this and hope that he will now be quite clear as to our meaning with regard to his experiments.

The laevo-rotation referred to by us was obtained since our original paper was published.—We are, etc.,

W. SMITH

Cambridge, June 9th.

L. B. WINTER.

## PERNICIOUS ANAEMIA.

SIR,—In reply to Dr. Gordon Ward's questions:

1. The reason why the erythrogenic marrow increases in area and activity surely denotes an attempt on the part of the host to manufacture new red cells to replace those haemolysed in the circulation.

2. In pernicious anaemia the spleen is only rarely enlarged, and there is no evidence that in this disease haemolysis takes place mainly in the spleen. The statistics of splenectomy show that no patient has ever been cured and only a degree of improvement occasionally results.

3. Inasmuch as the patient is not dead, how do we know that the marrow can return to normal?

4. The histological structure of the bone marrow is entirely different from that of the spinal cord and alimentary canal, and one would hardly expect fibrosis, for instance, to occur.

I repeat that I deprecate the opposition between the clinician and the pathologist. My point was that clinical signs of this lethal change in the bone marrow are indefinite, and that the characteristic changes in the blood, to which I have referred, usually establish the diagnosis. I am not surprised that even Dr. Gordon Ward admits that this view is widely held. I find that in 26 cases of my own where these changes were found, and in which pathological opinion was sought because the clinical signs were at the time indefinite, 21 ultimately died directly of the disease, and in the remainder it was not possible to obtain a reply from the clinician. In none, incidentally, was combined degeneration of the cord, which Dr. Gordon Ward apparently regards as an important part of the syndrome, present.—I am, etc.,

A. KNYVETT GORDON, M.B., B.C.,

London, W.C., June 1st.

B.A. Cantab.

\*\* We cannot continue this correspondence.

## POLYTHELIA.

SIR,—Either supernumerary nipples (without a supernumerary mamma) are less rare than Dr. Douglas Howat's memorandum in the BRITISH MEDICAL JOURNAL of June 2nd (p. 928) would indicate, or I have been fortunate. I happen to have seen three cases at least in my practice, and all had the following characters:

1. Position: on the left side, below the normal mamma, the accessory nipple being internal to the normal one.

2. Size: small, much less than the normal nipple. In no case did the patient recognize the nature of the "birth mark," which caused no symptoms.

3. Sex incidence: all the cases were males.

These little appendages are not, of course, "rudimentary," as is too often stated; many writers fail to comprehend the difference between a rudiment and a vestige, though the former is a dawning structure, the latter a disappearing one. The accessory nipple is hardly even a vestige, but rather an atavism, throwing back to the multiple nipples of mammalian ancestors.—I am, etc.,

Sale, Manchester, June 9th.

GRAHAM RENSHAW.

## THE ENDOWMENT OF GENERAL PRACTICE.

SIR,—Medical practice, especially general practice, is the subject of a good deal of discussion at the present time, much of it prejudiced and ill informed, but all of it, well informed or ill informed, demanding careful consideration by the medical profession, if it desires to control its own development instead of having this arranged for it by politicians and other more or less well meaning people. Two questions are now in the forefront of all these discussions: the Hospital Saving Association's scheme, and the panel system of National Health Insurance.

The latter question—that is, its retention, with or without modification, or its abolition—is of the two certainly the more widely and hotly discussed by the public. The panel doctor is being held up to much, I believe undeserved, opprobrium, not altogether regretted by the non-panel practitioner, who assumes that he would do better for the other man's patients. The other question is receiving attention from a number of general practitioners, who consider that it will lead to the hospitals encroaching still further on

the field of the family's doctor work, an encroachment which they consider will not be to the advantage of doctor, patient, or the community.

If the family doctor could employ for all his patients the methods of diagnosis, and, above all, the methods of treatment, which are employed in a hospital, his contention that any encroachment of the hospital on his present sphere of work would be bad for the patient and the community would hardly need arguing; even under present conditions there is much to be said for the contention that the good family doctor, the member of that largest section of the profession on which devolves the main work of maintaining the health of the community, is the one from whom in the majority of cases the patient will obtain the greatest benefit. But if the general practitioner with his more intimate knowledge of the life and surroundings of his patients possesses in this respect a great advantage over the hospital doctor, yet in the matters of diagnosis and treatment he is placed at a great disadvantage. It is, no doubt, in great measure because he recognizes these hospital advantages that the patient seeks hospital treatment and not only because by resorting to a hospital he will save his pocket. Again, it is because he lacks these advantages and not from laxity in his work that the panel doctor is unable to deal with the ailments of many of his patients satisfactorily, and the non-panel doctor is in no better position.

I have been saying and writing this for the past three years, but now I learn that Mr. Waring, vice-chancellor of London University, has been saying much the same thing, only his cure for this state of affairs—namely, extension of hospital accommodation—differs fundamentally from mine. I would suggest the development of centres on the lines of the primary centres of Lord Dawson's much discussed scheme. The Kensington (B.R.C.S.) centre for physical treatment demonstrates the lines on which such institutions might be run without interfering with general practice, but modifications associating the general practitioner more closely with the work are required. To a great extent these centres would ultimately be self-supporting, but, if not, is it not foolish not to endow the work of the general practitioner in the same way as is the work of the hospital physician or surgeon?

Sir Thomas Horder, demonstrating the work of one of the new consultants' clinics, expressed his belief in "the urgent desirability of great and even drastic changes in medical practice." Again, I agree, but here also my remedy is different. The future of medicine, as experienced by the general public, must lie in the work of the general practitioners. Are they never going to take their proper place in the direction of medical progress? Are they always going to content themselves with destructive criticism of schemes developed by other sections of the profession? Let them but develop the spirit of co-operation and all other things shall be added unto them.—I am, etc.,

Kensington, June 10th.

HAROLD H. SANGUINETTI.

## Obituary.

### J. DELPRATT HARRIS, M.D.,

Consulting Surgeon, Royal Devon and Exeter Hospital.

MR. DELPRATT HARRIS of Exeter died on May 30th, aged 73. He belonged to an Exeter family which had long been associated with the Royal Devon and Exeter Hospital, his grandfather, Mr. John Harris, F.R.C.S., having been appointed surgeon to the institution in 1815.

John Delpratt Harris received his medical education at St. Bartholomew's Hospital; he took the diplomas of L.S.A. in 1871, and M.R.C.S.Eng. in 1872, and graduated M.D.Durh. in 1903. On the death of Mr. C. H. Roper in 1881 he became surgeon to the Royal Devon and Exeter Hospital, and in 1904 was appointed to organize and take charge of the new electrical department installed through the munificence of Mrs. Sanders of Stoke Hill. On retiring under the age limit in 1915 he was appointed consulting surgeon. In 1889 he presented the hospital with a portrait in oils of his grandfather, which now hangs in the board room. He also presented the institution with £100 for

investment in order to provide a sum to assist the orthopaedic department to supply appliances to patients on their discharge. The gift was a thank-offering for thirty-four years' health and strenuous work, and in memory of his family's long connexion with the hospital, but more especially as a memorial to his son, who, after having passed all his medical examinations, died in 1915 from meningitis whilst holding an appointment at a hospital in London; his death was a very heavy blow both to Mr. and Mrs. Harris. Mr. Harris enjoyed a large private practice, and during the war provided electrical treatment for wounded soldiers at his residence in Southernhay.

After his retirement from the active work of the Royal Devon and Exeter Hospital, Mr. Delpratt Harris wrote a comprehensive history of the institution; this was reviewed in our issue of May 27th, 1922 (p. 841). He was president of the South-Western Branch of the British Medical Association in 1903, and subsequently became a vice-president. He was also president of the Section of Electro-therapeutics of the Annual Meeting of the Association held at Exeter in 1907. Mr. Harris took great interest in local affairs, and was appointed a sheriff in 1897; for many years he was a justice of the peace. A man of much culture, he was an interesting companion, being well informed on many subjects. He was interested in astronomy, having inherited from his father a well equipped observatory; he also took great interest in music, and was a talented amateur violinist.

### GEORGE FREDERICK MURRELL, M.B.LOND.,

Physician, Royal Berkshire Hospital, Reading.

THE death of Dr. G. F. Murrell, at the age of 55, after a brief illness has cast a gloom over the whole of Reading. A few weeks ago he suffered from a carbuncle under the arm, from which he apparently recovered, and after a short change in the country resumed his work. It was obvious, however, that he was not well, and no doubt his resisting power had been severely diminished. At the end of May he developed cellulitis of the scalp, which proved to be of streptococcal nature, and spread rapidly, the end coming on June 5th with virulent bronchopneumonia and thrombosis of the cavernous sinus.

He was born at Ealing, and received his early education at University College School; afterwards he entered as a medical student at St. Bartholomew's Hospital. He took the diplomas of M.R.C.S., L.R.C.P., in 1890, and graduated M.B. of London in 1893. He subsequently held the posts of house-surgeon at St. Bartholomew's Hospital and house-surgeon and house-physician at the West London Hospital. After serving as ship's surgeon on two occasions, he settled in Reading in private practice in 1896. From the commencement of his career it was obvious that Dr. Murrell was imbued with the highest ideals of the profession, and it is not surprising that he not only made his practice a success, but also gained the respect of his colleagues, and the confidence and affection of his many patients.

In February, 1913, he was elected assistant physician to the Royal Berkshire Hospital, and had been physician since 1919. During the war, as captain in the R.A.M.C.T., he served first in Oxford, and afterwards as officer in charge of a large Section Hospital in Reading. He was a member of the Reading Division of the British Medical Association.

Outside his profession Dr. Murrell interested himself in many social activities, was Warden of his Church, a Past Master of his Masonic Lodge, and as a keen Conservative assisted in numerous elections that took place in the borough.

The news of his death came as a great shock to his numerous patients and friends, to whom he had endeared himself by the charm and beauty of his character, his intense sympathy with those in sorrow or in pain, and by those sterling qualities which are well described as typical of the "Beloved Physician."

A memorial service was attended by very many of his medical colleagues and a vast number of his patients and fellow citizens on June 8th; he was laid to rest at Chideock with every manifestation of sorrow on June 9th. He leaves a widow, two daughters, and a son to mourn their loss.

## Universities and Colleges.

### UNIVERSITY OF OXFORD.

THE following candidates have been approved at the examinations indicated:

D.P.H.—Part I: W. H. Butcher, W. Champneys, M. J. Saldanha.  
Part II: W. Champneys, Mary P. Wilson.

### UNIVERSITY OF CAMBRIDGE.

At the special congregation held on June 12th Dr. William Henry Welch, Director of the School of Hygiene and Public Health of Johns Hopkins University, and President of the Board of Scientific Directors of the Rockefeller Institute for Medical Research, received the degree of LL.D., *honoris causa*. In his Latin speech of presentation Dr. T. R. Glover, the Public Orator, described Dr. Welch as having dedicated the whole of his life to medicine, working to search out the secrets of Nature and to combat disease before it made its appearance; he was the high priest in the temple dedicated by Rockefeller to the goddess Hygieia Propugnatrix.

At a congregation held on June 8th the following medical degrees were conferred:

M.D.—S. L. Bhatia.  
M.B., B.Ch.—G. Haggood.

### ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.

THE following have, after examination, been admitted as Fellows of the Faculty: Robert Alexander Anderson, George Dalziel, M.C., Leander Iowrie Fife, George William Hill, James Hogg Martin, and Sundar Das Soudhi.

### ROYAL COLLEGE OF PHYSICIANS OF IRELAND.

THE following, having passed the necessary examination, have been duly admitted Members of the College: Jamna Vinayak Dhuraudhar and Francis Joseph O'Donneil.

## The Services.

### ROYAL COMMISSION ON INDIAN SERVICES.

THE promised Royal Commission on the Superior Civil Services in India has been appointed, with Viscount Lee of Fareham as chairman. The other members are Sir R. H. Craddock, late Lieutenant Governor of Burma; Sir Cyril Jackson; Sir Chimanlal Harilal Setalvad, barrister, vice-chancellor of Bombay University; Sir Muhammad Habibullah, a member of the council of the Governor of Madras, who has in various ways shown his interest in Mohammedan educational movements; Pandit Hari Kishan Kaul, commissioner of the Jullundur Division, Punjab; Mr. David Petrie, Indian Imperial Police Service; Mr. Bhupendra Nath Basu, vice-chancellor of the Calcutta University and a member of the Council of the Secretary of State for India; and Mr. Reginald Comland, Beit professor of colonial history, Oxford. The reference to the Commission is as follows:

1. The organization and general conditions of service, financial and otherwise, of the Superior Civil Services in India.

2. The possibility of transferring immediately or gradually any of their present duties and functions to services constituted on a provincial basis.

3. The recruitment of Europeans and Indians respectively for which provision should be made under the constitution established by the said Act and the best methods of ensuring and maintaining such recruitment, and to make recommendations.

Communications should be addressed to the Secretary to the Royal Commission, India Office.

## Medical News.

THE annual general meeting of the Research Defence Society will be held at the house of the Medical Society of London, 11, Chandos Street, Cavendish Square, on Wednesday next, June 20th, at 3.30 p.m. The chair will be taken by Lord Lamington, and Dr. C. W. Saleeby will give an address on sunlight and disease. The annual report draws attention to the efforts, dating from 1909, of the opponents of scientific medicine to prejudice the minds of members of the Labour party by spreading falsehoods and fostering distrust of the medical profession. The society is prepared to assist in meeting such allegations on the spot and has a considerable collection of lantern slides suitable for illustrating lectures.

The Prince of Wales will visit the country branch of the Royal National Orthopaedic Hospital, Brockley Hill, Stanmore, Middlesex, on the afternoon of Saturday, June 23rd, when he will lay the foundation stone of the nurses' home and formally open the new hut.

SIR ROBERT PHILIP, Professor of Tuberculosis in the University of Edinburgh, will be the speaker at the annual meeting of the Paddington Tuberculosis Dispensary at 8.30 p.m. on Monday, June 25th.

By the death of Princess Christian, aunt of the King, the hospitals and the nursing profession have lost a good friend. It is said that as a girl Princess Christian was anxious to take a full course of training at a London hospital, and she always showed a great interest in nursing and in public health activities. She was long president of the Royal British Nurses Association; she was one of the founders of the training college for children's nurses at Manchester, which bears her name; she took up and helped forward schemes for improving workhouse infirmaries and for providing nurses for the sick poor; and at the time of her death she was president of the National Health Society, in the work of which she was deeply interested.

THE annual dinner of the Indian Medical Service will be held at the Trocadero on Wednesday, June 20th. Tickets and all particulars may be obtained from the joint honorary secretary, Colonel J. J. Pratt, I.M.S.(ret.), 63, Addison Road, Kensington, W.14.

OWING to the necessity of carrying out extensive repairs and alterations, Westminster Hospital will be closed for in-patients from July 2nd next for about six months. Out-patients will be treated at Westminster Hospital Medical School, 12, Caxton Street, but no casualty cases will be dealt with. There is no record of the doors of this historic institution having been shut in the whole period of over 200 years since it was founded. Substantial improvements will be made in the wards and in the out-patient department, an additional operating theatre will be built; the x-ray, massage, and other departments will be brought up to date, and better accommodation for the nurses will be provided in a home outside the hospital. The cost will be about £45,000, for which a special appeal will shortly be made.

RECENTLY conferences of the Presidents of the various Sections of the Royal Society of Medicine have been held to consider whether the Sections might work together without interfering with their entire freedom of action, and as the first result of these conferences it has been decided during next session (1923-24) that the following discussions should be arranged upon dates to be settled later and announced on the diary cards: By the whole society—(1) the possible substitutes for cocaine, (2) the grading of the population from the point of view of bodily fitness, (3) chronic abdominal pain in nervous women. By the sections concerned—(1) the treatment of severe gastric and duodenal haemorrhage, (2) birth injuries, (3) the uses and limits of vaccine therapy, (4) vertigo, (5) the surgical treatment of pulmonary tuberculosis, (6) post-operative and puerperal mental disorders.

At the meeting of the board of management of the King Edward VII Hospital, Cardiff, on June 7th, it was announced that Royal assent had been given to change the name of the institution, which will in future be known as the Cardiff Royal Infirmary.

DR. T. H. C. STEVENSON, C.B.E., of the General Register Office, will read a paper on the social distribution of causes of death in England and Wales, at a meeting of the Society of Biometricians and Mathematical Statisticians to be held in the theatre of the Galton Laboratory, University College, Gower Street, on June 25th, at 8 p.m. Visitors will be welcomed.

DR. F. M. ROWLAND, C.B.E., of Lichfield, vice-chairman of the Walsall and Lichfield Division of the British Medical Association, has been made a justice of the peace for the city of Lichfield.

THE Glasgow Post-Graduate Medical Association has arranged post-graduate courses in the various hospitals of Glasgow during the summer months. Full particulars can be obtained on application to the Secretary, Post-Graduate Medical Association, the University, Glasgow.

THE annual general meeting of the Medico-Legal Society will be held at 11, Chandos Street, W.1, on Tuesday, June 19th, at 8.30 p.m., and will be followed by an ordinary meeting, when Dr. A. S. Woodward will read a paper on some attempts to defraud life assurance companies.

THE Mayor and Corporation of Harrogate will, on Saturday, June 30th, entertain a party of guests who will have travelled to Harrogate by the new pullman car train which the London and North-Eastern Railway Company and the Pullman Car Company have arranged to run in future between London and Leeds and Harrogate.

AT the annual meeting of the Nottingham Children's Hospital on June 6th Mr. J. D. Player announced that plans had been prepared, according to the suggestions made by Dr. Mackintosh, for the erection of an entirely new wing which would when completed afford accommodation for 68 beds, or double the number at present available. He also stated that he and his wife had handed to the trustee a sum which it was thought would be sufficient to cover the cost of building and equipping the new wing.

At the last meeting of the Oldham Board of Guardians the resignation was accepted, with regret, of Dr. Frank Radcliffe, visiting surgeon to the Boundary Park Hospital. Dr. Radcliffe, who is a member of the Council of the British Medical Association and a member of the Insurance Acts Committee, has held the post of visiting surgeon for over eleven years. The Chairman said that by Dr. Radcliffe's retirement the board and the patients in the hospital were losing the services of one who had served the public well and faithfully. It was resolved that a record of the board's appreciation should be made in the minutes.

A SERIES of free lectures to nurses on venereal diseases, by Mr. Leonard Myer, honorary surgeon to out-patients at St. Paul's Hospital for Skin and Genito-Urinary (Including Venereal) Diseases, were commenced at the hospital, Endell Street, Holborn, W.C.2, on June 8th, and will be continued on Fridays, June 15th, 22nd, and 29th, at 5 p.m.

The following promotions in the Order of the Hospital of St. John of Jerusalem in England have been announced:—As Knights of Grace: Major Arthur H. Johnston, O.B.E. (from Esquire), Dr. George H. R. Holden (from honorary Associate), Dr. Harry George Waters (from honorary Associate); as Esquires: Captain James Anderson, M.D. (from honorary Associate), Major Cecil Henry Elmes, C.B.E., V.D., M.B. (from honorary Associate).

DR. WILLIAM MACKIE, medical officer of health for Elgin, was entertained at dinner on June 1st to signalize the honorary degree of LL.D. recently conferred upon him by the University of Aberdeen in recognition of his eminent work. During the proceedings Dr. Mackie was presented with a silver salver of Chippendale pattern and Mrs. Mackie received a diamond ring.

THE annual general meeting of the Lebanon Mental Hospital, Asfuriyeh, near Beyrout, Syria, will be held at 11, Chandos Street, W.1, on Tuesday, June 19th. The chair will be taken by Dr. E. W. G. Masterman at 3.30 p.m. The director of the hospital, Dr. H. Watson-Smith, O.B.E., will be present to give information and Bishop Bury has promised to speak.

THE Medico-Legal Institute, which was inaugurated in the Place Mazas, Paris, on May 24th by M. Strauss, the Minister of Hygiene, combines in the same building the Morgue, the laboratory of legal medicine of the Faculty, and the laboratory of toxicology of the Prefecture of Police. The old Morgue behind Notre-Dame has now ceased to exist.

## Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Aitiology, Westminster, London*; telephone, 2630, Gerrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate, Westminster, London*; telephone, 2630, Gerrard.
3. MEDICAL SECRETARY, *Mediscera, Westminster, London*; telephone, 2630, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus, Dublin*; telephone, 4737, Dublin), and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: *Associate, Edinburgh*; telephone, 4361, Central).

### QUERIES AND ANSWERS.

#### INCOME.

"A. B. UGANDA" inquires as to the liability of a British subject residing abroad in respect of (a) interest on French Government stock, and (b) dividends on British railways.

\*. (a) He is not liable to tax in respect of this (non-British) income, and can claim repayment of any tax that may have been deducted. (b) He is entitled to claim in respect of the usual allowances, but only on a proportional basis; for example, suppose he has £750 from Uganda, £250 from France, and £250 from this country, then he is entitled to claim repayment in

respect of 250/1250 of the usual allowances. The income tax statutes do not now allow the British income in such a case as this to be treated as if it were the sole income of the claimant.

### LETTERS, NOTES, ETC.

#### AUTOGENOUS VACCINE IN PUERPERAL FEVER.

DR. JOHN VEITCH (Cowdenbeath) writes: In a note on the curative use of autogenous vaccines in puerperal fever (October 7th, 1922, p. 644) I remarked on the futility of stock serums and stock vaccines. Recently I encountered another case of puerperal fever, and I ordered an autogenous vaccine to be prepared. Unfortunately the patient died before the vaccine was ready, so I laid it aside. Some time later I encountered two cases of puerperal fever. I examined the discharge in both and found streptococci. Further, from the cachectic appearance of both patients I concluded that haemolytic streptococci were causing grave damage. I immediately made use of the vaccine I had in hand, which contained a great number of streptococci. The results were excellent in both cases. This indicates the possibility of almost instantaneous specialized treatment in puerperal cases. I took the precaution of having an autogenous vaccine made from one of the cases to be in readiness for future use.

#### CARDIAC DILATATION AND HYPERTROPHY.

DR. ERNEST KINGSOTE (London, W.) writes: I was very much interested in Dr. Claude Wilson's able article entitled "Limitation of effort in heart disease" in your issue of June 9th, p. 962, and was glad to see that he emphasized enlargement as a definite sign of heart trouble. Two points, however, strike one: (1) Where he states "It is often impossible to distinguish between dilatation and hypertrophy," and (2) "all the means at our disposal for estimating the size of the heart are open to fallacy. Percussion is perhaps the least reliable." To these I would briefly reply: (1) The dilated heart can be reduced in size, then and there, by a few resisted movements, whereas, of course, the hypertrophic heart cannot be so reduced; and (2) my pleximeter, described in *The Lancet*, 1896, claims to be an instrument of precision, wherewith a deep-seated organ, even when overlaid by an air-containing viscus, may be percussed out to the fraction of an inch. The pleximeter may be obtained from Messrs. Down Bros., surgical instrument makers, Thomas Street, Borough.

#### CHRONIC TRAUMATISM OF SOFT TISSUES.

DR. CHARLES J. HILL AITKEN (Kilnhurst, near Rotherham) writes: A year ago a middle-aged man showed me an ulcer on the outside of the terminal phalanx of his right ring finger. He had noticed it for some weeks and he was worried as a near relative had died of cancer. Under a simple dressing, kept on continuously, the ulcer healed in a few days. A month later the ulcer reappeared. I was puzzled until I noticed his fingers were peculiar in that they were short and curved inwards, the right little finger especially, so that when his fingers were in apposition the nail of this finger touched the outer side of the ring finger exactly where the ulcer was. With a simple dressing and attention to keeping the nail cut the ulcer vanished and has not recurred.

A man complained of redness and scurfiness on the upper edge of his ears. This had worried him for a month or two. A friend of his had developed cancer of the ear. I thought of trauma but did not discover what it was till the patient put on his spectacles, remarking, "I find them a nuisance as I am always taking them on and off." (He was presbyopic.) The legs were of steel, rather hard, slightly rusted, and the curl ends were a tight fit. I recommended a pair of rolled-gold spectacles and of a larger size. Very soon the redness and scurfiness passed away and have not returned. The ointment I gave him was never used—"Too messy and I always forgot."

#### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 29, 30, 31, 34, 35, and 36 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 32 and 33.

A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 267.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, W.C.2, not later than the first post on Tuesday morning, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive *poste restants* letters addressed either in initials or numbers.

# A British Medical Association Lecture ON THE CAUSE AND TREATMENT OF DYSPNOEA IN CARDIO-VASCULAR DISEASE.\*

(Abridged.)

BY

JONATHAN MEAKINS, M.D., F.R.C.P.E.,  
CHRISTISON PROFESSOR OF THERAPEUTICS, UNIVERSITY OF EDINBURGH;  
PHYSICIAN, ROYAL INFIRMARY, EDINBURGH.

DYSPNOEA is an extremely common symptom in cardio-vascular disease; it is, in fact, so common that it is almost held to be pathognomonic of some cardiac disturbance.

## NATURE AND CAUSES OF DYSPNOEA.

What is dyspnoea? The following short definition may be given: Dyspnoea is the consciousness of the necessity for increased respiratory effort.

How is dyspnoea produced? If we confine this question to the diseases under consideration we may say that it is usually produced by two causes: (1) want of oxygen; (2) carbon dioxide retention, relative or absolute. Either of these or both must occur in the cells, which represent the functioning units of the body. The types of dyspnoea produced by these two factors are somewhat different, and in order to explain the differences it is best to take them up separately. If either condition be produced suddenly the symptoms will be much more violent than if the process were an insidious one.

In oxygen want there is always the question of the quantity or partial pressure of carbon dioxide present in the blood and also in the cells. If the oxygen want is acute, there remains a certain amount of carbon dioxide which has to be got rid of, as oxygen want makes the respiratory centre more irritable than normally to a given partial pressure of carbon dioxide. This has an important practical application. In mines where there is a rapidly increasing amount of black-damp, the presence of a sufficient amount of carbon dioxide gives the miner warning, as it produces panting and respiratory distress. In slowly increasing black-damp without carbon dioxide he gets rid of the carbon dioxide in his body by moderate over-ventilation and may lose consciousness without any appreciable distress.

The uncomplicated effect on respiration of increased carbon dioxide is best shown in acidosis, such as may occur in advanced cases of diabetes mellitus. In such cases, although the carbon dioxide be not increased, the hydrogen-ion concentration of the blood is increased, and it is by acting in a similar manner that carbon dioxide influences respiration. If the oxygen saturation of the blood be decreased and the carbon dioxide increased respiratory failure is apt to occur very quickly. This is really asphyxia, as is found in acute obstruction of the larynx. In such circumstances there is the typical deep purple cyanosis of suffocation.

## Dyspnoea in Cardio-vascular Disease.

Dyspnoea in cardio-vascular disease may be produced in two ways. One may be called the pulmonary method, and the other the circulatory method. In the pulmonary method anything that interferes with the proper aeration of the blood as it passes through the lungs may produce it. If the lungs remain normal, there being no oedema, congestion, nor gross exudate into the pleural cavity, the arterial blood will contain a normal quantity of oxygen. There is no decline of oxygen saturation of the blood as it passes to the systemic arterioles. We have been able to show this quite conclusively by examining the arterial blood of many cases of auricular fibrillation, valvular disease, and myocardial degeneration with and without pulmonary complications. If oedema of the lungs should develop there will occur a decrease in the oxygen saturation of the arterial blood. This may usually be inferred from the physical signs

in the lungs and the degree of cyanosis. If oxygen be given under these conditions the saturation of the arterial blood will as a rule rapidly return to normal. Even at rest certain of these patients have violent dyspnoea, orthopnoea, and Cheyne-Stokes breathing. As soon as oxygen is given the symptoms disappear and the patients become quite comfortable. At the same time there is no immediate change in the character of the physical signs in the lungs. This would indicate that by increasing the partial pressure of oxygen in the alveolar air from 100 to 280 mm. the diffusion of oxygen through the swollen alveolar cells and the alveolar exudate is greatly increased. Such an increase would naturally be expected. For this reason the blood has less difficulty in becoming adequately saturated with oxygen. In auricular fibrillation we found no accompanying reduction in the pulse rate to account for this improvement. Certain cases had very pronounced cyanosis with delirium, but on inspiring air with a high partial pressure of oxygen the cyanosis and delirium disappeared and the oxygen saturation of the arterial blood returned to normal.

These are cases of what one might call the pulmonary type of dyspnoea and cyanosis in cardiac disease. It is the dyspnoea which occurs when there are numerous crepitations and perhaps *sonorous râles in the lungs*. These signs are due to swelling of the epithelium of the bronchioles and alveoli and exudate into the alveolar spaces—conditions which interfere with the respiratory function. On the other hand, there may be a moderate hydrothorax compressing part of one lung through which the blood is still circulating. If that be the case the compressed lung will not aerate, the blood returning would merely pollute the fully aerated blood from the rest of the lungs. It is only in cardiac cases with indications of such pulmonary lesions that the administration of oxygen will relieve the dyspnoea, cyanosis, and other pulmonary symptoms.

On the other hand, there is another factor which must not be overlooked. This is the influence of vascular engorgement on the respiratory movement and pulmonary ventilation. This point I will defer until I take up the question of the circulation as a whole.

## Effect on Cells.

We now come to consider how interference with the general circulation affects the cells of the various organs, because it is the cell, as it occurs in its aggregate to form the organic units or functioning organs, that gives rise to pathological symptoms or signals of distress. As is well known, interference in the local circulation, such as results from occlusion of an artery, may produce death of the distal portion. This is really local asphyxia. Such vascular interference may be partial or complete, and thus the consequences may vary in degree—as, for instance, hemiplegia or mental degeneration, gangrene of the toes or "intermittent claudication," rupture of the heart or angina pectoris. On the one hand the myocardium and the brain may continue to function normally until renal degeneration due to arteriosclerosis leads to a general breakdown. You may, on the other hand, have stenosis or obliteration of a coronary artery. If a sufficient quantity of the myocardium is asphyxiated then the myocardial symptoms may predominate. In other circumstances symptoms due to cerebral degeneration may play the principal part. If, however, the arteries are fairly healthy, but some valvular or myocardial lesion interferes with the general circulatory efficiency, then widespread symptoms may develop. In so far as such lesions reduce or limit the amount of blood circulated per minute in relation to the amount of work attempted, so symptoms occur. In the average individual at rest the blood flow per minute through the heart varies between 5 and 8 litres according to sex and development. An increased circulation is usually accomplished by an increase of the cardiac rate, but in some instances this is also brought about by an increased output per beat. The systole is more complete. Therefore not only is the rate to be taken into consideration but also the completeness of the systolic contraction. Barcroft and others have reported a case of acute paroxysmal tachycardia where the cardiac rate increased to 135. The minute blood flow was one-half what it was under normal conditions, and the output per beat decreased from 76 c.cm. to between 16 and 13 c.cm.

\* Delivered before the Dundee Branch of the British Medical Association, March 14th, 1923.

In cases of auricular fibrillation and flutter a similar sequence of events occurs, although the decrease in the blood flow per minute is not as a rule so pronounced. Usually when the ventricular rate is increased above 100 there is a distinct decrease in the output per beat. This, of course, becomes much more apparent as the rate increases.

In mitral stenosis without evidence of myocardial disease, such as great cardiac enlargement, there is a very pronounced decrease in the output per minute and also on each systolic contraction. This decrease is particularly obvious when the individual attempts to do work. Tachycardia very rapidly supervenes and the blood flow may increase from 2 litres to as much as 5 litres per minute. This as a rule makes it necessary that the pulse rate shall increase two and a half times—that is from 70 to 180. The output per beat has never yet been found to be increased in this condition. Such a limitation of cardiac output necessarily limits the amount of exertion possible; in fact, in certain cases merely walking slowly about the room produces severe symptoms.

It might be supposed that in patients with greatly enlarged heart, but without any evidence of valvular disease, as well as hypertrophy of the wall, the capacity of the ventricular cavity would be greatly enlarged. If such a heart were completely emptying itself at each systole the amount of blood circulated per minute would be much above normal. It is found, however, that this is not the case, the output per minute being approximately normal if there are no symptoms at rest. On exercise, however, the symptoms may become extreme, while the cardiac output per minute is but slightly increased, although the cardiac rate may be greatly increased. When cardiac failure occurs there is a sharp decline in the output per minute as well as in the output per beat. The obvious conclusion is that the ventricular systole in these circumstances is not complete. Instead of the ventricle expelling 100 c.cm. per systolic contraction, as is found to occur frequently in these cases of enlarged heart, the output per beat may be only 15 to 25 c.cm. This occurs in spite of the fact that physical examination may give evidence of the cardiac dullness being increased. This is probably what occurs in acute and chronic cardiac failure. In such circumstances the ventricle on each contraction does not completely empty itself, and there is consequently a residue of blood left in the ventricle at the beginning of the diastole. This corresponds to the difference in the capacity of the ventricular cavity and the amount expelled at each systole. As the amount of this residue increases, so the symptoms of cardiac failure become more pronounced.

This decrease of circulation rate, whether due to pathological tachycardia, mitral stenosis, or myocardial inefficiency, is probably one of the most important factors in the production of symptoms in cardiac disease, but the question naturally arises as to how a decrease of blood flow would produce symptoms. There are many other symptoms besides dyspnoea—fatigue, exhaustion, vertigo, cyanosis, vomiting, loss of consciousness, etc. All these symptoms may be produced by a deficiency of oxygen and an increase of carbon dioxide in the cells. It is well known that the rapid circulation of blood through a part keeps up the partial pressure of oxygen and diminishes that of carbon dioxide. If, on the contrary, the blood flow becomes slow, the partial pressure of oxygen diminishes and that of carbon dioxide increases. This brings about in the cell a condition of cellular asphyxia and acidosis. In such circumstances there occurs a swelling of the cell, and fluid, chlorides, bicarbonates, and other salts, pass from the blood into the surrounding tissues and tissue spaces. The blood coming from the part becomes more concentrated and acid. This, we believe, is a most important contributing factor in the production of oedema and other symptoms in cardiac cases.

Such a condition occurring in the cells would affect the respiratory centre as well as other portions of the body. The severity of the symptoms will be influenced not only by the degree of slowing of the circulation but, as has already been pointed out, by the suddenness of the disturbance. If the organism be given time to accommodate itself to the new conditions, or if the new conditions develop slowly, it will be found that the skeletal blood flow is very much reduced. This is brought about in order that the blood supply to the nervous system, suprarenals, heart, liver, and other vital

organs, may be sufficient. If the general blood flow is still further reduced symptoms will then develop even when the body is at physical rest. If exertion be undertaken the muscles as functioning organs will require an increased blood supply which can only be provided at the cost of the blood supply to the viscera. Therefore symptoms will appear even though they were not present during the resting state. Consequently it can be seen that the symptoms in cardio-vascular disease are merely an index of the ratio between the blood flow and the amount of work done at the moment. The severity of the symptoms in relation to the work done bears a direct ratio to the inadequacy of the general circulation. From the severity of the symptoms and the appearance of the patient one can obtain a much better working index of the severity of the lesion than from the physical signs.

#### *Late Symptoms of Cardiac Failure.*

As cardiac failure progresses symptoms appear even at rest. There may be constant cyanosis, orthopnoea, and varying degrees of Cheyne-Stokes breathing. It has been demonstrated by Haldane, Meakins, and Priestley that the recumbent position is more apt to lead to irregular respiration than is the upright one. Further, that any interference with the pulmonary expansion or ventilation aggravates this respiratory irregularity. This may be caused by anything which interferes with the action of the diaphragm, such as hydrothorax and ascites. In addition there is the important factor of pulmonary engorgement. The lung has somewhat the character of an erectile tissue, and with engorgement or exudate into its spaces its elasticity is very much diminished. That such limitation of expansion, and therefore of ventilation, occurs in cardiac cases is very well known and can be demonstrated by the great decrease in the vital capacity of the lungs. There is no disease where this is diminished to such an extent as in cardiac failure.

Therefore when the cells of the body, and with them those of the respiratory centre, are suffering from a more or less severe asphyxia due to diminished circulation, one of the natural responses is by an increased pulmonary ventilation. This can best be accomplished by the patient assuming the upright position. With this increased capacity for breathing, over-ventilation occurs and the amount of carbon dioxide removed is greater than the oxygen taken in. A period of apnoea, therefore, will ensue, which in its turn is followed by a period of hyperpnoea, and thus more or less pronounced periodic or Cheyne-Stokes breathing is produced.

#### *Dyspnoea in Arterial Disease.*

In cases of arterial disease without evidence of a primary cardiac lesion, dyspnoea, orthopnoea, and Cheyne-Stokes breathing may frequently occur. In these cases the interference with the blood flow results from arterio-sclerosis with diminution in the number of arterioles as well as a decrease in the lumen in the larger vessels. As a result increased blood pressure usually ensues. This in time may show a secondary decline due to myocardial failure, and consequently the local blood supply is decreased. There is cellular asphyxia, which in turn stimulates a temporary increase of the blood pressure and therefore of the local blood flow. This for the moment supplies the cells with the necessary quantity of oxygen, but the hyperpnoea resulting from the cellular asphyxia produces an increased elimination of carbon dioxide, and as a consequence a condition of acapnia is produced leading to a period of apnoea. In this manner periodic breathing is perpetuated. The acute attacks of dyspnoea and the violent periods of hyperpnoea in this type of periodic breathing are probably the symptoms which occur in so-called cardiac asthma.

#### *TREATMENT OF CARDIO-VASCULAR DYSPNOEA.*

In regard to treatment, it is necessary to have a clear understanding of the underlying conditions producing dyspnoea in order that the symptoms may be relieved. As they are fundamentally due to lack of oxygen in the cell it would be naturally assumed that they can be relieved by supplying oxygen. In cases where this lack is due to an exudate into the alveoli or swelling of the alveolar membrane epithelium, and in those cases where engorgement of the pulmonary tissues prevents adequate expansion, increase of the partial pressure of oxygen in the alveolar air by enriching

the inspired air with oxygen usually, if not always, gives relief. On the other hand, when the symptoms are due primarily to a slowing of the whole circulation or a circulatory deficiency due to a local vascular lesion, the administration of oxygen may have little or no effect. The reasons for this would seem to be self-evident. In certain cases, however, the administration of oxygen may give relief when not expected to do so; on the contrary, its failure to be efficacious is sometimes experienced when a good result would be most expected. A more thorough examination of these cases usually indicates that a combination of these causes is operative. To what extent either factor predominates may, however, be difficult to ascertain.

If the partial pressure of oxygen in the alveoli is to be increased the inspired air must be enriched with oxygen by the time it enters the nasopharynx. This necessitates the administration of a sufficient quantity of oxygen a minute by some apparatus which will ensure its being inhaled. The placing of a funnel one inch from the patient's face will not accomplish this. In our experience only two methods are efficacious—by the use of a fairly tight-fitting mask, or by introducing a rubber catheter through the nose into the nasopharynx. Through this catheter there is passed an adequate supply of oxygen. The supply is frequently regulated by, in lieu of some better method, bubbling the gas through a Wolff bottle or other similar contrivance. In order that a sufficient quantity shall be administered it must enter the bottle through a tube of at least 1 cm. bore, and the bubbles must be so rapid as not to be countable.

The use of oxygen, of course, does not remove the necessity for adopting all other means of treating cardiac failure, and by no means the least important of these is physical and mental rest. It is remarkable how patients do improve by good nursing and general comfort. It would appear that the reason for this is the conservation of circulatory energy for those vital organs which of necessity require a good blood supply.

The employment of drugs which increase the cardiac power is not to be ignored. Of these there is, to my mind, only one which is of value, and that is digitalis. The indications for its use and the method of its administration must be left for consideration at another time.

Many of the observations upon which these conclusions have been based were undertaken in the Department of Therapeutics, Edinburgh University, in collaboration with Drs. Davies, Dutrebande, and Fetter.

## THE EFFECT OF HEAT UPON OPERATIONS FOR EXOPHTHALMIC GOITRE.

BY

A. J. WALTON, M.S., F.R.C.S., M.B., B.Sc.,  
LONDON HOSPITAL.

THAT the results of operative treatment in many cases of exophthalmic goitre are satisfactory is now generally admitted. Until some fifteen or twenty years ago the danger of such an operation was, however, so great that few physicians felt justified in advising it. To-day the results have been so enormously improved that the mortality is no higher than that of other major operations. At the discussion of the Royal Society of Medicine in 1921,<sup>6</sup> and again at the meeting of the British Medical Association in Glasgow, it was generally agreed that the mortality was somewhere in the region of 5 per cent. In the hands of individual surgeons it has often been lessened considerably below this. Romanis<sup>7</sup> was able to show a mortality of only 2.4 per cent. in a series of 250 cases, and the latest statistics from the Mayo Institute published by Pemberton<sup>4</sup> record a series of 1,093 operations with 11 deaths—that is, a mortality of 1 per cent. All who have operated on large numbers of these cases feel, however, that in spite of their care and attention to detail there is an element of uncertainty in the result which is absent in other cases. My own experience has been that although these cases can be divided into definite groups, one of which has a higher death rate than the others, yet now and again a death will occur when least expected. This feeling of uncertainty and anxiety has been expressed also by Berry,<sup>2</sup> Dunhill,<sup>3</sup> and

Romanis,<sup>5</sup> and all are agreed that there is some factor which is at present not fully understood.

If the causes of danger in the operation be analysed, it is possible to appreciate not only what are the means by which so much improvement in the operative results has been obtained, but also which is the factor at present uncertain and to which attention must be given in future. Pemberton<sup>4</sup> has well analysed these dangers. He classifies them into the three following groups:

1. Those directly resulting from the disease and the effects of the disease.
2. Those directly due to accidents such as haemorrhage, pulmonary embolism, etc.
3. Those the joint result of disease and accident.

Careful attention to the technique of operation, to the limitation of haemorrhage, to careful handling of the gland, etc., have done very much to lessen the dangers of groups 2 and 3; so that the risks arising therefrom are in no way specially applicable to operations of exophthalmic goitre. In the first group the dangers are twofold. If the hyperthyroidism has been present for a long period, secondary changes will have taken place in the heart and kidneys, and the patient will stand any operative measures badly. In the future it is probable that risks of this nature will be almost negligible, for the condition will not be allowed to progress too far before operation is undertaken. At present, however, but little can be done to reduce the mortality. The secondary conditions can be readily recognized, but the operation must be undertaken in spite of them, with a full knowledge of its danger, in order to give the patient her one chance. It is the inclusion of so many such cases that, in my own series of 140, has maintained the mortality at about 5 per cent. In fact, at the present time the reduction of the mortality much below this figure would, in my own hospital practice, made up as it is so largely of ignorant patients, lead to the suspicion that advanced cases were being unjustifiably refused the benefits of operation.

The second danger in this group is the presence of hyperthyroidism. If a patient dies unexpectedly after operation there are nearly always presented symptoms of profound post-operative hyperthyroidism, and hence it is to this danger that attention must in the main be directed. The importance of not operating in the first six months of the disease, when the symptoms can be most easily controlled and often, indeed, cured by medical treatment, I have previously laid stress upon. The fact that every case must be carefully watched in a nursing home or hospital until the hyperthyroidism is at its lowest ebb, the importance of the basal metabolic rate as an indication of the extent of the hyperthyroidism, and the value of medicinal measures in reducing the hyperthyroidism before operation, have been noted by many operators. In fact, more has been done by attention to such details to lower the mortality than by any other step. All surgeons have appreciated the fact that chloroform in such patients is a deadly poison and must be avoided. Some surgeons, indeed, advocate that all general anaesthetics should be abandoned, but here there is not so much unanimity of opinion, for many, and among them myself, have felt that the nervous upset of the patients which is produced when they are conscious at the time of the operation will more than balance the benefit gained by omitting a general anaesthetic. My own custom is to obtain unconsciousness by a minimal dose of rectal ether, and to continue the anaesthesia by means of ether administered on an open mask. Even with every care in the use of such methods, and in the administration of large doses of fluid before and after operation, it will be found that there is a post-operative reaction. In the more satisfactory cases this is slight, but in others the temperature may reach 103° for two or three days, and the pulse may rise to 160. The patient will sweat excessively, will suffer from dyspnoea, and will show a very considerable restlessness which is only controlled with difficulty by morphine. I have previously directed attention to the fact that two distinct groups of cases may be recognized, although there is every gradation between the two. The one occurs in young females who have a large soft, smooth thyroid, marked exophthalmos,

and a rapid pulse, and sweat freely. Such cases I have described as the "vascular group," and as a rule they show only a moderate reaction and rapid improvement after operation. The second group I have designated the "nervous type." Here the patient is more commonly between the ages of 40 and 45; the thyroid is smaller and more nodular, the pulse is less rapid, though often more irregular, and the nervous symptoms are much more prominent. These patients show considerably more reaction and make a slow post-operative recovery. Even when these two groups have been recognized and separated, a careful study of the immediate post-operative results will show a very considerable variation in the reaction, and it is to one cause of this variation that I wish to direct attention in this communication.

It has long been realized that the thyroid secretion has a very marked effect on the heat regulation. All cases of myxoedema feel the cold very severely, while those of hyperthyroidism are in a like degree affected by the heat, so that they are much more comfortable during the cold weather. In my own cases the post-operative distress in hot weather has been much accentuated, and special precautions, such as the use of electric fans, of ice, and of cold sponging, have long been used. In spite of all such precautions it has been my steadily increasing opinion that the mortality during the hot periods has been abnormally high. A careful analysis of my cases from this point of view shows very clearly that such is the case. In my own series there have been two deaths, occurring respectively in the months of January and December. Both of these were in patients with advanced degrees of the disease and were dependent upon secondary cardiac changes. All the others occurred during the hot months of June, July, and August, and all were what may be described as unexpected deaths in that they occurred in patients who by no means showed a pre-operative hyperthyroidism in excess of the others and in whom all the usual precautions had been taken. They also all showed extreme post-operative reaction passing on to acute hyperthyroidism and death. In the accompanying chart I have plotted out the percentage mortality among the total cases operated upon in the individual months of the year, and it is seen that whereas in February, March, April, May, September, October, and November there is no mortality, in the three months of June, July, and August it is in the region of 20 per cent. The effect upon the curve in January and December of the two deaths mentioned above is also shown.

Chart showing the percentage mortality among cases of exophthalmic goitre operated upon in the individual months of the year.

These figures have been collected over a period of ten years, and hence are of considerable value, for it is unlikely that any accidental factor should give so marked an alteration in the mortality which occurs for these three months. Moreover, a mortality of 20 per cent. which is present when the cases operated upon in June, July, and August are considered alone, is one that is much too high and must in fact be considered as an unjustifiable risk. These figures have made it manifest to me—and I publish them in the hope that they will warn others—that no operation on a case of exophthalmic goitre should be undertaken in extremely hot weather, for under such conditions the risk in spite of all precautions is too great and can be easily countered by awaiting more suitable conditions. Fortunately from this aspect the English climate is so variable

that seldom would it be necessary to postpone operation for more than two or three weeks.

## INTRAVENOUS INJECTIONS OF PEPTONE AS AN AID TO VACCINE TREATMENT.\*

(Abridged.)

BY

H. WARREN CROWE, M.D., B.Ch. Oxon.,

HARROGATE.

DURING the last eighteen months I have used intravenous injections of peptone in some seventy odd cases of patients who were very sensitive to vaccines, with satisfactory results. Patients to whom one could not give 100,000 streptococci or the same number of *M. deformans* without producing a reaction and general malaise, after peptone treatment were able to tolerate much larger doses.

For a good many years now Dr. Auld has given intravenous injections of peptone in cases of asthma, and claims a fair proportion of successful cases. It is fairly well established that most cases of asthma are due to an extreme sensibility on the part of certain cells of the body to a foreign protein. The slightest trace of this specific protein produces an attack of asthma. The disease, then, depends on a toxic idiopathy, and is strictly comparable with hay fever; urticaria, angio-neurotic oedema, and possibly a large variety of other diseases.

Apparently the poison may be air-borne and conveyed directly to the cells, as we suppose it to be in hay fever; or it may be derived from the blood stream, as is the case when food or certain intestinal bacteria excite the attack. There are a great many different proteins which are poisonous in this way. Susceptible individuals may be affected by several of them widely differing in source (Freeman,<sup>1</sup> Chandler Walker<sup>2</sup>). Dr. Auld<sup>3</sup> first brought forward peptone as a general non-specific immunizing substance, but its action in combating the cell sensibility is extremely obscure. There is no doubt that in some cases the effect is dramatic.

In Dr. Auld's present view, peptone acts by immunizing the system against any protein whatever, although itself incapable of acting as an antigen or producing any antibody, as he himself has shown by experiment. I cannot altogether subscribe to this view, because if peptone cannot function as an antigen, it does not seem to me possible that it should act as an immunizing agent.

It seemed a hopeful procedure to try the injection of peptone in other states of sensitiveness as well as in asthma. In my own experience the treatment of conditions like rheumatism, arthritis, and neuritis by streptococcal vaccine and *M. deformans* vaccine has frequently been rendered extremely difficult owing to sensitiveness—that is to say, that however small the dose given the patient gets a reaction and feels ill. Many cases have failed to benefit, or have obtained benefit only after very prolonged treatment with infinite patience and minute doses.

It is difficult to say why this condition of sensitiveness should arise; it may be that my method of giving frequent small doses excites sensitiveness, as some hold occurs in tuberculosis. On the other hand, patients are sometimes sensitive to the first dose. In a recent case half a million

\*Read before the Leeds Medico-Chirurgical Society.

stock streptococcus vaccine as an initial dose in a very chronic case of arthritis was followed by an acute flare-up of nearly every joint, lasting a week. In another case a similar initial dose of half a million *M. deformans* was followed by extreme suffering and four days' confinement to bed. Whatever the cause, hypersensibility to vaccine is an extremely troublesome and annoying complication of vaccine therapeutics. Dr. Pratt Johnson<sup>3</sup> regards sensitiveness to vaccine as an anaphylactic phenomenon comparable with toxic idiosyncrasy, and treats his cases by repeated small doses until this sensitiveness is overcome. He expects no real improvement until he can give large immunizing doses. I must, however, join issue with him in regard to his conception of a small dose. Ten million streptococci, which Dr. Pratt Johnson suggests as an initial dose, is, in my view, dangerously large.

I have tried many methods of getting over this sensitiveness. The first was combining the vaccine with beta eucaine lactate—a method quite successful in a proportion of cases. Sensitized vaccine I have used, and also detoxicated vaccine, but neither of these have I found satisfactory. Since using intravenous peptone I have had no further difficulty, except when the patient did not tolerate the drug. The following are given as some outstanding examples.

#### CASE I.

A male, aged 61, had a history of having had osteo-arthritis in the left hip-joint for twelve years, and in the right hip-joint for two years. He had acute pain on walking, but not much in bed. There was a large bony outgrowth over the left hip-joint and very considerable changes in the right hip-joint. Little movement was possible. This patient had very bad teeth and also a heavy infection of streptococci (four different varieties) in the faeces.

On December 27th, 1921, a dose of 500,000 of his dental vaccine was followed by a severe reaction lasting three days. He was extremely stiff, the pain was increased, and the weight dropped 2 lb. On December 30th injection of 500,000 of his faecal streptococci was followed by an attack of lumbago. On January 3rd, 1922, the dose was reduced to a tenth of a million and no reaction followed, but on the 7th of the same month a tenth of a million of his faecal streptococci was followed by a slight reaction.

From January 10th vaccines (dental and faecal streptococci combined with eucaine) were administered by his own doctor. The dose was always one-fifth of a million, and there was a focal reaction every time, lasting four to five days. Doses were given once a week. The general health improved. I then decided to give him a course of peptone. Simultaneously with this peptone a subcutaneous dose of vaccine of 500,000 streptococci was given twice a week. No reaction followed. The dose was then rapidly pushed up to 20 million without any trace of a reaction.

From December 27th, 1921, to March 19th, 1922, no progress was made whatever, and only very small doses could be tolerated. After the course of peptone which began on April 29th and was carried on until May 18th, doses were rapidly increased until the end of August—that is to say, within three months, 20 million could be tolerated.

#### Summary.

Osteo-arthritis of hip-joints. For three months reactions followed every dose of 200,000 streptococci. After peptone the patient was soon able to take 20 million without reaction.

#### CASE II.

Male, aged 47; a case of true rheumatoid arthritis involving the right wrist; twelve months' history. X rays showed nothing abnormal beyond some loss of calcium, but there was a very enlarged swollen joint, cyanotic in appearance, extremely painful, with gnawing and aching pains at night. The wrist was very tender and there was practically complete limitation of movement. Teeth had been extracted in the hope that this would cure the condition, but without result.

On January 13th, 1921, 500,000 *M. deformans* was given; this was followed by some pain in the left wrist. On January 21st he received a million *M. deformans*; there was some reaction the same night and the joint was worse for two days. Then an injection of a million *M. deformans* combined with eucaine was given; no reaction followed. On release three days later, 2 million combined with eucaine were injected; this was followed by reaction and swelling. The dose was then dropped on January 29th to half a million with eucaine. Again no reaction took place, but from this time onward to July 11th the dose had to be continually reduced owing to constant reactions, until extremely minute doses were given with eucaine. Even 20,000 *M. deformans* were frequently followed by a focal disturbance. On July 11th I decided to try detoxicated vaccine. It was specially prepared for me by the Genatosan Company. Fifty million *M. deformans* and, later, 100 million were not followed by a reaction; 200 million produced a reaction—exactly the same result as with ordinary vaccine, the only difference being in the nominal amount of the dose. Up to this time the urine had been sterile, but on July 15th I found a streptococcus in considerable numbers. A vaccine was made, and until the end of November small doses were continued, the patient being just as sensitive to the streptococcus as he was to *M. deformans*—that is, 20,000 streptococci produced a reaction, but the reaction of the streptococcus took a different form inasmuch as the areas surrounding the knee and hip-joints were affected, whereas when *M. deformans* excited reaction the wrist and feet always suffered.

On December 22nd a course of peptone was started. The vaccine doses when this was completed were very rapidly carried up to 5 million streptococci and 10 million *M. deformans*. It was after the course of peptone that real improvement started, and the patient rapidly progressed to complete cure. In this case occasionally a certain degree of sensitiveness supervened. One or two odd doses of peptone were then administered.

#### Summary.

A rare case of monarticular rheumatoid arthritis. For nearly twelve months minute doses caused reaction—for example, 20,000 germs. After peptone, doses were rapidly raised to 5 million streptococci and 10 million *M. deformans* without reaction, and the result was most satisfactory.

#### CASE III.

A female, aged 50, nine years ago had rheumatic pains in the left shoulder which moved about and were improved by massage. There was slight stiffness in the jaw and neck and some creaking. The wrists were swollen and fluid was present. The metatarsophalangeal joints in both feet were greatly enlarged. To my mind the condition was a typical streptococcal arthritis. X rays showed the teeth to be clear of any apical infection. The patient had been an extreme sufferer from hay fever for several years, and was also very sensitive to margarine and vinegar. Marked urticaria would appear after aspirin, presumably excited by the acetic acid radical. The mother, sister, and brother suffered from asthma, and one sister had had rheumatoid arthritis with extreme crippling for many years. This case is a particularly interesting one as demonstrating the frequent association between arthritic conditions and toxic idiosyncrasy—500 units of pollen vaccine on the skin produced a large wheal. In my experience it is the disease known as rheumatoid arthritis which is more frequently associated with conditions of sensitiveness, but in this case there was no symptom of that disease, except the slight creaking of the neck. The faeces were very heavily infected with a good many varieties of streptococci.

Treatment was commenced on April 13th, 1921. Alternating pollen and streptococcus vaccines were given to begin with, and then *M. deformans* vaccine was added in small doses of half a million. This was given on account of the suspicion that rheumatoid arthritis might develop. There was never any reaction, and the condition improved and cleared up apparently completely in the course of about three months. The doses were gradually increased from half a million to 10 million of combined *M. deformans* and streptococci. The pollen units were on an average 250. During the hay fever season itself they were dropped to 100. No hay fever developed.

The following spring the patient had a severe attack of tonsillitis. After that some symptoms of arthritis began to develop again, and she came under my charge once more in April, 1922. I treated her with pollen to prevent hay fever if I could, and found the skin less sensitive than it was before. The neck symptom was now very marked, and there were quite definite signs of commencing rheumatoid arthritis—pain and tenderness in the feet and weakness of the small muscles of the hands. I started to give vaccines of faecal streptococci, both from the old vaccines and from a new specimen, and combined them with *M. deformans*. The result, however, was not satisfactory, and although there were no definite reactions the patient felt ill. The hands grew more painful and weaker, and the feet were also tender. A little massage was given, but that made the condition worse. Under-water massage also had to be omitted for the same reason. I tried all sorts of doses, large and small, but the patient got steadily worse. I then came to the conclusion that possibly there were really reactions all the time, and that it was an atypical form of sensitivity with which I had to deal. Consequently peptone was given—on June 1st 0.2 c.cm. of a 2 per cent. solution, on June 3rd 0.4 c.cm., and on June 4th 0.8 c.cm.—together with 1 million streptococci; following this dose there was a very decided reaction and a drop in weight of 2 lb. lasting three days. On June 7th 1.4 c.cm. of a 2 per cent. solution was given with a million *M. deformans*. This was followed by a quite severe reaction lasting three to four days. On June 11th I repeated the dose of peptone with half a million streptococci; there was no reaction. On June 14th 1.4 c.cm. of a 2 per cent. solution and 100,000 *M. deformans* were given; again there was no reaction. On June 18th a million streptococci and half a million *M. deformans* were injected, and no reaction followed.

Now comes the interesting part of the case. The doses were carried on by Dr. Healey of Preston up to approximately two and a half million streptococci and a million and a quarter *M. deformans*. There was no reaction at all, but the patient still was getting no better. This time it was perfectly clear that there was no reaction, and I thought it worth while to push the dose, inasmuch as it seemed that the patient might have been desensitized completely by the peptone. On August 10th 4 million streptococci were given and 2 million *M. deformans*; on August 17th 6 million streptococci and 3 million *M. deformans*; then 15 million streptococci and seven and a half million *M. deformans*. No reaction followed any of these injections. I therefore sent three further doses—20 million and 10 million each. It was at this point that improvement began to set in.

#### Summary.

A successfully treated patient relapsed after an attack of tonsillitis. Treatment was very difficult owing partly to toxic idiosyncrasy and partly to sensitiveness to vaccine. Peptone injections marked the turning point of the disease.

It is quite clear in this case that the patient was desensitized, and so able to take larger doses, but that there was no improvement until after very considerable doses had been taken. Before the course of peptone it is probable

that the immunity mechanism was in a state of continuous irritability. Perhaps this may be the condition quite frequently when patients do not improve under vaccine treatment, and yet suffer no obvious reaction. So greatly was I impressed with the value of peptone injections, that it seemed possible that here might be a solution of the problem one often has to deal with—namely, that of the patient who can only come for 'three weeks' or a month's treatment, and then has to return to her own doctor to have her vaccines, and who for financial reasons will certainly not be able to return if the treatment does not succeed. The following case illustrates this. I started straight away with peptone injections, so as to prevent the development of sensitiveness. After returning home the patient's own doctor was able to carry on the treatment without difficulty.

## CASE IV.

On June 28th, 1922, I saw in consultation a case of general and severe arthritis, chiefly affecting the knee-joint, in a woman aged 48. She had not been out of bed for four months and was quite unable to walk, but happily there were no contractures. The knee-joints were at the time the worst parts, but practically every joint with the exception of the spine was affected.

Owing to financial and other reasons, it was impossible for the patient to come under my care except for a very short time. However, with only eight days to work upon, I started at once, on July 1st, with 0.1 c.cm. of a 2 per cent. solution of peptone. On July 3rd 0.2 c.cm. was given, on July 4th 0.4 c.cm., on July 5th 0.8 c.cm., on July 6th 1.4 c.cm., and on July 7th 1.4 c.cm., which I combined with half a million *M. deformans*. At the same time I had a bad tooth removed and cultured, and examined the faeces. There were nine varieties of streptococci at the apex of the tooth, and six varieties in the faeces. These were combined in one vaccine, and her doctor carried on with small doses, beginning with half a million combined streptococci and *M. deformans*. On September 29th much stronger doses were required. There have never been any severe reactions and the patient is improving.

## Method of Preparing Peptone.

Normal saline prepared from distilled water plus 1 per cent. carbolic acid is autoclaved in a flask at 120° C. for twenty minutes with a funnel fitted with rubber tubing and a clip. Vaccine bottles and caps are also sterilized. Ten per cent. of Armour's peptone is added to the hot carbolized saline and shaken up. The vaccine bottles are filled with the aid of the sterile funnel, capped and wired. After forty-eight hours a sample is removed and tested for sterility. When proved sterile, 1 and 2 per cent. solutions are put up in vaccine bottles already fitted with the requisite amount of 0.5 per cent. carbolized saline.

## Method of Dosage.

I have tried a good many different series of peptone doses, and find that for all intents and purposes the following method results in a fairly complete and satisfactory desensitization.

On the first day 0.1 c.cm. of a 1 per cent. dilution of peptone; on the second day 0.2 c.cm. of a 2 per cent. dilution; on the third day 0.4 c.cm. of a 2 per cent. dilution; on the fifth day 0.8 c.cm. of a 2 per cent. dilution; and on the seventh day 1.4 c.cm. of a 2 per cent. dilution; and thereafter, at three- or four-day intervals, 1.8 c.cm. two or three times. Having arrived at 1.4 c.cm., a subcutaneous dose of vaccine can be given at the same time, and this dose may be rather larger than the one the patient was sensitive to before treatment. No reaction will occur.

## Indications for Peptone Treatment as an aid to Vaccine Therapy.

From what has gone before, it will be clear that as soon as it is definitely determined that a patient is excessively sensitive to vaccines a course of peptone should be started without waste of further time; and secondly, if the patient is likely to be sensitive (and only experience, of course, can tell us when that will be) and can only give a very short time to special treatment, it is advisable to give a course of peptone before the vaccines are started.

## Contraindications.

Provided the proper form of peptone is used (Armour's No. 2 peptone, as recommended by Dr. Auld), there are very few contraindications to the use of the drug intravenously.

A few people seem to be unable to tolerate it, and after as small a dose as 0.4 c.cm. of a 2 per cent. solution complain of nausea and occasionally cardiac distress at night. In cases like this I have not pursued the treatment.

I should not give peptone to cases of grave anaemia or other serious constitutional diseases. The most important contraindication seems to be the presence of albumin in the urine, and especially any history of chronic or acute nephritis. In three cases I have seen recrudescence of nephritis which I think might be ascribed to the injections of peptone. On ceasing treatment, however, the symptoms have disappeared.

## Summary.

A good many cases of infections by streptococci and *M. deformans*, particularly in the arthritic group, become so sensitive to vaccines that treatment is very difficult and tedious. It is in these cases that intravenous peptone will do away with the sensitive condition, and enable treatment to be renewed.

Peptone provides the best method of overcoming the difficulty of sensitiveness in vaccine treatment.

In cases where sensitiveness is likely to occur peptone can be given as an initial course before vaccines are started.

The contraindications to the treatment are personal intolerance, grave anaemia, severe illness, and chronic nephritis.

## CARBON TETRACHLORIDE AND OIL OF CHENOPodium IN HELMINTHIASIS.

BY

J. G. REED, M.R.C.S., L.R.C.P.,

DIVISIONAL MEDICAL OFFICER, SARAWAK CIVIL SERVICE, BORNEO.

AN article appeared in the *BRITISH MEDICAL JOURNAL* of July 1st, 1922, reporting favourably on the use of carbon tetrachloride for hookworm infection. The drug also expelled *Oxyuris vermicularis* in large numbers and some *Trichuris trichiura* and *Ascaris lumbricoides*. The drug acts as a moderate purge and it is not necessary to prepare the patients as for thymol treatment. Oil of chenopodium is soluble in carbon tetrachloride, and a mixture of the two was suggested for ascariis infection. Since then several other articles have appeared on the subject.

Treatment with the drug was commenced in the General Hospital, Kuching, in August, 1922, and the immediate results warranted its continuance. It has been given to 82 patients in the hospital. It has been given also to several school children and to one European; the results from the former have been very good, but they have not yet been tabulated as it is hoped to examine the faeces of all the school children in the near future, and to give treatment to those who require it. The European patient showed no ova in his faeces after one dose of m 60, and during the six weeks following he gained 5 lb. in weight.

The faeces of the majority of patients in the General Hospital, including all those who showed any signs of hookworm infection, have been examined in the pathological department. The films have been made direct from the faeces; three slides have been examined before the specimen has been considered to be free from ova, and, wherever possible, two such examinations have been made before the patient has been pronounced free from worms. Of course it is realized that such methods are not absolute—a fact which in a few cases has been demonstrated by post-mortem examination.

It has been found that carbon tetrachloride alone is a fairly efficient anthelmintic for ascariis, but in combination with oil of chenopodium it has a much higher efficiency and practically never fails. This combination is believed

to be somewhat more effective than carbon tetrachloride alone for a pure hookworm infection also. Doses up to 1 drachm of carbon tetrachloride alone are being given to adults. Formerly  $\pi$  80 were frequently given, but cases that were resistant to 1 drachm were usually found to be equally resistant to the larger dose. The dose is given first thing in the morning before eating, and no purge is given.

After trying various combinations the following standard treatment is given to adults: one ounce of castor oil is given at night, and the next morning a mixture containing 1 drachm of carbon tetrachloride, 1 c.cm. of oil of chenopodium, and 1/2 oz. of liquid paraffin. As a rule the faeces are examined again a week to ten days after treatment, and if necessary the treatment is repeated. The immediate effect on the patients does not seem to be any more marked when this mixture is used than when the carbon tetrachloride is given alone. Almost all the patients complain of feeling drunk for a time varying from a few minutes to a day. As a rule three or four motions are produced in the twenty-four hours following the treatment, and these often contain numerous worms (ascaris). Occasionally slight vomiting, headache, or pain in the abdomen occur.

The treatment has been given to Chinese, Dyaks, Tamils, and one Japanese, and the series of 84 cases contains one European and one Chinese schoolboy who were not in the General Hospital. Almost all the Dyaks examined have been found to harbour ascaris, and a large percentage hookworms also. In spite of this fact, almost all the very heavily infected cases, exhibiting extreme anaemia, oedema, and debility, occur in Chinese, and no death from ankylostomiasis can be recollected among the Dyaks at the General Hospital. The Chinese also appear to be somewhat more resistant to treatment. The results as regards actual clinical improvement among the heavily infected Chinese have been somewhat disappointing. In several the stools have been reported free from ova after treatment, and the patient has left the hospital without oedema and feeling much stronger, though probably with still a high degree of anaemia; only to return shortly afterwards with oedema again, though the faeces still show no ova. In many cases a weekly haemoglobin test by the Tallqvist method was made, but few showed a rapid or extensive rise. Many cases of this nature were heavy opium smokers. All cases were given *mistura ferri arsenicalis*, and many showed an immediate, rapid, and apparently permanent improvement, in contrast to the type of case mentioned above.

The drug appears to have no effect against *Trichocephalus dispar* and *Strongyloides stercoralis*, and specimens containing ova or embryos of these worms only, have been counted as negative. The drug has been given to patients with fever from various causes and has also been given in conjunction with courses of novarsenobillon and emetine injections, without ill results. In a few cases a full dose has been given on two alternate mornings. This caused no ill effects but did not apparently increase the anthelmintic power of the drug. The majority of the hookworms were of the species *Necator*.

In 35 out of the 84 patients treated two negative examinations of the faeces were obtained after treatment, and in 17 one only. In 26 instances the patients received several treatments, but still showed ova in the faeces or left the hospital before treatment was completed.\* Six patients died; they were as follows:

*Case 1.*—A Chinese, aged 54, was admitted on March 14th, 1922, with a heavy hookworm infection. He received in all 8 c.cm. of oil of chenopodium and 140 grains of thymol. Ova of hookworms were still reported very numerous. On September 1st he received  $\pi$  60 of carbon tetrachloride; on September 8th ova of hookworms and ascaris were reported as scanty. On September 15th he died. The necropsy revealed oedema of lungs and purulent bronchitis with numerous hookworms and trichocephalus in the intestines.

*Case 2.*—A Chinese, aged 38, was admitted on August 14th, 1922, with a heavy hookworm infection and a mild ascaris infection. He had marked ascites and cirrhosis of the liver. The abdomen was tapped ten times. He received three doses  $\pi$  60 of carbon tetrachloride, after which scanty ova of hookworms and

embryos of *Strongyloides stercoralis* were reported. On November 20th he died. The necropsy revealed typical cirrhosis of the liver of the alcoholic type and a few hookworms in the small intestine.

*Case 3.*—A Chinese woman, aged 26, was admitted on October 16th, 1922, with a heavy infection of hookworms and amoebic dysentery. The haemoglobin index by the Tallqvist method was 30 per cent., and later fell to 10 per cent. The dysentery cleared up under emetine, and she received three doses  $\pi$  60 of carbon tetrachloride, after which on one occasion no ova were found in the faeces. She was intolerant of any form of control and frequently left the hospital and returned. On February 1st, 1923, she died with diarrhoea and ascites. At the post-mortem examination about twenty hookworms were found in the small intestine.

*Case 4.*—A Tamil, aged 38, admitted November 13th, 1922. He harboured ankylostomoses, ascites, and *Trichocephalus dispar*. He received 1/2 c.cm. of oil of chenopodium with  $\pi$  60 of carbon tetrachloride. He then left the hospital, but returned on December 25th, his faeces showing ova of *Trichocephalus dispar* and hookworms, both very scanty. On January 29th, 1923, he died. The necropsy showed pyopneumothorax. No worms were found in the intestines.

*Case 5.*—A Chinese, aged 34, admitted on November 22nd, 1922, with subtertian malaria and an infection of hookworms. The malaria responded to quinine treatment, and on November 29th he received  $\pi$  80 of carbon tetrachloride. On December 5th he became mentally deranged, and later violent, so that he was removed from the hospital. On February 19th, 1923, he died of amoebic dysentery. The intestines were not examined for worms.

*Case 6.*—A Chinese, aged 64, admitted on December 7th, 1922, with epithelioma of the external auditory meatus. He also harboured hookworms, ascites, with which he was heavily infected, and *Trichocephalus dispar*. He was later found to be suffering from quartan malaria and developed amoebic dysentery. He received 1 c.cm. of oil of chenopodium in a mixture with  $\pi$  45 of carbon tetrachloride; after this no ova were found in his faeces. He died on December 27th. At the necropsy about six hookworms were found in the small intestine and numerous *Trichocephalus dispar* in the large. There were no ascaris. Macroscopically the heart and liver did not appear to be fatty.

I wish to express my indebtedness to Miss E. J. O'Driscoll, under whose supervision all the faeces examinations were carried out, and who made suggestions as to dosage. I also wish to thank Mr. W. E. le Gros Clark, Principal Medical Officer of Sarawak, for permission to publish the cases.

## AN EXTREME CASE OF DIFFUSE SYPHILITIC FIBROSIS OF THE LUNGS.

BY

F. PARKES WEBER, M.A., M.D., F.R.C.P.

In the work on *Fibroid Diseases of the Lung*, by Sir Andrew Clark, Dr. W. J. Hadley, and Dr. Arnold Chaplin (London, 1894, p. 84), it is stated that "syphilis is undoubtedly, etiologically, concerned in fibroid disease; but it is with extreme rarity that cases capable of being ascribed to this cause are to be met with." It is further stated that most syphilitic cases take "the form of patches of gummatous material with induration around them. In some few cases a diffused form is met with, much resembling pure fibroid disease."

It is of this diffused form that the following case is a most remarkable example.

The patient, a man aged 53 years, was admitted to the German Hospital on March 28th, 1923, under the care of my colleague, Dr. E. Schwarz. I saw him later during the temporary absence of Dr. Schwarz, by whose kindness I am permitted to publish the case. On admission the patient was thin and emaciated-looking, with dyspnoea and an extreme degree of "clubbed fingers." There was no fever. The history was that he had had a chance twenty years ago, and that his wife had had three or four miscarriages. He had had influenza in 1918, but had otherwise enjoyed fairly good health until about six months ago, when he commenced to suffer from shortness of breath. His wife thought he had been ill for a somewhat longer time. In the hospital, besides the dyspnoea and clubbed fingers, the chief sign was extreme dullness to percussion over the upper parts of both lungs, especially in the supraclavicular regions, and at the back, from the apices down to the middle of the scapulae, with breath sounds of vesiculo-bronchial type. At one part of the left back slight cavernous breathing was heard; over the bases there were some pleuritic sounds. The cardiac dullness was increased to left and right, and there was an accentuated pulmonary second sound. There was apparently no enlargement of the spleen or liver. The urine was free from albumin and sugar.

At first the case appeared to be one of chronic pulmonary fibrosis of tuberculous origin, with dilatation and hypertrophy of the right

\* The clinical reports of these cases have been omitted owing to pressure on space.

side of the heart, and with clubbed fingers connected with the chronic obstruction in the pulmonary circulation. Roentgen-ray examination of the lungs likewise suggested the changes met with in cases of diffuse chronic pulmonary tuberculosis. But the absence of crepitation and all signs of active pulmonary tuberculosis was remarkable. There was very little expectoration and in the scanty mucous sputum obtainable no tubercle bacilli could be found. The Pirquet cuti-reaction for tuberculosis was weakly positive, as it is in most adults. On the other hand the patient's blood serum (April 5th) gave a strongly positive Wassermann reaction. During a prolonged attack of the "cardiac dyspnoea" type the patient died on April 6th. From April 3rd there had been occasional slight fever.

The necropsy (Dr. Lang and Dr. Welsch) showed diffuse fibrosis of both lungs, especially of the upper lobes, so that little pieces cut from the upper lobes sank in water. In the middle portions of the lungs the fibrosis was not so extreme as in the upper lobes, and pieces did not sink in water. Over the lower lobes there was old pleurisy. The cavernous breathing heard (as above mentioned) over the left back during life was obviously due to solid fibrosed lung over a bronchus. The heart was hypertrophied, especially on the right side, doubtless owing to the obstruction in the pulmonary circulation. The wall of the right ventricle was relatively so thick as almost to resemble that of a left ventricle. There was an old calcareous patch in the arch of the aorta, and the left coronary artery was considerably calcified. Elsewhere in the body there was nothing special to note, excepting what suggested a small infarct under the capsule of the liver; it might have been of local syphilitic origin. A careful search was made for old tuberculous lesions, but no caseous or calcareous foci were found in either lung and there was nothing in the lymphatic glands to suggest old tuberculosis.

A microscopic section from the upper lobe of the left lung shows extreme fibrosis, with irregularly distributed lymphocytic infiltration, but no characteristic tuberculous feature. Professor S. G. Shattock, who kindly examined it, writes: "I should think that the fibrosis is syphilitic, because of the positive Wassermann reaction, and because of the diffuseness of the change and the lymphocytic infiltration of the fibrous tissue and comparatively unaffected state of the alveolar epithelium."

Besides Dr. Schwarz, I have to thank the house-physicians, Dr. Lang and Dr. Welsch, for their kind help.

Since reading a paper on acquired syphilis of the lungs at the Medical Section of the Royal Society of Medicine in November, 1916,<sup>1</sup> I have become inclined to think that syphilitic changes in the lungs occur more frequently than is even yet commonly supposed. In patients with old tertiary syphilitic lesions elsewhere it is not very rare by Roentgen-ray examination of the lungs to find appearances suggesting tuberculous changes, though all other signs and symptoms of active tuberculosis are absent, notably in regard to examination of sputum. In some of these cases I think that there are minor degrees of syphilitic fibrosis of the lungs present. I believe, moreover, that in some cases diffuse syphilitic fibrosis of the lungs commences insidiously, and runs an insidious and progressive course, the patient being supposed to suffer from ordinary chronic bronchitis and pulmonary emphysema with or without acute exacerbations.

## VOLVULUS OF THE LARGE INTESTINE.

BY

A. H. SOUTHAM, M.D., M.Ch.Oxon., F.R.C.S.Eng.,

ASSISTANT SURGICAL OFFICER, MANCHESTER ROYAL INFIRMARY; HONORARY SURGEON FOR CHILDREN, MANCHESTER NORTHERN HOSPITAL.

ACUTE volvulus of the large intestine is one of the rarer and most fatal forms of intestinal obstruction. Out of 199 cases of acute colonic obstruction operated upon at the Manchester Royal Infirmary during the ten years 1913-22 there were only six cases of this nature; of these two died after operation. In the six cases the caecum and the sigmoid colon were each involved on three occasions. By the term "volvulus" is meant the twisting of the bowel upon its mesenteric axis, resulting in obstruction to the passage of the intestinal contents and arrest of the circulation in the involved loop when the torsion exceeds 180 degrees. A rare type of volvulus has also been described where the sigmoid colon is intertwined with a coil of small intestine.

## ETIOLOGY.

Torsion can only occur in that part of the large intestine which possesses a mesentery and where its base of attachment is narrow; such conditions are found in the

sigmoid loop, which is said to be implicated in about 70 per cent. of cases. Torsion is less often met with at the ileo-caecal region and is possible only when the caecum or ascending colon has some degree of freedom of movement. This unfixed condition may be of congenital or acquired origin. The congenital form is seen when the caecum and ascending colon have a mesenteric attachment to the posterior abdominal wall—a result of failure of obliteration of the foetal mesentery, which normally fuses with the posterior parietal peritoneum in this region and leads to fixation of the gut. Perhaps more often the condition is acquired and is found associated with a long history of constipation, where the bowel is more or less constantly distended, and the retained contents drag upon and elongate the mesentery, thus bringing the ends of the loop close together, as may not unfrequently be seen in the sigmoid colon. In Hirschsprung's disease (idiopathic dilatation of the colon), a condition which is characterized by lengthening and dilatation of the colon, and in which the most marked clinical features are constipation and meteorism, all the conditions favourable to the occurrence of volvulus are found. This disease, though more commonly seen in children than adults, is not so rare as is generally supposed, and it is not unlikely that it may be an important predisposing factor in the etiology of volvulus, when the disease pursues a chronic course. Cases of so-called megacolon in the adult have been recorded from time to time, and these may be examples of Hirschsprung's disease dating from infancy which have reached mature age, or the dilatation of the colon may only commence when adult life is reached. The anatomical arrangement of the redundant sigmoid invites kinks and twists, and it is not difficult to see how such cases may result in a volvulus.

One of the predisposing causes of torsion is a laxity of the attachments of the colon. In children, however, torsion is a rare occurrence, and at this period of life want of fixation of the bowel tends to predispose rather to intussusception. In elderly persons, on the other hand, intussusception is seldom met with, and with advancing age the liability of the bowel to become twisted appears to be greater.

The sex incidence is remarkable in relation to these affections of the colon; all of them occur more frequently in males—intussusception 70 per cent., volvulus 80 per cent., and Hirschsprung's disease 85 per cent.<sup>1</sup> This fact is difficult to explain. It appears not unlikely that the actual onset of volvulus is dependent on some disorder of the neuromuscular mechanism of the bowel. Keith<sup>2</sup> has demonstrated the presence of special neuro-muscular junctions, situated at certain points in the intestine, which he considers control its movements. It may be that, owing to some abnormal cause of irritation, this specialized tissue is thrown into a state of spasm and a temporary obstruction is set up. Acute distension of the bowel is thereby produced and a kink or twist may follow, when the bowel is freely mobile, as the result of irregular peristaltic action.

## SYMPTOMS.

The onset of the condition is generally acute, as both obstruction and strangulation will be produced. The sudden onset in a patient usually over 40 years of age, with abdominal pain, absolute constipation, and meteorism, is the combination which should suggest a volvulus. Abdominal distension is the most marked clinical feature of the condition, and in no other variety of intestinal obstruction is the distension produced so rapidly and to such a marked degree.

A tumour may sometimes be palpated, or the outline of the distended loop seen through the abdominal wall. Vomiting is not as a rule marked, as the obstruction is situated low down. Collapse appears later, and, where operation is delayed, death usually follows within a week.

## MORTALITY.

The prognosis depends on the time when operation is carried out, and recent figures show a marked improvement with earlier diagnosis and more prompt surgical intervention. Barnard<sup>3</sup> records a mortality of 93 per cent. out of

27 cases in thirteen years at the London Hospital. In a series of 9 cases at the Massachusetts General Hospital from 1893 to 1907 the mortality was 100 per cent. Richardson<sup>4</sup> records 16 cases (8 affecting the large intestine) operated on at the same hospital between 1908 and 1917, with a mortality of only 25 per cent.

#### TREATMENT.

The treatment is necessarily surgical. On opening the abdomen the volvulus presents as an enormously distended coil of gut, which appears almost to fill the abdominal cavity. The loop is delivered through the incision, and if healthy is untwisted, and a Paul's tube is then fixed in the summit and brought out through an abdominal incision. This allows the contents of the intestine to be evacuated and the easy reposition of the bowel. Further, the fixation of the bowel to the anterior abdominal wall by the Paul's tube prevents a recurrence of the twist, a complication otherwise liable to occur. Should the intestine prove to be gangrenous or impossible to untwist, the affected segment is resected and Paul's tubes fixed in the divided ends. Later, if the patient recovers, an anastomosis can be carried out.

The following three cases have come under my care:

#### CASE I.

The patient, a female aged 63 years, was admitted to the Manchester Royal Infirmary on January 23rd, 1921. She had been seized with abdominal pain three days previously, and the bowels had not been moved in spite of repeated enemata. On examination the abdomen was considerably distended, but no definite tumour could be detected on abdominal or rectal examination. The abdomen was opened by a right paramedian incision, and the sigmoid loop was found very dilated. It was seen to have undergone two complete twists on its mesenteric axis. These were untwisted without difficulty and a Paul's tube tied in the summit and fixed to the abdominal wall. The wound was closed, and the bowels moved subsequently each day. She was discharged from hospital seven weeks later with the colostomy practically closed.

#### CASE II.

A male, aged 50 years, was admitted to hospital on July 28th, 1920. He had been ill for five days with abdominal pain, constipation, and vomiting. His general condition was poor. The abdomen appeared very distended and a tumour was detected in the right side. Laparotomy showed this to be a greatly ballooned caecum which had a gangrenous patch on its anterior wall. The bowel had undergone one and a half twists. After detorsion a Paul's tube was fixed in the caecum through the gangrenous area and the wound closed. The patient failed to rally after the operation and died the following day.

#### CASE III.

I was asked, a short time ago, to see a gentleman, aged 67 years, whose illness had commenced with abdominal pain three days previously. He had suffered from chronic constipation, which had now become absolute, for many years. The abdomen appeared considerably distended, and on laparotomy an enormously ballooned sigmoid was found which had undergone rather more than one complete twist, whilst the remainder of the colon appeared both dilated and hypertrophied. The volvulus was untwisted, a Paul's tube tied in the apex, and the abdomen closed. He made satisfactory progress for six weeks, but subsequently succumbed to a sudden attack of heart failure.

It is still a debatable question among surgeons whether, in cases of acute intestinal obstruction, a general exploration of the abdomen should be carried out or a simple caecostomy performed. In sudden obstruction it may be impossible to exclude cases of volvulus, and caecostomy under such conditions would certainly be liable to end in disaster. Though cases of this nature are not common, yet it is under such conditions, where the pre-operative diagnosis may be uncertain, that the blind caecostomy is open to objection.

## AUTOPLASTIC OVARIAN TRANSPLANTATION.

BY

J. H. NATTRASS, M.D., B.S.,

HONORARY GYNAECOLOGICAL SURGEON, WOMEN'S HOSPITAL, MELBOURNE.

THE following case is of interest because the patient has been under observation for thirteen years after an operation for transplantation of the ovaries, and because it was possible to make macroscopic and microscopic examinations nine years and seven months after the transplantation was performed. The clinical and histological evidence combine to show that the organs are still in a healthy condition.

On March 5th, 1911, a married woman, aged 17, was admitted for her confinement to the obstetrical department of the Women's Hospital, Melbourne. She had suffered from tuberculous disease of the hip, had gone on crutches since the age of 7, and presented a discharging tuberculous sinus over the right trochanter. Scars of healed sinuses were seen over the lower lumbar vertebrae and right buttock. Caesarean section was performed and a full-time female child, weighing 6 lb., delivered. In order to prevent further conception I transplanted the ovaries into the anterior abdominal wall. Three and a half years later I reported the case, with observations to date, in the *Medical Journal of Australia* of January 16th, 1915, vol. 1, No. 3. Since then the patient has been under continual observation; owing to the strenuous use of crutches a ventral hernia developed in the upper part of the scar.

The patient's health has been generally good. During the last five years she has gradually put on weight; her skin is fresh and her eyes are clear; the tuberculous lesions in the bones of the right lower extremity have practically healed, there being a little discharge only occasionally. The menstrual flow occurs every 28 days, with slight variations of two or three days on either side. She cannot remember ever missing a period. The duration is four days. There is no pain whatever in the region of the uterus, but some tenderness usually indicates which ovary is providing the Graafian follicle, it may be each ovary alternately, or either ovary two or three times successively. The pain has not been more than what would be called tenderness at any time, and is usually more marked in the subcutaneous graft than in the one more deeply placed in the rectus sheath. Sometimes slight swelling accompanies the tenderness. The sexual appetite is not decreased.

The right ovary, which was placed on the aponeurosis of the external oblique abdominal muscle, is easily felt; it feels a little larger than normal. The left ovary, more deeply placed in the rectus sheath, is more difficult to feel, but it can be located as a slight thickening, and each of them on pressure produces a sickening sensation. The uterus is normal in size. There is no leucorrhoea. There is no evidence of atrophy. Bartholin's glands are observed to function.

On October 15th, 1920, the patient complained that two days previously, during a fit of coughing, she suddenly felt a severe pain, with some swelling in the hernial sac. An irreducible strangulated hernia was at once diagnosed, and the patient was hurried to the Women's Hospital for immediate operation. After the hernia had been dealt with, and the peritoneal cavity closed, opportunity was taken to examine the graft in the rectus sheath. As its situation was so well known, a few touches with the knife were sufficient to reveal it, snugly contained in the sheath, and firmly adherent to the surrounding tissues. It had been placed in this situation roughly nine years and seven months before (March 5th, 1911). It was about 1½ inches in length, 1/2 to 3/4 of an inch in breadth, reddish in colour like the tissue around it, firm in consistence. Several Graafian follicles could be felt, varying in size, the largest being about the size of a small pea. Some follicles could be seen, greyish in colour, projecting slightly, and when pricked with a knife exuded liquor folliculi. A small piece was removed for microscopic examination. Sections of the graft showed its histology to be quite consistent with the clinical history of the patient. Perfectly formed Graafian follicles and corpora lutea in normal ovarian stroma can be demonstrated, whilst the abundant arteries, veins, capillaries, and nerves indicate how completely the graft has been adapted by its new environment.

April 28th, 1923: The patient, now in the thirteenth year of observation, is still menstruating regularly, and her sexual life is apparently normal.

This case is interesting, for the following reasons:

(1) The length of time during which the patient has been under careful observation—that is, nine years and seven months. (It is also thought that this is the only case on record where a human ovarian graft has been microscopically examined after being transplanted so long.)

(2) The sexual life of the patient has been quite normal. The grafted ovaries have apparently discharged their functions quite as well as if they had not been grafted. Opinions have been expressed by some<sup>1</sup> that a graft would not continue to function longer than a few months, or perhaps a year or two; but the information obtained from this case clearly shows that

the grafted ovaries may carry on their function for a much longer period.

(3) Except for a little tenderness, and occasionally slight swelling about the time of menstruation, not the slightest inconvenience has been caused by the grafted ovaries in their new location.

The conclusions resulting from the consideration of this case, especially when taken in conjunction with the reports on this subject by other operators,<sup>2</sup> demonstrate beyond all doubt that autoplasmic transplantation of the ovaries is a most valuable gynaecological procedure, and is a definite step forward in the conservative surgery of these organs. The simplicity of the operation, the ease and rapidity with which it can be done, the absolute assurance of success, if a few simple facts are observed,<sup>3</sup> justifies its use beyond all doubt in suitable cases.<sup>4</sup>

I am much indebted to Mr. W. J. Owen, of the Australian Institute of Anatomical Research, Melbourne, for preparing the microscopical sections, and for microphotographs.

## A CASE OF PITUITOUS CATARRH.

BY

SIR PERCIVAL HORTON-SMITH HARTLEY, C.V.O.,  
M.D., F.R.C.P.,

PHYSICIAN TO ST. BARTHOLOMEW'S AND TO THE BROMPTON HOSPITALS;  
AND

IVOR J. DAVIES, M.D., M.R.C.P.,

ASSISTANT PHYSICIAN, ROYAL INFIRMARY, CARDIFF.

Cases of that variety of bronchitis known as "pituitous catarrh," originally described by Laënnec, are exceedingly rare, and for this reason it appears to us of interest to report the following instance. The patient was under the immediate care of one of us (I. J. D.), and on February 9th was seen by us together in consultation.

The patient was a married lady, aged 34; her height was 5 ft. 2½ in., her weight 9 st. Her maternal grandmother had died of bronchitis, but otherwise the family history was unimportant. She was of a cheerful disposition, and had enjoyed fair health, except that since 1919 she had been subject to attacks of bronchitis. These occurred twice in 1919, and once each in 1920 and 1922, and were respectively of six, four, three, and two weeks' duration. In each the sputum was of the peculiar character seen in the present attack (1923), and there can be little doubt that they were also attacks of pituitous catarrh, though the nature of the malady was not recognized at the time.

The present attack commenced with a "cold" at Christmas, 1922. This was followed by bronchial catarrh, with the expectoration of some phlegm of the peculiar character to be shortly described. This lasted for about a week and then improved, but the cough and phlegm did not entirely disappear. In the middle of January, 1923, the bronchial catarrh became worse and she commenced to bring up larger quantities of the peculiar expectoration. There had been hitherto little, if any, pyrexia, and the patient had been getting up, though confined to the house. On February 5th, however, owing to the increasing cough and distress, she took to her bed, where she remained for the following three weeks.

On February 9th, when seen in consultation, her condition was as follows:

She was sitting up in bed, racked by a harassing cough. The lips were faintly cyanosed. Temperature 99.5°; respiration somewhat hurried. She was well nourished; tongue clean; teeth satisfactory; no pyorrhoea. Throat natural.

The chest was a little deeper than natural, but there was no marked emphysema. Heart natural; pulse 90, regular, soft.

Sonoro-sibilant râles were audible all over the lungs, with also some scattered moist sounds. There were no signs pointing to tuberculosis or of consolidation.

The abdomen, nervous system, and urine were natural.

The cough was very troublesome from continual efforts to bring up the sticky expectoration. At intervals of an hour or so a paroxysm would occur, and these attacks, especially at night, were often distressing, a good deal of cough being required to bring up a small quantity of phlegm.

The sputum, which was coughed up as a rule in small amounts at a time, was quite unusual in character, and quickly formed a thick, ropy homogeneous mass in the sputum pot. This was found

to consist of mucus, looking just like unboiled white of egg, as described by Laënnec, and was covered on the surface with a white froth. The mass of mucus was lightly streaked with small plugs, whitish or yellowish-white in colour, composed of muco-pus from the smaller bronchi.

The expectoration was expelled in small quantities at a time, varying from a teaspoonful or two to half an ounce. But later, when improvement set in and some sleep was possible, several ounces were expectorated in a short time, and more than once a mug of 6-ounce capacity was filled in a quarter of an hour. A bout of coughing would last until the sticky mucus was expelled, relief finally coming with the expulsion of one of the small plugs of muco-pus to which we have referred. For a period of a fortnight the average daily amount of sputum was 20 ounces, but on several days a greater amount was brought up, 30 ounces being the largest quantity expectorated in twenty-four hours.

A characteristic feature of the sputum was the ease with which it could be emptied from vessel to vessel, the whole flopping out *en masse*, leaving the sputum pot clean, save for a little froth near the rim. Its tenacious character was also well shown by the fact that if a small portion were seized with a pair of forceps, the whole mass could be pulled as a string from one pot to another.

The patient was kept strictly in bed, a steam-kettle was ordered, and poultices and antiphlogistine to the chest. Since the sputum was so sticky and difficult to bring up, belladonna seemed contraindicated in spite of the amount of expectoration, and a mixture containing sodium bicarbonate, ammonium carbonate, vinum ipecacuanhae, and syrup of squills was prescribed. Under this treatment the symptoms slowly improved, and the cough and phlegm gradually lessened, but it was three weeks before the patient was able to leave her bed, and four weeks longer before she could leave the house. At no time, we may add, did the temperature reach 100°, though ranging at night between 99° and 100°.

The patient's cure was finally completed by a stay of three weeks at Bournemouth, which she left on April 22nd, free from symptoms, and with her chest quite clear.

Dr. H. A. Scholberg, joint pathologist and bacteriologist to the Royal Infirmary, Cardiff, examined the sputum in more detail, and reported that the bulk of the material was, as its appearance indicated, mucus. He also found that a small quantity of albumin (but no globulin) was present, amounting to roughly just under 0.5 per mille, as measured by the Esbach's tube. The tenacious yellowish-white plugs were found under the microscope to consist of mucus and pus cells (with Gram-positive diplococci), clearly coming, in Dr. Scholberg's opinion, from the bronchioles.

Cultivation of the sputum showed the presence of no unusual organisms, but many colonies of streptococci and of *Micrococcus catarrhalis*, with a few staphylococci, were grown. Tubercle bacilli were not found, nor had they been detected at a previous examination.

#### Commentary.

In his original description of "pituitous catarrh" Laënnec wrote as follows: "I call that variety of catarrh 'pituitous' which is associated with an expectoration which is colourless, transparent, ropy, frothing on the surface, and which when the foam has been removed resembles white of egg diluted with water."

Defined in this way the case which we have described falls into this type of bronchitis, though in this instance there was but little "dilution" of the "white of egg" appearance. It is a variety which is, in our experience, extremely uncommon, and is one in which the stress of the malady would appear to fall upon the mucous glands of the bronchial tract, leading to very excessive secretion of mucus. In this connexion it may be of interest to add that the lady whose case we have recorded, for many years on first waking in the morning had been obliged to remove an accumulation of sticky mucus from the roof of the mouth, thus indicating possibly a perverse activity on the part of her mucous glands.

But few cases of pituitous catarrh are described in the literature, and it would appear to us from the clinical descriptions that in some of those published confusion has arisen between this variety of bronchitis and acute oedema of the lung, the abundant frothy sputum met with in each case having led to the mistake.

A careful investigation of the sputum should, however, at once distinguish them. In acute oedema of the lung, as we have shown elsewhere,<sup>2</sup> when the froth has been removed the expectoration will be seen to be yellow or amber colour; in pituitous catarrh it is like white of egg. In the former there is no mucus in solution, or, if present, it occurs in small and varying quantities, depending on the duration of the attack and the admixture of ordinary muco-purulent sputum; in the latter the secretion is chiefly composed of mucus, and thus is much more viscid. Thirdly, and most important, while the former contains so much protein as to become solid on boiling, whence the name "albuminous expectoration," the latter contains only a

trace of albumin. The diagnosis, therefore, should not be difficult, provided the sputum be carefully examined.

## LACERATED KIDNEY DUE TO INDIRECT VIOLENCE.

BY

JOHN C. JEFFERSON, F.R.C.S.,  
HONORARY SURGEON, ROCHDALE INFIRMARY.

THERE are several points of interest in the following case, which will be discussed after the facts have been related.

Mrs. C., aged 53, was first seen on January 1st, 1923. She stated that thirty-six hours previously she had fallen from a chair on which she was standing, and immediately afterwards was seized with abdominal pain. She went to bed, and some time during the night vomiting commenced, and continued up to the time of my seeing her on the morning of the second day after the accident. She then appeared very ill. The pulse was 110 and rather weak, the temperature 100°. There were no signs of external violence. The abdomen was distended and acutely tender in its lower segments, particularly over the right iliac fossa. It exhibited an intense rigidity below the level of the umbilicus; above that level rigidity was not so marked. The liver dullness was not diminished; rectal and vaginal examinations yielded no information. The urine was scanty and high-coloured, but contained no blood. A diagnosis of peritonitis was made, though I was unable to determine its cause.

## Operation.

She was removed to hospital, where operation was at once performed. On palpation under the anaesthetic a fixed mass was felt in the right iliac fossa, passing backwards into the right lumbar region and upwards beneath the ribs.

An incision over the right rectus was made, and it was at once seen that there was a considerable quantity of free blood and clot in the abdominal cavity. The mass felt on palpation was found to be a haematoma around the right kidney. This haematoma had tracked downwards along the psoas, had stripped up the peritoneum, and lifted forwards the caecum and ileo-caecal valve; further, it had percolated into the lower part of the mesentery of the small intestine.

To the outer side of the ascending colon there was a small tear in the parietal peritoneum not more than one inch long. Through this blood had evidently made its way into the peritoneal cavity. It was interesting to note that the caecum, appendix, and terminal part of the ileum were deeply ecchymosed, and presented the appearance that they would have shown had they been involved in a recent strangulation. The blood and clots were rapidly cleared out, the rent in the peritoneum sutured, and the abdomen closed.

An incision was now made exposing the right kidney. The haematoma was cleared away, and, on gentle examination of the organ *in situ*, a laceration was felt on the anterior surface of the lower pole extending from the lateral border inwards towards, but not involving, the pelvis. As there was now no bleeding from the laceration its depth was not determined, and I contented myself with packing the cavity resulting from the evacuation of the haematoma and closing the wound as far as practicable around the pack.

## After-History: Recovery.

The patient's condition at the end of the operation was grave and continued so for two days, there being much post-operative vomiting. From then on, however, she made good progress. The packing was removed in two or three stages and a drainage tube substituted. Through this urine was discharged in small amount for five weeks. There was never any blood in the urine passed naturally. The patient left hospital at the end of the eighth week.

In the first place, the laceration was caused by indirect violence. In such circumstances the injury to the kidney may arise from acute flexion of the body with corresponding acute flexion of the kidney on its transverse axis (Thomson Walker); or where there is no such flexion but where the accident consists of a fall from a height on to the buttocks, the kidney may be injured by direct impact against the twelfth rib or transverse process of the first lumbar vertebra (Tuffier). In the case under consideration I think the laceration was produced by the first mechanism, for the distance from the seat of an ordinary chair to the ground would hardly be sufficient to cause it by the second method.

Secondly, though lacerations of the kidney usually radiate outwards from the hilum, in this instance the laceration was produced in the cortex only, and, though small, had given rise to much haemorrhage.

Thirdly, there was no haematuria so far as I was able to observe. There may, of course, have been blood in the urine when the patient, who was by no means an intelligent type, was not in a condition to notice it. On the other hand, since the laceration was in the cortex only, there may have been none at any time.

Fourthly, although the laceration was caused by indirect violence the peritoneum was torn and there was accompanying haemoperitoneum.

There is no doubt that haemorrhage had already ceased at the time of operation, but it is highly probable that but for the treatment adopted urine would sooner or later have found its way into the peritoneal cavity, with fatal results.

I employed treatment by packing, rather than suture of the laceration, in order to save valuable time. In this connexion it is interesting to note that Albarran has collected six cases in which packing was resorted to; all recovered (Thomson Walker).

## Memoranda:

### MEDICAL, SURGICAL, OBSTETRICAL.

#### LACTIC ACID IN THE TREATMENT OF CHRONIC ENTERITIS.

A NUMBER of cases of chronic enteritis are associated with excessive fermentation of the intestinal content. The condition frequently arises *de novo*, although in a certain proportion of cases it follows an acute stage.

It occurs in babies as a result of the food becoming contaminated by micro-organisms. The motions are frequently loose, green, and malodorous. This is usually associated with abdominal distension, excessive flatus, and attacks of screaming due to colic. There is nothing palpable abdominally. In adults the following syndrome is present:

(1) Colic of either the small or large intestine. The pain is variable in intensity, and usually moves from one part to another. In the small intestine it is usually referred to the region of the umbilicus. The large intestine may be definitely palpable and tender to touch. I have seen one case where the caecum was palpable.

(2) The stools vary in consistency and colour. There may be looseness alternating with normally formed motions or constipation. The stools may be paler than usual, or even greenish. They are frequently offensive, and are likely to be associated with excessive flatus.

(3) There may be an associated gastric dyspepsia. Where the condition has lasted some time mental depression, loss of weight, anaemia, and headache may occur as a result of toxic absorption.

Cases of the types referred to respond very well to lactic acid. The rationale of the treatment lies in the fact that *B. coli*, which is as a rule unusually active in those cases where the motions are unduly offensive, cannot grow in a concentration of lactic acid of more than 1 per cent.<sup>1</sup> The treatment is a result of Metchnikoff's teaching, and given in this way is a satisfactory alternative to curdled milk preparations. The latter cannot always be tolerated by patients,<sup>2</sup> and involves a certain amount of difficulty where there is not the proper convenience for making bacterial preparations.

The following prescription is useful for adults:

R	Ac. lact.	...	...	...	...	...	3ij
	Syr. aurant.	...	...	...	...	...	3j
	Aq.	...	...	...	...	...	ad 3viij

Sig.: 3ss t.d.s. p.c.

Where there is gastric dyspepsia the following may be substituted:

R	Ac. lact.	...	...	...	...	...	3ij
	Liq. strych.	...	...	...	...	...	℞℞
	Tr. card. co.	...	...	...	...	...	3j
	Aq.	...	...	...	...	...	ad 3viij

Sig.: 3ss t.d.s. p.c.

## Reports of Societies.

### TREATMENT OF DYSMENORRHOEA.

At a meeting of the Section of Obstetrics and Gynaecology of the Royal Society of Medicine on June 7th, with Dr. T. W. EDEN in the chair, Mr. L. G. PHILLIPS read a paper on the treatment of dysmenorrhoea, with an analysis of 100 cases.

Mr. Phillips said that fifty cases were treated with extracts of ductless glands, either alone or in combination with antispasmodics. Only four cases of this group came eventually to operation as they failed to be relieved sufficiently to carry on their work in comparative comfort. When the ductless gland tablets were omitted the painful periods often returned. Forty cases were treated by antispasmodics alone, and of these thirty-four were benefited and the remaining six came to operation. Ten cases were treated between the periods with bromides and salicylates, combined with laxatives and small nightly doses of luminal during the periods; all were relieved.

In treating the cases an attempt was made to interpret all the available information and to evolve a plan of treatment based on the recognition of the following clinical types:

In Type 1 dysmenorrhoea was a disease of faulty hygiene, upbringing, and surroundings. This type was thin, anaemic, constipated and poorly developed, with visceroptosis and faulty posture and breathing; they followed sedentary lives with little exercise and fresh air. The feeble musculature of the uterus was easily exhausted and gave rise to cramp and pain when called upon to make expulsive efforts in the exhausted state. The treatment was directed to the correction of these faults. The correct mental attitude was cultivated by teaching the patient that menstruation was natural and that she must continue to bathe and take exercise as usual. No constricting clothing should be worn and stays must not be permitted to do the work of the abdominal muscles. Constipation was corrected by drinking plenty of water and eating fruit, combined with abdominal kneading night and morning. Exercise such as walking or tennis, and special exercises designed to strengthen the abdominal wall, formed an important part of the treatment.

In Type 2 the dysmenorrhoea was functional. These women complained not only of menstrual pain, but generally of headache, nausea, and constipation as well; they were usually nervous and worried. Ten such cases were treated successfully by sedatives: bromides and salicylates between the periods; one to one and a half grains of luminal nightly during and just before the period; and general hygienic measures.

In Type 3 the symptoms suggested some form of obstruction as the causal factor. The pain resembled ureteral and biliary colic in its intensity and sudden onset, and subsided rapidly when the clot was passed, just as in biliary and ureteral colic the pain ceased when the stone was passed. Gynaecologists still continued to employ cervical splitting operations, such as anterior hysterotomy, for the relief of pain. In three cases of hysterectomy for dysmenorrhoea performed during the period the uterus was found to contain clots. Whether the intrauterine clot was normal and was not dissolved because of endometrial defect, or whether clotting *in utero* was pathological, must be decided before the pain could be treated rationally. It was reasonable to suppose that a uterus with a poorly developed musculature might be unable to expel casts or clots even through a normal os.

Type 4 was a type of patient in whom there existed signs of arrested development of the genital organs. They complained of pain in one or other iliac region alone, or before the central pain. Menorrhagia was as common as scanty flow, because an undeveloped endometrium and musculature were linked up with a normal ovarian stimulus. The obvious treatment was to stimulate development of the uterus, and this was often successful. In addition to the general hygienic treatment organotherapy and electrical treatment were useful.

In ten cases where medical treatment had failed two were cured by curettage and one by anterior hysterotomy. Hysterectomy was performed in two cases where the uterus contained clots and showed marked arterio-sclerosis, and the remainder (very severe cases) were sterilized by radium.

One hundred cases treated surgically were followed up and compared with 100 cases treated medically. It was found that 25 per cent. were cured and 50 per cent. were unaffected, while the best results were in cases treated by curettage. These results, however, were inferior to those obtained in the series of 100 cases treated medically. Mr. Phillips believed that most gynaecologists felt that the surgical treatment of dysmenorrhoea without physical signs was disappointing.

In the discussion that followed, the PRESIDENT said that he was particularly impressed by the small number of patients who came to operation; in his experience operation cured 50 per cent. and relieved to some degree 25 per cent. Mr. BONNEY pointed out that the figures of results of treatment of dysmenorrhoea were confused by the variety of causes. If dilatation was limited to cases of the "virginal type" of dysmenorrhoea the operative results would be much better. It was remarkable that very small uteri were so often associated with extreme haemorrhage, for which hysterectomy was required. Retroversion was often a cause of dysmenorrhoea in a virgin, and could be cured by reposition of the uterus. Dr. J. M. BRYDGE said that as a general practitioner he had been called upon to treat many cases of dysmenorrhoea, and found that while patients aged 24 or less could generally be cured, those over that age generally failed to respond to medical measures. There was a large element of suggestion about the treatment, and success was likely to follow care and perseverance. Many of the "masculine type" of women who suffered from dysmenorrhoea played too many games, and got better with rest.

A number of specimens were exhibited by Dr. HERBERT SPENCER, including a sarcomatous ovarian dermoid cyst, a ruptured carcinoma of the ovary, and a microscopical preparation showing the effect on the Fallopian tube of torsion of an ovarian tumour. Dr. RUSSELL ANDREWS described a case of carcinoma of the cervix associated with prolapse of the uterus in a woman aged 77. Mr. VICTOR BONNEY read a short paper on diurnal incontinence of urine in women. In its early stages, he said, this form of incontinence only occurred when women made some effort producing sudden violent abdominal strain, such as coughing or sneezing, but as it grew worse it was provoked by any movement which involved a sudden jerk. Clinical examination showed that the escape of urine was associated with an abnormal descent of the bladder and urethra immediately behind the symphysis pubis.

### MUSCULATURE OF THE AORTA AND CARDIAC VALVES.

At a meeting of the Edinburgh Medico-Chirurgical Society, June 6th, with Dr. WILLIAM STEWART in the chair, Dr. A. BLACKHALL-MORISON read a communication on the musculature of the aorta and of the cardiac valves, anatomically, physiologically, and clinically considered.

Dr. Blackhall-Morison compared the work of the anatomist and of the physiologist, and pointed out the generally insufficient study of the valvular apparatus of the heart. He made special reference to the valuable and largely forgotten work of H. S. Savory, published in 1851 and 1852. With slight modifications, as the result of modern methods of investigation, Savory's observations and teachings were still accepted. The advantages were emphasized of a comparative study of the subject by serial sections, stained by modern methods. Dr. Blackhall-Morison then described the anatomy and physiology of the right venous entrances; he regarded the superior vena cava and coronary sinus as para-auricular structures, and the latter as the venous heart of the coronary circulation. He explained the progressive nature and complex function of auricular systole, and maintained that the muscular action of the lower segment of that chamber persisted during ventricular systole. Specializations in local valvular musculature were described, and the grounds given for belief in a local nervous control in the heart. The mechanism of muscular closure of the mitral orifice was described in detail, and what the speaker believed to be a hitherto unnoted series of *rotatores basis aortae* was demonstrated. The difference of the aortic and pulmonary arterial musculature was dealt with, and the relations shown of the

auricular muscle to the aorta and posterior aortic valve, together with conclusions as to the function of these muscle bundles. The general principle of centro-peripheral nervous influence on the heart was discussed, and the myogenic nature of some cardiac irregularities was called in question. Finally, an explanation was suggested of certain clinical conditions and their physical signs.

The paper was illustrated by lantern slides and microscopic sections, and was discussed by Professor RUSSELL and Dr. W. T. RITCHIE.

#### *Extensive Resections of Small Intestine.*

Mr. PIRIE WATSON read a communication on extensive resections of the small intestine, illustrated by a case on which he had operated.

This patient, a woman aged 63, was admitted to hospital suffering from acute intestinal obstruction, the result of mesenteric thrombosis; at operation it was necessary to resect seven and a half feet of gangrenous small intestine (ileum). Her former good health was quickly regained, with no nutritional or digestive disturbance; on a mixed diet the faeces and urine remained practically normal.

The term "extensive" was by consent limited arbitrarily to resection exceeding 200 cm. (6 ft. 7 in.); because of individual variation in the length of the bowel this length might equal one-fifth or almost one-half of the whole small intestine. Above the 200 cm. limit metabolic disturbances were common. Mr. Watson then presented an analysis of seventy-three recorded cases, of which sixty-four were "surgical recoveries," the death rate being 12.3 per cent.; this latter figure was, in his opinion, probably too low, because as a rule only successful cases were published. Good "functional recoveries," in which no disturbance of general health or digestion resulted, were obtained in 64 per cent. of cases—a high figure when one considered not only the magnitude of the operation, but also the grave nature of the lesion for which operation was performed. In a survey of the recorded cases it was found that age was apparently an unimportant factor, equally good results having followed operation on patients at both extremes of life; this was in contrast to Flint's animal experiments, which showed that operation was better borne by the fully developed than by young growing animals. The morbid conditions necessitating extensive resections were mentioned. As regards methods of operating, the majority of cases had been treated by an end-to-end anastomosis, but recently lateral anastomosis was being preferred; in eight successful cases Murphy's button had been employed. With reference to the part resected, clinical records seemed to show that resection of jejunum was not more serious than that of ileum. Untoward post-operative symptoms were not always in direct proportion to the length of bowel removed, other factors being of importance, such as the length and condition of the remaining bowel, its power of compensation, and the condition of the patient prior to operation. It was necessary to bear these points in mind in forming deductions from the result of experiments on healthy animals. The metabolic disturbances which might follow operation were described. In this connexion it was stated that carbohydrates were digested with greater ease than fats or nitrogenous foods, the most suitable diet being one rich in carbohydrates and poor in fat. Metabolic disturbances were absent in proportion to compensatory hypertrophy in the remaining bowel. This compensation was occasionally unstable, Brenner's case being recalled, in which compensation broke down two and a half years after operation. In conclusion, the speaker urged that where the choice at operation lay between closing the abdomen and a heroic resection, the latter should be attempted as affording the only chance of saving life.

The communication was discussed by Mr. STRUTHERS and Mr. QUARRY WOOD.

#### *Exhibition of Specimen.*

Dr. H. L. WATSON WEMYSS showed a specimen of a large gastric ulcer from a man aged 39, admitted to hospital with haematemesis and profound anaemia. Medical measures were unavailing, and death occurred from haemorrhage before blood transfusion or other surgical treatment could be carried out.

## Reviews.

### TUBERCLE BACILLI IN THE BLOOD.

A HANDBOOK of the treatment of tuberculosis<sup>1</sup> which has been edited by Professor Ernst Loewenstein of Vienna contains articles by various contributors, but only that by Professor G. LIEBERMEISTER seems worthy of extended notice. His researches upon the changes found in veins, especially in the pulmonary veins, arteries, and lymphatics, and upon the presence of tubercle bacilli in the blood stream, will tend to modify current opinion.

Liebermeister assures us that with patience any master of methods can demonstrate the presence of tubercle bacilli in the blood in every case of open pulmonary tuberculosis and in many cases of early disease. He therefore supports Rosenberger's much criticized view. According to these authorities it is more consistent with histological and biological facts to look on the pulmonary lesion as a part of a general disease. No doubt in many cases tuberculosis may begin in the lungs, and it is not possible to say when it becomes general. This happens when the tubercle bacilli enter the blood stream, and there is no way of fixing the time of this event. In rabbits and other animals, if free tubercle bacilli in not too great numbers are injected into the arteries, the tuberculous disease may become concentrated in the lungs.

It seems to be proved that even in acute military tuberculosis there are not more tubercle bacilli circulating in the blood than in cases of open tuberculosis of the lungs. Tubercle bacilli do not increase and multiply in the blood stream—nor do pneumococci or typhoid bacilli. It may be that the production of antibodies in the blood inhibits the growth of the bacilli, and so prevents acute military tuberculosis. If the tubercle bacilli in the blood stream are free and few in number they pass through the capillaries apparently unchanged and remain inert. Some of them may reach the tissues by the lymphatics and still remain inert. But if they are numerous and form clumps or become agglutinated with leucocytes they tend, like cocci, to cause emboli in vessels, especially the smallest, and these, with their bacilli, produce military tubercles in organs. The emboli may be large enough to form infarcts, and then to produce perplexing results; for example, cases have been reported in which hemiplegic symptoms suddenly arose, suggesting cerebral haemorrhage. In other circumstances large numbers of free bacilli may escape into organs and cause acute tuberculosis, and the lesion, for example, in the meninges, may be very similar in its histology to the lesions caused by streptococci, pneumococci, or influenza bacilli; but careful examination of the inflammatory new formation may disclose myriads of tubercle bacilli in the tissues without any tubercles. Thus tuberculosis in an acute form may be mistaken for sepsis. At the other extreme free bacilli may escape into the tissues in small numbers and cause mitosis of the fixed cells of the organ or chronic inflammatory changes of varying nature and degree terminating in fibrosis.

Possibly these bacilli have been attenuated in their virulence during their long or short career in the blood. They may even be disintegrated by the action of the blood and its antibodies and then liberate locally toxins—mainly endotoxins—which cause mild local inflammations. These vascular effects and lesions can be directly seen in lesions of the eye (conjunctiva, iris, and sclerotic coat), and their histology is different from the tubercles in the choroid first observed by Cohnheim. The same effects may be seen in the skin, but not so clearly. Thus many eye lesions and skin lesions, chronic or mild in character and apt to recur, are nothing else than the effects of tubercle bacilli lodged in these organs. Liebermeister considers that there are good reasons for thinking that similar chronic and mild lesions frequently occur in other organs beyond the range of direct vision, and produce symptoms and disturbances which we fail to trace to the true cause, sometimes because we do not

<sup>1</sup> *Handbuch der Gesamten Tuberkulose-Therapie*. Herausgegeben von Professor Dr. med. E. Loewenstein. Band I, Teil I und II. Berlin and Vienna: Urban und Schwarzenberg, 1923. (Teil I: 74 x 104, pp. 283; 26 figures, 6 plates. Teil II: pp. 756; 30 figures.)

suspect tuberculosis, and often because the specific test with tuberculin is not used. These mild secondary lesions of tuberculosis are rarely associated with the tertiary manifestations. The general symptoms of early tuberculosis—such as digestive disturbances, anaemia, loss of energy, altered pulse rate and low tension, flushings, laryngeal catarrh, and in women amenorrhoea or metrorrhagia—may be the effects of mild lesions in the digestive tract, bone marrow, nervous system, larynx, and uterine mucous membrane respectively. Like some other observers, Liebermeister has found tubercle bacilli in several cases of callous ulcer of the stomach. It follows that the successful treatment of tuberculosis demands that we should attack the disease before it has developed the tertiary manifestations. This is only possible if specific measures are adopted both for diagnosis and treatment, because the appearance of tubercle bacilli in the sputum is a relatively late event. These are the views of Professor Liebermeister, and they are not very different from the views I expounded a quarter of a century ago, but it is satisfactory to find them confirmed by Professor Liebermeister.

But because tubercle bacilli are in the blood and even in the tissues it does not follow that there is definite disease. They may remain inert or they may cause merely slight symptoms and changes. In such cases the bacilli may be few, and the natural or specific resistance of the tissues may be fair or good. But this disposition and reaction of the invaded tissues exist, though they cannot be expressed in mathematical terms. Certain tissues, such as nervous structures, muscles, and the pancreas, resist infection. The lungs, kidneys, and lymphatic glands are prone to disease, and in certain families there is a special liability to disease of a particular organ. Certain diseases (influenza and paratyphoid B) favour infection by tubercle bacilli. Traumatism is often a factor—especially in the bones and joints and epididymis. The tubercle bacilli are in the tissues or in the blood before the injury, which may be toxic or chemical as well as produced by force. Further, in miliary tuberculosis, since the tubercles are generally of the same size and age, their formation must be favoured by some predisposing cause—that is to say, the relative specific immunity of the infected tissues must be depressed.

The frequency of lung disease may be due to oft-repeated mild infections, but the source of the infection may still be the blood stream. Liebermeister thinks it probable that, except in lupus, the blood stream is probably the chief source of the infective agent. It is interesting that in Australia abundance of sunlight seems to render the skin immune. On the other hand, in children organs beyond the reach of sunlight—such as lymphatic tissues—are prone to tuberculosis; in adults these tissues are less affected. Disposition of tissue is a variable and indeterminate factor. The effect of specific treatment in tuberculous diseases of the eye affords a visible demonstration of the value of tuberculin, and there is reason for assuming that similar effects may be produced when the lesions are out of sight. In fact, the more we realize that tuberculosis is a general disease the more reason there is for applying a remedy that affects the body as a whole, and the sooner the remedy is applied the more radical the cure is likely to be. Loss of resistance may activate the tubercle bacilli at any moment, and since there is no easy way of determining the degree of resistance which exists in organs or in the body, we should be alive to the need of constant efforts to create relative specific immunity. Absolute immunity we cannot at present hope to establish, but relative. Liebermeister holds that the ordinary sanatorium measures rarely if ever secure biological cure. His opinion is summarized as follows:

"It is far more difficult to heal the established disease of an organ than to cure the general symptoms produced by disease in the blood vessels. Therefore it follows that the success of treatment is the greater the earlier the stage of the disease in the organ and the more the general symptoms are in evidence. The general symptoms accompanying the secondary stage of tuberculous disease (Petruschky, Ranke) belong directly to the domain of active and specific treatment. The early diagnosis of tuberculosis by specific tests and the prompt use of specific remedies ensures the biological cure of tuberculosis which cannot be secured by non-specific measures."

He believes that many so-called rheumatic affections of the eye are the effect of the tubercle bacillus. The term

"rheumatism" embraces a medley of joint inflammations which differ radically in their etiology—some due to gonorrhoea, others to acute rheumatism, and others again to tuberculosis. In 1909 (Weber-Parkes essay) I advanced evidence to prove that erythema nodosum should be regarded as a tuberculous infection because it reacted to tuberculin and yielded to tuberculin treatment when salicylates failed. On similar grounds I concluded that there was an asthmatic form of tuberculosis.

The view now so strongly supported by Liebermeister that there is a haematogenous form of tuberculosis is well worthy of consideration. His essay suggests an explanation of many baffling forms of chronic disorder which, in the light of the researches here recorded, may possibly be subacute and chronic forms of infection with tubercle bacilli.

W. CAMAC WILKINSON.

#### POULSSON'S "PHARMACOLOGY AND THERAPEUTICS."

A VALUABLE service has been rendered to the English-speaking portion of the medical profession by the publication of a translation of Professor Poulsson's *Textbook of Pharmacology and Therapeutics*.<sup>2</sup> The English version has been edited by Dr. W. E. Dixon, and the translation is excellent. The *materia medica* and doses have been brought into line with the British and the United States Pharmacopoeias. Professor Poulsson's textbook is a standard work in Scandinavia and in Germany and therefore affords an excellent means of comparing the therapeutic practice of those countries with the opinions prevalent in England.

Pharmacology is a science with very wide boundaries, and it is always of interest to note to which portions of the subject the author of a textbook devotes chief attention. The book under review is written rather more from the point of view of the clinician than is the case with most English textbooks of pharmacology, for chief attention is devoted to the action of drugs upon man, although adequate attention is paid to the facts discovered from animal experiment. A full account is given of the effects produced by the therapeutic administration of drugs, and the toxic effects produced by poisonous doses are also dealt with fully.

The matter is classified roughly according to the pharmacological actions of the drugs, and groups of drugs producing similar effects are placed together. The translator has succeeded in maintaining an easy and readable style throughout and gives a concise and clear account of the important actions of each of the drugs dealt with.

The book is thoroughly up to date and deals with such recently discovered substances as ergotamine, insulin, the hydroquinine derivatives, and the bismuth compounds used in syphilis.

When the opinions expressed in this book are compared with those enunciated in the leading British textbooks, the reader is impressed chiefly with the large measure of general agreement that exists. On various points, however, differences in therapeutic practice are revealed. The statement which most surprised us was that "Nitrous oxide is employed only for very brief operations, almost exclusively in dentistry—where it has now been superseded by local anaesthesia—and for relieving the pains of childbirth." This statement is apparently intended to cover both the use of pure nitrous oxide and the use of nitrous oxide and oxygen. The practice of giving ether by mouth as a cardiac stimulant is referred to as well known, although it is not endorsed by the author. The use of camphor as a cardiac and respiratory stimulant in febrile diseases is also much more firmly established on the Continent than in this country.

These differences are on the whole exceptions, and in general the therapeutic measures recommended in the book are very similar to those employed in Great Britain. Moreover, the author has succeeded in maintaining a very fair

<sup>2</sup> *A Textbook of Pharmacology and Therapeutics*. By E. Poulsson, Professor of Pharmacology in the University of Christiania, English edition, edited by W. E. Dixon, M.A., M.D., F.R.S. London: William Heinemann, 1923. (Roy. 8vo, pp. xi + 519; 32 figures. 25s. net.)

balance between the opinions of the laboratory and the opinions of the ward as regards the action of drugs.

The textbook deals with all the drugs commonly used in clinical practice, and in addition discusses the action of organ extracts, vitamins, antitoxic serums, and vaccines. It is of interest to note that polyglandular therapy is not merely a local trouble confined to England, for the author remarks, "all sorts of mystic productions have been called to life by organotherapy, and manufacturers with a keen eye to business have very readily fallen in with the demand for a specific remedy for each organ. In this way one can obtain cerebrine for diseases of the brain, pulmonine for pneumonia and tuberculosis, cardine for heart disease, oculine for eye diseases, prostatine for hypertrophy of the prostate gland, kidney tablets for nephritis, etc. Discussion of these absurdities is superfluous." As this quotation indicates, the author maintains an attitude of healthy scepticism and does not mind expressing his opinion about preparations which he considers worthless. The only criticism we have to make is that the book would have been improved by the addition of more illustrations; there are only thirty-two.

The author gives no references, which is perhaps wise, since it would be impossible for reasons of space to refer to more than a small fraction of the literature in pharmacology; it is, however, satisfactory to note that he quotes the more important British and American work in pharmacology; this is a pleasant contrast to many of the textbooks published on the continent of Europe.

Detailed criticism of an extensive textbook such as that before us is of course impossible, but enough has been said to show that this translation of Professor Poullsson's work is a valuable addition to the textbooks of pharmacology published in English.

#### OPERATIVE TREATMENT OF GLAUCOMA.

A NOOK on the operative treatment of glaucoma by an authority of such a wide knowledge of the subject as Lieut.-Colonel H. HERBERT<sup>2</sup> is sure of a welcome from all those who are interested in diseases of the eye. At an early date the author was convinced of the inadequacy of the classical operation of iridectomy as a remedy for glaucoma, and, during the early years of this century he was one of the pioneers in devising other forms of operative treatment which might afford a better prospect of cure.

Much of the book is devoted to the description and to the advocacy of a measure which aims at the production of a subconjunctival iris-prolapse through a corneo-scleral wound, and at the incarceration of the uvea in the scar. The author claims that this form of operation affords a relative certainty of relief without risk of serious hypotony, is permanent in its effect, and is a safe proceeding if due care be exercised. He recognizes, however, that if proper precautions are not taken there is an increased risk of early infective complications, including sympathetic ophthalmitis; but he argues that this risk can be practically eliminated by ensuring an effective conjunctival covering, by avoiding unnecessary traumatism of the iris, and by paying proper attention to conjunctival antiseptics. Colonel Herbert claims that this form of operation has stood the test of time; and he suggests that "in Egypt, India, and the East generally, treatment by iris-inclusion might apparently with advantage become at once the routine practice for the great majority of primary glaucomas." It is assumed that a prolapsed iris, which becomes adherent to its conjunctival covering, is, by a thickening of the membrane, fully protected against the occurrence of a late infection or of sympathetic disease; but it must be noted that such an adhesion may not occur if there is an early leakage of aqueous in front of the iris, and that a dangerous rarefaction of the conjunctival covering may then develop and lead to loss of protection.

Some space is devoted to a discussion of the conjunctival changes associated with the passage of the aqueous through

a scar beneath the membrane, and to the evil effect which follows an over-stretching of the tissue caused by an inability of the fluid to diffuse readily into the surrounding subconjunctival tissue. The author considers that the aperture made in sclero-corneal trephining and the drainage afforded by the operation are the worst conceivable with regard to the danger of late infection.

It is difficult to accept Colonel Herbert's view that the iris-inclusion operation he recommends is relatively free from the risk of sympathetic disease. Many, if not the majority, of the operations on which he bases his conclusions appear to have been performed in India. Sympathetic ophthalmitis rarely occurs in that country, even in those cases in which one would most expect to see it. He admits that the prolapsed uvea does not always become attached to the covering membrane, and that localized vesicular changes may then develop in the conjunctiva and render the eye liable to a late infection. The deliberate induction of a prolapse of the uvea—even though it is protected by intact conjunctiva—must appear a most dangerous proceeding to the majority of ophthalmic surgeons; if the integrity of the covering cannot be guaranteed in every case, it will be judged to be all the less appropriate. The prospects of a patient attacked by sympathetic ophthalmitis are so dreadful that any operation which needlessly incurs the smallest risk of the disease should be condemned without hesitation.

The value of the author's criticisms upon the operation of trephining is qualified by his admission that he has never himself practised the method, and that his experience of the results of the operation is limited. His picture of the type of subconjunctival diffusion which ordinarily follows a properly performed trephining will not be accepted by those surgeons who have had experience of the operation. He acknowledges that the diversity of the results in different hands shows that imperfect technique has been responsible for some of the late infective danger. That this danger is often exaggerated is shown by the fact that some surgeons who were formerly inclined to magnify it have with further experience completely altered their views.

The author's wedge-isolation operation and small flap sclerotomy are of value, and his description of these and the discussion upon their indications will be read with interest. The book contains many valuable hints upon points of technique which are applicable to most operations in which the eyeball is opened; it will be read with pleasure by all ophthalmic surgeons, although it is likely that few of them will feel inclined to agree with the author in his views upon the safety of an iris-prolapse operation.

#### A VETERINARY ENCYCLOPAEDIA.

DURING recent years veterinary literature in England has been more inclined to specialize, and the textbooks which the general practitioner and the student have had as works of reference have been, with a few exceptions, translations from foreign publications. The truth, of course, is that the subject is so vast, and the veterinary surgeon of the present day has so many animals to deal with, that it is a matter of great difficulty to put together in a book of reasonable size even a summary of the different diseases to which each animal is liable.

It has to be remembered that the animal physician has to deal with patients whose anatomical arrangements vary very much, and whose digestive and other physiological attributes are often equally variable in individual species. For this reason the varieties of ailment are many, and the symptoms often of an entirely different character. Besides this, each class of animal has its own idiosyncrasies to drugs.

The veterinary profession owes Professor WOOLDRIDGE a debt of gratitude for the immense labour which he has put into the compilation of the *Encyclopaedia of Veterinary Medicine, Surgery and Obstetrics*<sup>1</sup> which has just been

<sup>2</sup> *The Operative Treatment of Glaucoma*. By H. Herbert, F.R.C.S., Lieutenant-Colonel, Indian Medical Service (Retd.). London: Baillière, Tindall and Cox. (Demy 8vo, pp. viii + 152; 31 figures. 10s. 5d.)

<sup>1</sup> *Encyclopaedia of Veterinary Medicine, Surgery and Obstetrics*. Vol. I. Veterinary Medicine; Vol. II. Surgery and Obstetrics. Edited by G. H. Wooldridge, F.R.C.V.S., M.R.I.A., F.Z.S. London: H. Frowde, and Holder, and Stoughton, 1923. (Cr. 4to: Vol. I, pp. xiv + 526 + xxiii; 143 figures, 1 plate. Vol. II, pp. viii + 450 + xxx; 205 figures, 4 plates. 45 s. net.)

published in two volumes; to it, in addition to his duties as editor, he has himself contributed a very large portion.

He has obtained the collaboration of a large number of colleagues, each a specialist on the subject on which he writes; in this way he has presented to his readers, whether medical or veterinary, a work which is up to date and of standard quality.

We cannot enter on a detailed consideration of the various sections of the book, but it is sufficient to say that they are of value, not only to veterinary practitioners and students, but also to pathologists who desire to study the comparative aspect of disease. The publishers have done their work well, and the plates are excellent.

#### SCIENCE AND PHILANTHROPY.

VARIOUS as are the types of men who do big things in pure and applied science, a certain resemblance in the temper of mind may be detected among them. They may be pricked on by ambition for fame, or money, or both, but the underlying influence ever acting is something else—easy to recognize but difficult to define, a mixture of curiosity to know why and of impatience to overcome an obstacle, a sort of pique because the problem is baffling. In the man of applied science the terms of the mental process seem to be, "The thing won't work: why won't it work? it shall be made to work." This is exemplified all through the life of Sir Alfred Yarrow which his wife has just written,<sup>5</sup> from the time when, as a boy, he rigged up a device to put out his aunt's candle, much to that lady's indignation. As a young man he undertook to build a steamboat for Lake Nyassa, fulfilling conditions other engineers had declared incompatible; later on he designed and built destroyers faster than any boats afloat, and finally—he was over 72 when it began—he made invention after invention during the war.

By reason of all his successes as an engineering inventor and constructor, Sir Alfred Yarrow became rich, and being a man in whom an ardent desire to help his fellows is combined with common sense and knowledge of the world, he studied the question of how a man might best dispose of his money with the detachment he brought to bear in designing a steamer to go up the rapids of the Nile, or in contriving how to get another knot out of a destroyer. One of his benefactions was the Yarrow Home for Convalescent Children at Broadstairs, an institution which has frequently been described in our columns. It is for the children of educated people, and the endowment was deliberately limited so that contributions from the parents should be necessary. Again Sir Alfred Yarrow made, subject to certain conditions, the initial gift which rendered possible the erection of the new out-patient department at the London Hospital; one of the conditions was that every out-patient (children excepted) should pay something towards the expenses of material, though medical advice should be free. It was found that nine out of ten patients were ready to give something; this was twenty years ago. Until the other day Sir Alfred Yarrow's chief gift to experimental science was the tank built at the National Physical Laboratory for testing the design of ships. This has been surpassed by the magnitude (£100,000) and by the conditions of the gift he made to the Royal Society last February. He directed that the fund should be administered for the Society with unfettered discretion "by the best people from time to time available," and "that the money should be used to aid scientific workers by adequate payment, and by the supply of apparatus or other facilities, rather than to erect costly buildings, because large sums of money are sometimes spent on buildings without adequate endowment, and the investigators are embarrassed by financial anxieties." The donor went on to record his "firm conviction that a patriotic citizen cannot give money, or leave it at his death, to better advantage than towards the development of science."

The book contains a large number of pictures which really illustrate the text.

<sup>5</sup> *Alfred Yarrow: His Life and Work*. Compiled by Eleanor C. Barnes (Lady Yarrow). London: E. Arnold and Co. 1923. Demy 8vo, pp. xv+328; illustrated. 10s. 6d. net.)

#### NOTES ON BOOKS.

WE have received the first two volumes of a collection of reports written by various members of the Pará Public Health Service and edited by Dr. H. C. DE SOUZA ARAUJO<sup>6</sup> to commemorate the centenary of the independence of Brazil. The first volume contains a frontispiece which appropriately consists of a portrait of Oswaldo Cruz, to whose pioneer work in the domain of sanitary science in Brazil we recently drew attention (March 3rd, 1923, p. 391). The history of rural sanitation in Pará down to 1920 is related by Dr. J. A. Dias Junior, who ascribes the remarkable decline within recent years in the prevalence and mortality of malaria to improved sanitation. Dr. B. L. Rutowicz gives a description of the hospitals at Belem, the capital of Pará; the water supply, sewage system, markets, and slaughter-houses of the town each forms the subject of a separate report. Special mention should be made of that by the director, Dr. J. Aben-Athan, on the recently established Institute of Hygiene at Belem, which combines the functions of a State laboratory with those of a Pasteur institute; it has seven sections devoted respectively to cop., . . . . . venereology, immunology, chemistry, . . . . . dermic products, and treatment of rabies. Three inquiries undertaken at the institute are reported—on the principal causes of error in the Wassermann reaction, on the results of treatment for rabies, and on a new method of cultivating the gonococcus and preparing antigenococcus vaccines. Considerable interest also attaches to the report by Dr. Araujo on the frequency and extent of helminthiasis and malaria in the State of Pará, as well as on the prophylaxis of other diseases, especially small-pox and plague. The second volume<sup>7</sup> is devoted to an account of the prophylaxis and treatment of leprosy and venereal disease in Pará. The editor describes the organization of the service for the treatment of venereal diseases and an institution recently established at Belem. The volume is illustrated by numerous photographs of the hospitals, sanatoriums, dispensaries, and municipal buildings of Pará.

We noticed the appearance of the seventh edition of Professor Hawk's *Practical Physiological Chemistry* only some sixteen months ago; the eighth edition,<sup>8</sup> which has now appeared, has been revised and some additions have been made. The book, however, remains very much the same as it was before, and is an excellent work for the student and of value to the general practitioner who wishes to become acquainted with present-day methods.

We have received a copy of the sixth edition of a *Tabular View of the Income Tax and Super Tax from 1842 to 1921*.<sup>9</sup> The information given is in a condensed but easily intelligible form and will be found useful by many taxpayers. The publication has been brought up to date and we can recommend it to anyone requiring an abbreviated statement for reference, though, in our opinion, something would have been gained by expanding the "Reminders and Advice" at the expense of crowding out some of the information as to the early income tax rates—for example, the fact that the maximum rate of tax fell from 7d. to 5d. in the £ in 1858 does not assist a perplexed taxpayer greatly in these days, nor is it conducive to that peaceful frame of mind appropriate to the task of rendering a return for income tax purposes.

"In Geography there is still much to be desired." So wrote Miss Barbara Pinkerton from her academy for young ladies on Chiswick Mall to the parents of Amelia Sedley, when Amelia and the last century were both in their teens. Geography was a very dry "subject" then, and the idea of making it a pleasure would have horrified Miss Pinkerton; it was not made very interesting in our own school days. Fortunate, therefore, is the child of to-day whose teachers put into his hands such attractive little textbooks as the *Junior Regional Geographies*, of which Book II, *The British Isles*,<sup>10</sup> has (for some reason or another) been sent to us for notice. According to the joint authors, Mr. W. H. BARKER and Mr. LEONARD BROOKS, the aim of this series is to furnish "a preparatory course for more advanced regional studies." It is intended for use in the upper classes of elementary schools and the lower forms of secondary schools.

SATURDAY, JUNE 23RD, 1923.

### VACCINE TREATMENT OF TUBERCULOSIS BY A NEW METHOD.

As to the efficacy of vaccines in the treatment of bacterial infections there have been many opinions, but there must be few who have not felt some degree of disappointment at the slow and limited progress which has followed the classical researches of Pasteur and of Koch. The methods described by Professor Dreyer in the paper an account of which is given at page 1065 aim at the removal of one difficulty, and probably an important difficulty, in the production of active immunity.

If antibodies are to be produced it is essential that the antigen should come into intimate contact with the cells of the body of the patient. Dreyer assumes that the absorption of bacterial antigens is hindered by the fatty envelope by which the body of certain classes of micro-organisms is surrounded. This fatty envelope is intimately associated with the staining properties of those bacteria which we designate "acid-fast" or "Gram-positive." It is for this reason that antibody formation has been more readily evoked by the injection of Gram-negative bacteria, and that comparatively little success has been obtained by the inoculation of emulsions of acid-fast or Gram-positive varieties.

The essential feature of the investigations lies in the separation of the more soluble constituents of the bodies of bacteria from the relatively insoluble fatty and lipid substances which form the bacterial envelope. The greater part of the experimental data is concerned with the tubercle bacillus, and the methods employed in the case of this micro-organism are described in detail. Tubercle bacilli obtained from a glycerin broth culture are treated in the way outlined at page 1066, and eventually a product is obtained which is entirely non-acid-fast and is described as a "defatted antigen." In the case of Gram-positive bacteria, such as staphylococci and the anthrax bacillus, the object of the method is to obtain a product which has lost the property of retaining the stain by Gram's method.

The defatted antigens are either suspended in saline and used for the production of active immunity by injection, or digested with trypsin for the preparation of a reagent suitable for use in precipitation or complement fixation experiments. Rabbits injected with the defatted products of the tubercle bacilli developed antibodies which could be demonstrated by precipitation, complement fixation, and agglutination experiments. The published experiments show that animals injected with defatted antigen produce a serum which reacts not only with the defatted antigen but also with a recognized antigen of the usual type prepared from tubercle bacilli. For this purpose Boquet's and Nègre's antigen was chosen. On the other hand, the defatted antigen reacted *in vitro* not only with the serum of animals which had been injected with this defatted antigen, but also with the serum of animals which had been injected with an ordinary emulsion of living tubercle bacilli. Suitable control experiments,

in which normal serum and immune serums other than antituberculous serum were employed, were of course made. These experiments showed that the defatted antigen was specific, and could be used with success for the production in experimental animals of antibodies to the tubercle bacilli. Moreover, the antigen after treatment with trypsin proved to be a very useful reagent for the detection of antibodies in the blood of tuberculous animals. Apart from the all-important therapeutic possibilities of this new preparation, it seems probable that a significant step has been made towards obtaining a trustworthy serum test for tuberculous disease. It is worthy of note that, while well marked serum reactions took place in mixtures of the antigen both with the serum of animals injected with this antigen and with the serum of animals injected with living tubercle bacilli, the most pronounced reactions were obtained with the serum of animals which had been injected with living tubercle bacilli and were subsequently given doses of the defatted antigen.

The most interesting and at the same time most important of the experiments are those which related to the treatment of tuberculous guinea-pigs with defatted antigen. Full details are given of experiments on four guinea-pigs. These animals were infected with a strain of living tubercle bacilli. The culture which was used is, on the whole, of slight virulence, and has usually produced death in four to ten months after infection. In the first experiment described, treatment was commenced twenty-eight weeks after infection. The animal then weighed 630 grams, some 200 grams less than the average weight for its age. The spleen was large, and could easily be felt, and there were three or four enlarged glands in the inguinal region. Treatment consisted in ten injections of defatted antigen at intervals varying from three to thirteen days. The whole treatment occupied eighteen weeks. Two weeks after the cessation of treatment the animal looked perfectly healthy, and was of normal weight for its age (906 grams). As a result of treatment the animal gained 300 grams in twenty weeks. The spleen and glands seemed smaller. In two other animals satisfactory results were obtained. In the fourth animal considerable improvement was observed as the result of treatment, but the animal died shortly after the birth of young. The histological appearances of the organs of this animal presented an appearance of anaemic necrosis with fibrosis.

Encouraging results were also obtained by the treatment of tuberculous rabbits with the defatted antigen. Professor Dreyer is careful to point out that only time can show whether this beneficial effect is permanent, and that to attain certainty it will be necessary to watch the animals for a long period without further treatment, and then kill them and make a search for tuberculous lesions in their organs. Nevertheless, the results obtained are very striking. The susceptibility of the guinea-pig to the tubercle bacillus is well known, and the results already obtained are sufficient to justify considerable confidence in the value of the method.

As regards the treatment of human disease, a beginning has been made. A few cases have been treated at the Brompton Hospital, and 60 cases are under treatment at the London Hospital; the interim report on these cases by Drs. Fildes and Western is quoted in full at page 1067. They have observed in nearly all cases improvement which, in their opinion, is of an order which exceeds obviously that obtainable by any other form of treatment applicable to these conditions. It is, of course, too soon to attempt to express any

judgement on the results obtained on human cases of tuberculosis, but the experiments carried out on animals justify us in entertaining great hope of the efficacy of this method, and we shall look forward with the greatest possible interest to the full report of the first batch of cases treated.

The possibility of a cure for tuberculosis which is contained in Dreyer's work is of such outstanding importance that we have given little space to the consideration of the results obtained with other bacteria. But from a theoretical, and eventually perhaps from a practical standpoint also, the most interesting observations are those concerned with the anthrax bacillus. Pasteur had succeeded in attenuating the virulence of this micro-organism by growing cultures at 42° C. Dreyer has shown that when grown at this high temperature the anthrax bacillus loses its capacity to retain the stain by Gram's method. Moreover, by suitable experiments Dreyer has demonstrated that bacteria from cultures grown at 42° C. are more readily killed by both normal and anti-anthrax serum than bacteria from cultures grown at 37° C. The attenuation of virulence produced by growth at the higher temperature is thus associated with and presumably directly caused by the loss of the fatty envelope.

In this experiment may lie an explanation of such success as has been hitherto achieved by the vaccine treatment of bacterial infections. To many people it has seemed remarkable that a patient grievously ill from the presence of millions of micro-organisms in his tissues should be expected to benefit from the subcutaneous injection of a few millions of the same micro-organism grown on an agar slope. Dreyer has shown that the *Staphylococcus aureus* and the anthrax bacillus grown on artificial media have more resistance and a thicker envelope of fat when grown at 37° C. than at 42° C. It is possible that micro-organisms, when actively pathogenic in the human tissues, may have envelopes thicker still, and so possess still greater powers of resisting antibacterial substances than micro-organisms growing on artificial culture media even under the most favourable conditions which we can contrive. The favourable effect of the injection of a vaccine seems to be due to its providing the tissues of the patient with micro-organisms which are more easily soluble, and hence of higher antigenic value, than those already present in his tissues.

It is difficult to summarize the result of Professor Dreyer's experiments, and it is impossible to forecast the effect they may have on the further development of methods for the diagnosis and treatment of infective disease. But putting the matter at the lowest, he has made an important contribution to our knowledge of bacterial immunity, and has devised methods by which it may be obtained where hitherto it has been unobtainable. It is the originality of the methods employed and the nature of the results he has obtained which invest his communication with such great interest. It must be regarded, as we feel sure he would wish to have it regarded, as a preliminary communication. The experiments on animals are few, and the time during which these animals have been observed, having regard to the importance of the issue, is short. From the full details published it is clear that every effort has been made to avoid experimental error and the mistake of drawing premature conclusions which the facts so far established do not warrant.

It is only a tribute to the value and importance of Professor Dreyer's experiments and observations to say that we shall await their confirmation and extension with the liveliest interest. The results already obtained are few, but they are in themselves of the

greatest importance and sufficient to justify the fullest possible investigation of methods which have been employed with such striking success. It is evident that the investigation now reported is a milestone on the path of progress towards the cure of bacterial disease.

## AMBULANCE TRAINS.

FIVE years have not yet elapsed since the armistice, but many people seem already to have forgotten that the great war, endured for over four years, entailed fighting operations by the British on at least six fronts, and went through several fairly distinct phases. Furthermore, in discussions concerning its events and its possible lessons, even among those whose experience of matters was too personal not to be vivid, it is commonly easy to perceive that the speakers or writers, whichever they may be, fail to realize that, however active a part they played in matters, their experience of the war as a whole was in all cases inevitably limited either by space, owing to the nature of the work assigned to them, or by time, owing to wounds, sickness, or other causes. But for discussions on the subject to be fruitful, or for lessons to be soundly drawn, the knowledge on which the two are based should extend to all the fronts concerned and to all the phases that the war as a whole underwent.

This is why we are disposed to welcome the short history of the early days of British ambulance trains in France, by Colonel G. A. Moore, C.M.G., M.D.<sup>1</sup> It is of special value for two reasons in particular: in the first place because it deals with a phase of the war of which few, even of its veterans, had any experience, seeing that the whole British force at the time was not much larger than some of the latter-day army corps; and in the second place because here and there in its pages is to be found internal evidence—to adopt the phrase of the old theologists—that most of it must have been compiled almost contemporaneously with the events that it records. In the memory of most medical men who served in France, as in that of most combatants and most departmental officers and men, the term "ambulance train in France" must mean a long corridor train, of which all parts, when the internal doors were open, were visible from end to end, its different compartments fitted with close equivalents to ordinary ambulance vans, provided with heating arrangements, possessing facilities for the performance of operations when necessary, and carrying an ample staff of nurses. An ambulance train in France must seem to them to have been—as in fact for several of the later years it was—a moving hospital on wheels. But this, as some must recollect, and as Colonel Moore clearly shows, was not always the case. In the first six months of the war there were no hospital trains in France in the sense in which that term was used at a later date; the nearest equivalent to them was a train made up of carriages, 1st, 2nd, or 3rd, whichever could be got, in which the patients sat or lay on the ordinary seats to be found in such compartments. At an earlier period still the difference was even greater; there might be one or two passenger coaches, but the bulk of the train consisted of luggage and freight vans fitted up for lying-down cases by Brechot stretcher apparatus. That this was the case was no fault of the Army Medical Department nor even of the War

<sup>1</sup> *The Birth and Early Days of our Ambulance Trains in France, August, 1914.* By Colonel G. A. Moore, C.M.G., D.S.O., M.D. Second edition. London: J. Bale, Sons, and Danielsson, Ltd. 1922. (Med. Bro. pp. 24; 5 plates. 1s. net.)

Office. The two combined had gone as far as could be expected by providing in anticipation of a great war an adequate supply of Brechot apparatus, and by sending it over to France in one of the very first ships to sail after war was declared. To have provided hospital trains such as those eventually formed would have been impossible, partly owing to lack of knowledge as to the exact kind of vehicle required, partly owing to the impossibility of finding in England sidings sufficiently large to hold any considerable number of trains so lengthy as a hospital train. When the occasion for their use arose it was only little by little that exact knowledge was gained of the requirements in respect of accommodation, the number of patients that could conveniently be carried, the height of the carriages from the ground, the right kind of heating, the engine power required, and other technical details.

The change from the initial to the second form of hospital train was due chiefly to the immense energy of twelve medical officers and some forty-five of the rank and file told off for train work, but also to the good temper of the French officials of one kind and another. They allowed the English to beg, borrow, and steal coal carriages wherever they could find them, at a time when the French themselves were very hard up for like accommodation, owing to so much of the rolling stock of the French railways having been sent to the South of France to be out of the way of the enemy. Whether the British soldier actually gained very much by the change in respect of having his chances of eventual recovery increased is perhaps more open to question than might at first seem to be the case. The question is perhaps impossible of solution. There can be little doubt that his comfort was increased and suffering diminished, but the two classes of train did not bring down men in directly comparable condition. The later type carried men who for the most part had already received all the active surgical treatment they required; most of the occupants of the earlier trains arrived at the base straight from the field ambulances, the casualty clearing stations of the time being then few in number and embryonic in point of development. The patient was still more or less dull from the initial shock of his wound, but had undergone no further shock such as operation must cause. No doubt, of course, the later system was infinitely superior, inasmuch as among the men it brought down a much larger percentage finally recovered. In view of the introduction of air fighting, it is impossible to foretell what part of the mechanism of warfare will at some future date be useful, but remembering that front lines will always have to be cleared of sick and wounded, and that the Brechot apparatus can be fitted into any kind of vehicle on wheels, there is room for the belief that this apparatus or its equivalent will be found playing a part in future wars, whatever else may disappear.

#### THE ASSOCIATION'S HOUSE.

THE Supplementary Report of Council printed in this week's SUPPLEMENT contains a piece of information which, though necessarily guarded in its terms, will be recognized by every member as something of the greatest significance for the future work of the British Medical Association. We refer to paragraph 266, headed "Association Premises." The announcement is brief, but to the point. It will be followed in due course by a full statement which there is every reason to hope will receive the cordial approval of the Association at large. To those acquainted with the

work carried on at 429, Strand, it has become evident in recent years that these premises are inadequate for the greatly increased and still increasing activities of the various departments. One result of this has been that accommodation, originally meant for the use of members generally, has been absorbed for office purposes in order to meet urgent demands upon the limited space available. Meanwhile, and for the same reason, notwithstanding the growth in the number and work of committees and sub-committees, rooms intended for committee meetings have had to be taken over for business purposes. Expansion of the existing premises was found not to be feasible. The urgency of the situation was represented to the Council in April, and the Council, after full consideration, decided that the time had come when steps should be taken towards securing a British Medical Association building, not merely adequate for immediate office requirements, but sufficient to provide accommodation for future needs and developments. As a result of very full inquiries it was possible to make a definite report to the Council on June 13th, and the outcome—so far as can be announced at the moment—is recorded in the Supplementary Report of Council.

#### THE SERVICE OF EXPERIMENT TO PRACTICAL MEDICINE.

THE address Sir Walter Fletcher gave at the opening of the new biochemical laboratory at St. Thomas's Hospital well deserves to be read and filed for future use; it is printed in full at page 1068. He takes, if we may presume to say so, the right line in the discussion of the services scientific medicine is rendering to human welfare. It may be all very obvious to persons of scientific training, however far their particular line of work may be from biology or medicine, but we are apt to forget how small a proportion of even the educated public possesses such training. Sir Walter Fletcher instanced the use of insulin, which is obstructed by a regulation that animal experiments may be done at the medical college but not in the hospital, although they are done directly for the hospital and although the hospital cannot do its work without them. As he truly said, in tending the sick and suffering we can show no effective mercy without knowledge, and this knowledge can only be gained by the study and pursuit of truth. Ought we not to say boldly, as Sir Walter Fletcher implied, that the action of those who do all they can by falsehood and innuendo to hamper the advance of knowledge is, in this matter of preventing, curing, or alleviating disease, gross inhumanity? The excuse made for such persons is that they are ignorant. If only they would make barren ignorance their gaoler! But they do not. They rush from platform to platform shouting their infamies, revelling in false stories of cruelty until they come under a form of obsession not wholly unlike that of which the miserable sadist is a victim.

#### PREVENTION OF OPHTHALMIA NEONATORUM IN DENMARK.

WE have received through the Ministry of Health a communication written by Dr. Gordon Norrie, vice-president of the Royal Danish Board of Health and oculist to the Royal Danish Institutes for the Blind, after reading the final report of the Departmental Committee on the Causes and Prevention of Blindness. He rightly thinks that information on the methods established in Denmark for the reduction of ophthalmia neonatorum and blindness resulting therefrom may be of interest "in the country of his ancestors." In the Royal Lying-in Hospital at Copenhagen Credé's method was adopted as a routine practice in 1832, and with the best results. From the year 1835 he himself instituted propaganda with a view to making the method compulsory upon all midwives, and since 1900

every midwife is required immediately after birth to instil a solution of silver nitrate (1 in 150) into the eyes of the child. The midwife is forbidden to wash the eyes before the instillation, as it is considered that some infectious matter may thus be washed into the eyes; midwives are taught to wipe the eyelids with dry gauze or cotton-wool. In Denmark midwives assist at almost every delivery, and it is rarely that a doctor alone is present. A legally regulated midwifery system has existed since 1714; the midwives undergo a strenuous training for one year. He writes of them as "excellent." Until the year 1857 private effort provided for the training of blind children, but in that year the State opened the Royal Blind Institute (Det Kongelige Blindeinstitut) in Copenhagen. Education of blind children at the institute is not compulsory, but with rare exceptions application for admission is made in the case of every blind child, so that the figures for the institute give the number of blind children in the country. They are admitted at the age of 10 to 11 years; but for the past twenty-five years there has been a preparatory school at the seaside sixty miles from Copenhagen to which children from 6 to 7 years of age are admitted, and some two years ago at the same place a home for blind babies was opened. Dr. Norrie has charge as ophthalmic surgeon of these three schools for the blind. A table is given showing the difference in the incidence of blindness from ophthalmia neonatorum before and after 1900, the year of the institution of compulsory prophylaxis. In the twenty-five years 1875-99 the total number of cases was 55; the highest number (15) occurred in the quinquennium 1890-94, and the lowest (7) in 1880-84. In the first quinquennium after compulsory prophylaxis was established there were 16 cases, and Dr. Norrie attributes this failure to insufficient instruction of the midwives. In the succeeding quinquennia the number of cases were 3, 3, and 1, and there was one case in 1920. The expectation of blindness from this disease is now no more than one case every other year, a very good result for a country with a population of three millions and a quarter. He does not expect this cause of blindness to disappear altogether, for "it is impossible by prophylaxis to prevent the infection taking place at the time of birth." He adds that he has never seen a case of blindness due to small-pox, for in Denmark vaccination has been compulsory since 1810.

#### HYPERPLASIA OF EPITHELIAL AND CONNECTIVE TISSUES OF THE BREAST.

SIR GEORGE LENTHAL CHEATLE's researches on the changes which take place in the breast as a prelude to the later development of papillomata and of duct and acinous carcinomata have been reported in this journal (*BRITISH MEDICAL JOURNAL*, June 3rd, 1922), and the recent paper which he has published in the *British Journal of Surgery* (vol. x, No. 40, 1923) deals with the development of the hyperplasia of the connective tissues of the breast, which he classifies under three heads according to its relation to the layer of elastic tissue which surrounds the ducts and acini. "Hyperplasia intra-elastica" mainly occurs in the delicate connective tissue which lies immediately internal to the elastica in the ducts and acini, and occurs in breasts of women over 30; it may manifest itself as a diffused condition affecting the whole length of a duct and all or some of the acini from which it leads, or as a localized tumour in a duct or in the acini. The diffused type rarely occurs in breasts in which no other lesion can be discovered; it may be associated with carcinoma and multiradicular papillomata, but it is important to note also that it may be absent in breasts where carcinoma and papillomata occur. The localized condition is a tumour formation which is usually superimposed on the diffused condition above described. In its simplest form the tumour forms an oval swelling

inside the elastica which bulges into the lumen of the duct, and from the intra-elastica fibrous tissue large intracanalicular fibro-adenomata may develop. When growing in acini the connective tissue around the acini may undergo hyperplasia so marked that a collection of acini thus affected resolves itself into a distinct isolated tumour and forms a fibro-adenoma. The class of cases to which the term "hyperplasia elastica" is applied exists only in the diffuse form affecting ducts and acini. There is a combined hyperplasia of the elastica and the fibrous tissue with which it is intermingled, the growth being delimited at the margin of the fibrous tissue that immediately surrounds the ducts and acini. The process is usually widely distributed, and affects most of the ducts and acini in a breast, being accompanied by desquamative hyperplasia of the epithelium. Most breasts which contain carcinomata do not show enormous hyperplasia of the elastica, and the same may be said of breasts containing multiradicular papillomata; but Sir Lenthal Cheatele declares that he has been so impressed by the hyperplasia he has noticed in "proemial" breasts and in those suffering from Paget's disease of the nipple that he would be "most careful to examine the entire breast in which there was enormous hyperplasia of the elastica before passing the gland as free from carcinoma." The third class—"hyperplasia extra-elastica"—concerns the fibrous tissue immediately outside the ducts and the intralobular connective tissue of the acini, and includes many well known varieties of fibro-adenoma of the breast. This type can be subdivided into pericanalicular and periacinous tumours, of which there is both a localized and a diffuse form, and the intracanalicular tumours. Except in the type of the diffuse fibro-adenomatosis, which occurs after 30 years of age, all forms may grow in young and old breasts. Sir Lenthal Cheatele believes that it is exceedingly rare for carcinoma to originate in a localized fibro-adenoma. Unsuspected fibro-adenomata, often only just visible to the naked eye when examining a section of a whole breast, occur in at least 28 per cent. of all breasts containing carcinoma. There are no special clinical signs of the different types of tumours described, and the chief practical outcome of these observations seems to be that it is safer to take away the segment of the breast in which fibro-adenomata grow. Although the different forms of hyperplasia are described as three distinct classes, any one class may be complicated by the presence of some pathological changes of another order, and all the pathological changes to which attention has been drawn may, in fact, be phases of a consecutive evolution of disease. Lastly, the author insists that all hyperplasia of epithelium confined within the ducts of the breast is not necessarily benign.

#### THE HISTORY OF THE CARDIO-VASCULAR SYSTEM.

THE selection of the matter for an address, seldom an easy task, requires a broad outlook in order that the varying minds in the audience may all be interested. This is perhaps best accomplished by choosing a relatively common disease or condition and reviewing the most recent views thereon. In his historical sketch of the heart and circulation given before the Queen Margaret Medical Club Dr. G. A. Allan<sup>1</sup> of Glasgow has adopted this course. Beginning with Egypt, B.C. 1400, he points out that the word "heart" is derived from a Sanskrit word meaning "to leap," and that the Egyptians regarded the heart as the seat of life and the source of good and evil thoughts, and that the individual's claim to everlasting life would be tested by the weighing of the heart, which should not be removed from the body during the process of embalming. After glancing at the views of Hippocrates, Aristotle, and Erasistratus of Alexandria, who described the valves of the

<sup>1</sup>Allan, G. A.: *Glasgow Med. Journ.*, 1923, N.S. xvii, 296-313.

heart, Galen's doctrines on the cardio-vascular system, which held the field for 1,400 years, are explained. The first to dispute his authoritative statements was Leonardo da Vinci, who discovered the action of the cardiac valves and threw doubt on the passage of blood through the interventricular septum. The next advance came from an unexpected source—the bitter disputations connected with the Reformation—for in his *Restitution of Christianity*, which was responsible for his martyrdom, Michael Servetus (1553) clearly described the lesser circulation through the lungs. The weakness of the claim made for Cæsalpinus that he anticipated Harvey's great discovery is briefly explained, and then a quotation from Shakespeare is utilized to show the popular conception of the circulation at the time of Harvey's demonstration. In the three hundred years since then percussion and auscultation, of which the latter was advocated by William Stokes of Dublin in 1825 in his *Introduction to the Stethoscope*, are milestones which lead up to the use of instruments of precision; Dudgeon's sphygmograph of 1860 was expanded into Mackenzie's ink polygraph; Marey in 1876 laid the first foundation of Riva-Rocci's sphygmomanometer; and A. D. Waller's work in 1889 was followed by Einthoven's string galvanometer and Thomas Lewis's researches with the aid of the electrocardiograph. The description of the auriculo-ventricular bundle by Stanley Kent (1892) and by His (1893), Tawara's account of the auriculo-ventricular node (1904) and Keith and Flack's discovery of the sino-auricular node are further landmarks worthy of permanent recollection. In answer to the self-imposed question, "What amount of work is accomplished by the heart?" Dr. Allan calculates that during seventy years the heart drives out about 250,000 tons of blood.

#### VITAL CAPACITY.

Dr. JOHN HUTCHINSON, in 1846, suggested that the volume of maximum expiration following a maximum inspiration, which he called "vital capacity," was a valuable measure of physical fitness; he tried to establish precise quantitative relations between vital capacity and other physical measurements. From observations on 2,130 persons of varied classes, but all considered to be healthy, he deduced that for every inch of height from 5 ft. to 6 ft. eight additional cubic inches of air at 60° are given out by a forced expiration, and that the relation between vital capacity and weight was not linear throughout. He estimated that the effect of age was to decrease vital capacity by rather more than 1 cubic inch for each year. He also thought that the standing height was correlated with sitting height, and that the latter was approximately constant. He held that vital capacity was governed by the mobility of the chest rather than its volume, and endeavoured to show that disease affected vital capacity and might be detected thereby. Later Fabius of Amsterdam attempted to prove that stem length was more closely related to vital capacity than height, but the results he published do not bear this statement out. In 1858 Arnold of Heidelberg confirmed Hutchinson's conclusions, but attached more importance to chest circumference. In 1911 Dr. Edgar Schuster published in *Biometrika* the results of his observations on 959 Oxford undergraduates. The mean of the vital capacity for these was higher than in any of Hutchinson's healthy classes. Garvin, Lundsgaard, and Van Slyke investigated the vital capacity of tuberculous subjects. When their figures are examined in the light of variations in fit persons it appears that it was only in the more advanced cases of disease that the difference in vital capacity between the diseased and healthy could be regarded as far beyond the probable range of chance fluctuations. In 1919 Professor Georges Dreyer urged that stem length and not height was the appropriate correlate of vital capacity. Biological evidence led him to believe the constants to be in

proportion to body surface, and with Henson he published tables for the estimation of normal weight and vital capacity from stem length and chest circumference and for the estimation of vital capacity from weight. In a recent paper<sup>1</sup> in *Biometrika*, Cripps, Greenwood, and Newbold have made an attempt to show how closely vital capacity can be expressed as a function of stature, sitting height (stem length), and body weight, by linear equations or simple exponential functions. They obtained measurements of 1,238 candidates for commission in the Air Force. They analysed the sample and repeated the analysis on the measurements of candidates passed as fit. Very little difference was found between the constants of the whole sample and of this selection. From a comparison of the coefficients of correlation and the correlation ratios they inferred that the regressions were not strictly linear, though nearly so. A large number of technical analyses were made, involving the computation of many regression equations. The conclusions they draw are that, taking vital capacity as the dependent, and weight and height as the independent variables, multiple linear regression formulae gave slightly closer results than the "rational" formulae of Professor Dreyer, and that the former method has the advantage of showing the extent of the improvement in the estimate of vital capacity by the use of more independent variables. Their results agree substantially with Hutchinson's and show no advantage in the substitution of stem length for height. A further conclusion is that "upon the evidence now available it does not appear that either biometric or 'rational' formulae can deduce from the non-physiological or ordinary anthropometric constants, estimates of normal vital capacity confined within sufficiently narrow limits to possess real prognostic value in individual cases."

#### ANNUAL DINNER OF THE HARVEIAN SOCIETY OF LONDON.

AN unusual number of distinguished guests attended the annual dinner of the Harveian Society of London, held at the Connaught Rooms, Great Queen Street, on Thursday, June 14th. The President of the Society, Sir T. Crisp English, presided at the dinner, and 137 members and guests were present. The toast of the Harveian Society was proposed by Mr. G. K. Chesterton, who modestly described himself as a journalist. He dealt humorously with the profession to which he claimed to belong and warned his hearers against attaching too much importance to the heavily typed headlines which are designed to advertise the journalist's wares. The President replied for the Society, and said that the membership of the Society was now 314, and that the average attendance of members and guests at the meetings held during the past year was 54. Sir StClair Thomson proposed the health of the sister societies, which included the Royal Society of Medicine (represented by its President, Sir William Hale-White), the Hunterian Society, the Chelsea Clinical Society, the West London Medico-Chirurgical Society, and the Kensington Medical Reading Club, represented by their respective Presidents, Sir Bruce Bruce-Porter, Dr. J. Campbell McClure, Mr. A. G. Wells, and Mr. Debonnaire Maunsell. Sir William Hale-White replied in a speech which scintillated with many appropriate little anecdotes. The toast of the guests was proposed by Dr. Charles Buttar, who referred to the wide range of positions and professions of the guests. They included Lord Elphinstone, who, as Lord High Commissioner, represents the King in Scotland; Lord Montagu de Beaulieu, a member of the Road Board, interested in aviation and motoring; Mr. J. Monteith Erskine, Member of Parliament for St. George's, Hanover Square; Sir Robert Hill, Director-General of the Medical Department of the Navy; Sir

<sup>1</sup> *Biometrika*, vol. xiv, Parts 3 and 4 (March, 1923).

William Leishman, who shortly succeeds Sir John Goodwin as Director-General of the Army Medical Service; Sir Arthur Sloggett; Sir Edward Worthington; and Sir Hercules Read, Keeper of the British Museum. Literature was represented by Sir Anthony Hope Hawkins and Mr. G. K. Chesterton; art by Sir William Llewellyn and Mr. Ralph Peacock; the law by Sir Richard Muir, Sir Edward Marshall Hall, Sir Henry Curtis Bennett, and Mr. Claughton-Scott. The Borough of Paddington, in which the Society holds its meetings, was represented by Prebendary G. N. Sharp, the Vicar of Paddington, and the Mayor, Alderman H. V. Kenyon. In reply to the toast Lord Montagu spoke of his connexion with the Road Board, comparing the traffic on the roads with the circulation of the blood, with occasional aneurysms where the thoroughfares had been widened; Sir Anthony Hope Hawkins, in a witty speech, referred to the subconscious state; and Sir Richard Muir gave his views on doctors in the witness-box. He concluded with a story of how an expert medical witness was cross-examined by a medical man in the dock. He regarded this as one of the best pieces of medical cross-examination he had heard, for what the medical man in the dock did not know about abortion would have gone on a threepenny bit. The Harveian Society of London is to be congratulated on the success which has attended its activities since the war. The Society, which is one of the oldest of general practitioner societies, is now approaching its centenary, but it displays all the energy of youth. The inclusion amongst the guests at its dinner of so many representative men from other professions is a practice worthy to be copied by other medical societies, since it will tend to establish understanding between the medical profession and those with whom it is brought into relation in questions which affect the community.

#### OXFORD OPHTHALMOLOGICAL CONGRESS.

THE fourteenth annual meeting of the Oxford Ophthalmological Congress will begin on Thursday, July 5th, when, after a formal opening by the Master, Mr. Sydney Stephenson, a discussion on the relation of dental sepsis to diseases of the eye will be opened by Mr. W. R. Ackland of Bristol and Mr. W. Lang of London. A number of members have given notice of their intention to join in the discussion. In the afternoon several papers will be read, including one by Mr. Harrison Butler on the organization of ophthalmic clinics and hospitals. On Friday morning, after the reading of two papers—one of them by Dr. Lundsgaard of Copenhagen on the Flinsen treatment of conjunctival diseases—the Doyne Memorial Lecture will be delivered by Mr. H. Moss Traquair, assistant ophthalmic surgeon to the Royal Infirmary, Edinburgh; his subject is the differential characters of scotomata and their interpretation. Afterwards a paper will be read by Professor J. Van der Hoeve of Leiden. An afternoon meeting will be held to hear papers read. On Saturday morning a discussion on coal-miners' nystagmus will be opened by Mr. R. J. Coulter, ophthalmic surgeon to the Royal Gwent Hospital, Monmouthshire. The discussion is to be strictly limited to the diagnosis of the condition from the clinical point of view and its relations to the Workmen's Compensation Act. There will be two dinners, the one on Wednesday, July 4th, and the other—the annual dinner of the Congress—on Friday evening.

#### NURSING IN FRANCE.

THE Act which was passed in France in June, 1922, and amended in February, 1923, instituting a State diploma for French nurses, after a suitable period of study and examination, recognized the new standing that nursing had gained in France during and since the war. The foundation of a monthly professional journal has now given an impetus to

the improvement of educational facilities for nurses in France and the development of a corporate spirit among them. *L'Infirmière Française* is intended primarily for nurses, but makes an appeal also to medical practitioners and others interested in the organization of nursing. It is published under the patronage of the French Minister of Health, and under the scientific direction of Professor Calmette, of the Pasteur Institute, who contributes an eloquent introduction to the first number. The other articles cover a considerable range of subjects. Dr. Courcoux writes on the feeding of tuberculous patients and of patients with a predisposition towards tuberculosis. Dr. Raymond Grégoire discusses the first dressing that should be applied to a compound fracture until the surgeon arrives. Dr. Henri Paillard contributes an illustrated article on the care of the mouth during acute infectious fevers; shorter articles are on such subjects as domestic disinfectants, and on how to put drops in the eye. A section of the journal is devoted more particularly to the professional interests of the organized body of nurses. In the first number this section includes an article on the professional moral of nurses, and another on nursing in America; the Act instituting a nursing diploma is printed in full, with comments, and answers to correspondents are given. In future it is intended to discuss month by month questions of practical importance to nurses, the contributors including physicians, surgeons, general practitioners, nurses, and other specially qualified persons. It is hoped to aid in the development of the professional knowledge of all nurses, without overstepping the limits of their normal activities.

#### NATIONAL ASSOCIATION FOR THE PREVENTION OF TUBERCULOSIS.

THE ninth annual conference of the National Association for the Prevention of Tuberculosis is to be held in Birmingham, the proceedings extending over July 12th, 13th, and 14th. There could be no more appropriate centre for this conference, for nowhere has the problem of tuberculosis been attacked more vigorously, and a tuberculosis service more efficiently and progressively administered, than in the great Midland city. The provisional programme lacks little of comprehensiveness either in the names of those who have promised to take part in the discussions or in the range of subjects embraced by the agenda. The wide field of activity covered by the programme of the conference indicates how great is the effort still necessary, more particularly in co-ordination of method in the common aim. Foremost of the subjects down for discussion is the very formidable problem of advanced tuberculosis, more especially with reference to the prevention of infection. This is a question that will have to be faced more courageously and dealt with more drastically than has hitherto been the case in this country. Hardly less in importance is the discussion on the industrial side of the question, which will occupy the morning session of the second day. There is great scope in this direction for the educational activities of the National Association, for the problem of tuberculosis in many trades is not so much a purely occupational question as one of the conditions under which work is carried on. The issues raised in this year's conference are fundamental, and the importance of the sociological aspect of tuberculosis cannot be too strongly emphasized.

THE honorary Fellowship of the Royal College of Surgeons in Ireland will be conferred on Monday next, June 25th, on Sir Harold Stiles, K.B.E., M.B., C.M., Regius Professor of Clinical Surgery in the University of Edinburgh. The ceremony, at which the President, Sir William de Courcy Wheeler, will preside, will be followed by the Charter Day dinner in the College Hall.

## A SPECIFIC TREATMENT OF TUBERCULOSIS.

ABSTRACT OF A REPORT ON  
SOME NEW PRINCIPLES IN BACTERIAL IMMUNITY AND  
THEIR APPLICATION IN REFRACTORY INFECTIONS,  
INCLUDING TUBERCULOSIS,

BY

PROFESSOR GEORGES DREYER, F.R.S.

(From the Department of Pathology, University of Oxford.)

In a lecture delivered at the Institute of Pathology and Research, St. Mary's Hospital, London, on June 14th, Professor Georges Dreyer set forth some new principles in bacterial immunity, stated their experimental foundation, and discussed their application to the treatment of refractory infections, and to tuberculosis in particular. The following account of Professor Dreyer's researches and results is founded upon the text of his full paper published in the current number of the *British Journal of Experimental Pathology*<sup>1</sup> (June, p. 146).

## GENERAL STATEMENT OF THEORIES AND RESULTS.

If the whole field of experience in bacteriotherapy and serotherapy, using those terms in their widest connotation, be reviewed, it will be perceived that in spite of the great successes obtained in some directions, notably as a consequence in this country of work done by Sir Almroth Wright and his colleagues, there is a disappointing lack of uniformity in the results. When an explanation of this is sought it is at once seen that, speaking in a general way, the great successes of bacterial therapy and prophylaxis have been won in that group of diseases—including, for example, typhoid and paratyphoids and plague—which are due to non-acid-fast and Gram-negative micro-organisms, whereas failure is the general rule in diseases caused by acid-fast and Gram-positive micro-organisms, such as *B. tuberculosis*. This generalization applies only to the bacterial bodies themselves, not to their soluble products such as toxins. The rule is not absolute; for example, partial success has been obtained with pneumococcal antiserum and with staphylococcus vaccines; yet failure is very far from rare with vaccines of Gram-negative bacteria such as the gonococcus. But although the rule does not hold absolutely, it is in the main correct.

## Bacterial Lipoids.

Since acid-fastness and Gram-positiveness have been clearly proved to be associated with the presence in the bacterium of certain waxy or fatty substances, which may be spoken of collectively as lipid or lipoidal substances, there was an *a priori* probability that the failure to produce immunization was due to them. Though little is at present known about the chemical questions involved, yet it seems possible that these substances protect the specific bacterial proteins and prevent their liberation from the body of the bacterium, thus checking or completely stopping the production of the sole adequate stimulus for the immunity reaction of the infected organism. Support for this view is to be found in certain work done by Douglas in 1921 at the National Medical Research Institute on the digestion by trypsin of bacteria extracted with acetone. He was invariably successful in digesting and obtaining immunity responses with Gram-negative bacteria, such as the dysentery bacillus, the typhoid bacillus, and the gonococcus, but the Gram-positive organisms either were not digested at all (staphylococcus) or underwent apparent digestion, but gave rise to no immune bodies (*B. welchii*).

## THEORY OF "DEFATTED" BACTERIAL ANTIGEN.

This being so, it was decided to attack the problem by attempting the removal (by extraction) of the lipoidal fraction of some representative acid-fast and Gram-negative bacterium. The tubercle bacillus was selected because it has a highly developed lipid constituent, and is, in many respects, a very robust and resistant micro-organism. A large quantity of tubercle bacilli was killed by heat and extracted with acetone. Though large amounts of lipoidal

substances were removed, the bacilli remained acid-fast. It was then recalled that a tuberculous tissue fixed with formalin often, when suitably stained, showed far fewer tubercle bacilli than the same tissue fixed with mercury perchloride. Various experiments made it plain that the bacilli could not be deprived of the quality of acid-fastness by formalin alone; in the preparation of tissues for section a number of other reagents are used, including fat-solvents such as alcohol, xylol, and chloroform. The suggestion, therefore, arose that the phenomenon might be due to the application of formalin and fat-solvents in succession to the bacilli, and this was found to be the case, the tubercle bacillus becoming non-acid-fast. As it was known that bacteria killed with formalin or extracted with acetone retain their antigenic power, there was good reason to hope that the residue of the tubercle bacilli after treatment with formalin and extraction with acetone would retain all or part of the specific properties of the bacillus and that this residue could be used for immunization. The truth of this expectation was established by numerous experiments. It was also found that it was possible to deal with other acid-fast bacteria in the same manner and to reduce Gram-positive micro-organisms to the Gram-negative condition.

## Retention of Antigen by "Defatted" Bacilli.

The next step was the demonstration of the capacity of the "defatted" bacteria to react with specific antisera, and this led on to the experimental proof of their antigenic action in the animal body, where they gave rise, on injection, to the production of well known "immune substances," such as bacteriolysins, complement-fixing bodies, precipitins, and agglutinins. It was next established that these antigens could exert definite curative effects on animals suffering from bacterial infection.

## Retention of Antigen by "Defatted" Bacilli.

In order to complete this section of the work it was thought desirable to ascertain whether this somewhat heroic process of extraction with formalin and acetone had a destructive effect on the essential antigen of Gram-negative bacteria. The *B. typhosus*, a rather sensitive micro-organism, was chosen; it was subjected to the same process as the tubercle bacillus, and it was found that it retained its ability to cause the production of immune substances. It has not been proved that none of the antigenic power is lost during the process, but it was clearly established that any loss that occurs is only partial and therefore unimportant. These observations were held to prove that the protective action of the lipid substances in the micro-organisms had a very important effect on the treatment by vaccines of the infections caused by the acid-fast Gram-positive micro-organisms, and that these "defatted" micro-organisms, when injected, would readily be digested by the body fluids, and their substances thus set free to produce the antibodies desired.

## NATURE OF "ATTENUATION."

At this point of the investigation a second and closely related train of thought suggested itself. No clear explanation has ever been given of Pasteur's classical demonstration of the immunizing properties of anthrax cultures "attenuated" by growth at 42° to 43° C. The new knowledge that "defatted" anthrax bacilli can be digested by trypsin, whereas the untreated bacilli are in the main not digested, justified the hypothesis that growth at 42° to 43° gives rise to a deficient formation of the normal "fatty" constituent, and thus renders the bacilli more easily susceptible to the digestive action of the body fluids. Such bacilli, when injected into the living body, would be, at least in part, readily disintegrated, and the release of their antigen would cause a rapid immunity-response in the animal before the Gram-positive, and therefore more resistant, bacilli developed in sufficient number to overwhelm the normal resistance of the body.

The prediction that growth at 42° to 43° would give rise to a weakening or disappearance of the Gram-positiveness of anthrax bacilli was verified by a few simple experiments not only for that bacillus, but also for a stock laboratory strain of *Staphylococcus aureus*.

<sup>1</sup> London: H. K. Lewis; Toronto: The Macmillan Company of Canada. 7s. 6d.; annual subscription 42.

## POWER OF THE LIPOIDAL SUBSTANCES TO PRODUCE LOCAL REACTION.

The formalin-acetone process which produces a relatively complete separation of "fatty" substances from the specific proteins made it possible to throw light upon another set of unexplained phenomena. It was well known that the subcutaneous injection of dead tubercle bacilli or staphylococci caused a severe local reaction with infiltration and sometimes necrosis, often unaccompanied by any noteworthy general disturbance. The observations already detailed suggested that the local disturbance might be due entirely to the highly indigestible and irritating "fatty" constituents of the bacilli and not to their specific antigenic proteins.

Subcutaneous injection into suitable animals of the acetone extracts of tubercle bacilli and of staphylococci, previously treated with formalin, showed that the theory was completely in accord with the facts. The injection into normal animals of lipoids from tubercle and from staphylococci gave rise to infiltrations which might persist for a long time; in one instance the undissolved mass of lipoids ulcerated through the skin and discharged itself, while a larger dose of "defatted" bacilli than corresponded to the dose of lipoids caused no local reaction; this was an additional proof that the lipoids of the bactericidal body formed an important obstacle to the solvent and protective action of the body fluids.

The arrows show the date of injection and the quantity.

## THE METHOD OF PREPARING "DEFATTED" ANTIGENS.

The method by which Professor Dreyer prepares "defatted" antigens is fully described in his paper in the *British Journal of Experimental Pathology*, and those who propose to follow in his footsteps will refer to this; we propose here to give only some general indications. It is to be remembered that the term "defatted" is not intended to indicate that all the lipoidal substances present in the micro-organisms have been removed, but merely certain lipoidal substances, soluble in acetone after formalin treatment. In the case of the acid-fast and Gram-positive bacteria the indication that the extraction

has proceeded far enough for the purpose is the change of the staining reactions to non-acid-fastness or Gram-negativity respectively.

Tubercle bacilli are grown on the surface of glycerin broth or other suitable liquid medium for two or three weeks; the fluid is decanted off and the mass of tubercle bacilli ground up into a paste in an agate mortar with a few drops of formalin. More formalin is gradually added with constant grinding until 150 to 200 c.c.m. of formalin have been added to each 5 grams of bacilli weighed wet. The suspension of tubercle bacilli in formalin is heated in a flask to 100° C. for four hours, filtered, and the residue washed three or four times with a acetone. The suspension is then filtered through calcium-free paper and the residue extracted three or four times with acetone, and then in a Soxhlet apparatus. The insoluble residue is dried and ground in a sterile

mortar. A weighed quantity of the extract is ground up with sterile saline solution into a paste, more saline being added during the grinding; it is then centrifuged. The supernatant fluid is pipetted off and when diluted with saline containing formalin constitutes the antigen suspension. The actual weight of "defatted" organisms is ascertained by methods which are fully described, and the fluid suspension is so adjusted with saline that one cubic centimetre contains one-fifth of a milligram of dry "defatted" tubercle bacilli. Suspensions

The arrows show the date of injection and the quantity.

for use are made up to contain a definite weight of "defatted" tubercle bacilli per volume of fluid, the actual proportion varying with the purpose for which the injection is to be made.

## Digestibility by Trypsin.

Although it is generally accepted that proteins after treatment with formaldehyde cannot be digested with trypsin, this does not apply to the "defatted" micro-organisms, but the rate and completeness of digestion depend on a number of factors as yet undetermined. The irregularities appear to be more pronounced with the tubercle antigen than with the others.

### Production of Immune Substances by "Defatted" Antigen.

Four rabbits were injected with "defatted" tubercle bacillus antigen and developed, in varying degrees, anti-substances the presence of which in the serum was demonstrated by test tube experiments. These substances were complement-fixing bodies, precipitins, and agglutinins. So far as complement fixing was concerned, it was clearly established that tubercle bacillus antigen is specific in its reaction not only with the serum derived from a horse immunized with whole tubercle bacilli, but also with the serum of a rabbit suffering from tuberculosis. A precipitinogen was prepared by digesting "defatted" tubercle bacilli with trypsin, and proved to be specific in its reaction. It was also ascertained that the injection of "defatted" antigen into normal rabbits caused the production of specific agglutinins, and that these substances were present also in the serum of animals infected with tubercle bacillus, whether they had or had not received subsequent injection of "defatted" antigen.

### EXPERIMENTS ON INFECTED ANIMALS WITH "DEFATTED" TUBERCLE ANTIGEN.

Experiments were performed with a view of studying the therapeutic effects of "defatted" tubercle antigen on animals suffering from well defined tuberculosis. In his paper Professor Dreyer gives full details of an experiment on four guinea-pigs inoculated with tubercle bacillus of the human type, but of low virulence. Animals infected with it usually die in six to eight months after infection, the extremes being four to ten months, and *post-mortem* examination has invariably shown generalized tuberculosis affecting the spleen, liver, lungs, and lymph glands.

One guinea-pig (No. 4, male) was inoculated with this strain on June 15th, 1922; treatment was begun twenty-eight weeks later (December 29th, 1922). The animal was then under the average weight for its age, the spleen was large, and there were enlarged glands in the inguinal regions, three or four in the right and one or two on the left. Injections of "defatted" antigen were given at the dates indicated by the arrows in Chart I. Twenty weeks after the beginning of treatment the animal looked healthy, was of the normal weight for its age, the spleen was smaller, the glands on the right side had become smaller and harder, and on the left had practically disappeared, being replaced by what felt like a pad of fibrous tissue. This was forty-eight weeks after inoculation; had it been untreated the animal would have been expected to die within ten months (about forty-two weeks) from the date of infection.

Another guinea-pig (No. 26, male) was inoculated with the same strain of tubercle bacilli some months before treatment was begun. The animal, though it looked healthy, presented an enlarged spleen and large masses of glands in both inguinal regions. As will be seen from Chart II the animal, after an initial fall, steadily gained weight. Eight weeks after the beginning of treatment the glands in both inguinal regions had entirely disappeared.

A third guinea-pig (No. 28, male) thirty-nine weeks after inoculation with tubercle bacilli was greatly under weight, had an enlarged spleen, and large glands in both inguinal regions, one of which was ulcerating and discharging caseous material. Four days after the first injection the ulcer was smaller, and after six days more had healed. Within twenty-four hours after the second injection the scar had broken down, but healed again within a week; by this time the glands on both sides had become smaller. After the third injection the scar again opened in about sixty-six hours, but healed in six days. This occurred again after the fourth injection, and after the sixth and seventh. Four months after the treatment was begun the glands were greatly reduced in size, the ulcer was soundly healed, but the animal had decreased in weight (Chart III).

A fourth guinea-pig (No. 27, female) was inoculated and treated in a similar manner, but the experiment was vitiated by the animal becoming pregnant. After littering it went rapidly downhill and died on the fifth day. The cause of death was not ascertained; the heart blood was sterile. Its organs were carefully examined by Dr. A. G. Gibson, whose detailed report is published in the *British Journal of Experimental Pathology*. The organs affected were the inguinal and axillary lymphatic glands, the liver, the lungs, and the spleen. The lesions in all were tuberculous granulomata; very few tubercle bacilli were found in the sections. All the lesions, especially those in the liver, showed abundant fibrosis, and throughout there was an absence of the lymphocytic reaction seen in active tuberculosis. Dr. Gibson observes that "the presence of giant cells, together with the increase of fibrous tissue, lend support to the evidence which points to a tendency to heal."

Experiments were also made on four rabbits, three being submitted to a course of treatment with "defatted" tubercle antigen, while the fourth served as a control. These experiments, which have extended over three months,

are not yet regarded as complete. The animals were inoculated with living bovine tubercle bacilli: the results in the three animals treated appear to indicate arrest of the disease; in the control animal it had made slow progress. The conclusions Professor Dreyer draws from the results of treatment of animals are expressed in the following terms:

"The experiments just described justify, in my opinion, the conclusion that treatment with the 'defatted' antigen brings about a definite improvement, both general and local, in animals infected with *B. tuberculosis*. Additional evidence for this view is given by the guinea-pig No. 27 which died, for its organs show what seems indubitably to be a healing of tuberculous lesions. Of course only time can show whether this beneficial effect is permanent. In order to attain certainty on this question, it will be necessary to watch the animals for a long period without further treatment, and then kill them and make a search for tuberculous lesions in their organs."

### TREATMENT OF TUBERCULOSIS IN MAN.

The fact that small quantities of the "defatted" antigens were devoid of toxic action having been established, it was felt to be justifiable to begin to test their effect in minute doses on human patients and to attempt to ascertain whether their action would be more favourable than that of the various tuberculins and vaccines of the usual types.

Early in April Dr. A. C. Inman injected "defatted" tubercle bacillus antigen into two patients suffering from active febrile tuberculosis of the lungs and pleurae. The patients, who were in the care of Dr. Bosanquet, had been under observation for a long period and were steadily getting worse. They were selected as being cases only likely to improve if some extra aid could be given. No local or focal reaction followed the initial inoculation, nor was there any appreciable febrile reaction. It was then decided to undertake the treatment of a case of acute toxic pulmonary tuberculosis in a patient aged 21. No local, focal, or general reaction followed; the temperature became lower and there was some amelioration of the general condition. The doses used were very small. Professor Dreyer recognized that it is too early to express any opinion on the effect of the treatment on the disease.

Drs. P. Fildes and G. T. Western also used the treatment in some cases in the London Hospital in April and at the conclusion of his lecture Professor Dreyer read the following report from Drs. Fildes and Western:

We have under treatment with Dreyer's antigen 60 cases of tuberculosis. Among these are 36 cases of tuberculous adenitis, 11 cases of cutaneous tuberculosis, 4 cases of pulmonary tuberculosis, both active pyrexial and apyrexial, 3 cases of joint and bone tuberculosis, 1 case of peritonitis, 1 case of tuberculosis of the urinary tract, 1 case of irido-cyclitis, and 3 cases of epididymitis. Most of these cases have been under our personal observation for considerable periods, up to five years, and have been selected for treatment as having shown little improvement under treatment with tuberculin B.E. (Koch).

Improvement has taken place in nearly all cases, and is, in our opinion, of an order which exceeds obviously that obtainable by any other form of treatment which is applicable to these conditions.

We have not observed any toxic effect following on the inoculations.

With regard to the effect of these antigens on other bacterial infections, we have treated 6 cases of streptococcal infection such as septicaemia, erysipelas, and osteomyelitis, 17 cases of staphylococcal infections, such as syphilis barbae, furunculosis, etc., and 5 cases of gonorrhoeal infection. Undoubtedly the course of the disease in many of these cases has been satisfactory as compared with previous experience with vaccine-treated cases. The issue, however, has not always been so straightforward, and therefore an opinion based on three weeks' experience must be more reserved.

In due course a detailed account of these cases will be published.

Professor Dreyer expressed his thanks to Mr. R. L. Vollum for his assistance in the preparation of antigens and the performance of the tests; to Dr. A. D. Gardner and Dr. H. K. Ward for their help in many experiments; to Captain S. R. Douglas, F.R.S., for help in many ways; and to Drs. A. C. Inman, P. Fildes, and G. T. Western for their willingness to apply the antigens in cases of human disease.

## BIOCHEMISTRY AND CLINICAL MEDICINE.

*Address by SIR WALTER FLETCHER*

AT THE OPENING OF

## THE NEW BIOCHEMICAL LABORATORY AT ST. THOMAS'S HOSPITAL.

THE new biochemical laboratory at St. Thomas's Hospital Medical School was formally opened on June 15th by the Marquess of Cambridge, in the absence of the Duke of Connaught, owing to the death of Princess Christian.

SIR JEREMIAH COLMAN, chairman of the Dunn Trustees, in formally presenting the laboratory to the Hospital, explained that the late Sir William Dunn, a very successful South African merchant who amassed a large fortune, appointed the directors of the Commercial Union Assurance Company to decide after his death how a large portion of his estate should be distributed. The trustees had endeavoured conscientiously to carry out the duties involved, but, naturally, they were aware of their limitations as business men, and on scientific questions they had sought authoritative help from outside. In this connexion they owed a great deal to Sir Walter Fletcher, for whom no amount of trouble had been too much. The moneys of the trust were now exhausted or earmarked, but he was able to announce—what came as a complete surprise to the beneficiaries—that along with the gift of the laboratory the trustees would ask the hospital to accept the sum of £5,000 to equip it with scientific instruments and to provide a certain amount for future use.

*Sir Walter Fletcher's Address.*

SIR WALTER FLETCHER said: I have been honoured by the request that I should give a brief account of the origin of the laboratories just visited and inaugurated, and speak of the share they are designed to take in the work of this great Hospital. In that well arranged new building we have just seen Professor MacLean and his colleagues engaged in all the high and delicate ritual of the biochemical laboratory, and within it you will have noticed some of the instruments of precision and the carefully ordered arrangements of glass apparatus which, with the help of the benefactors, the Dunn Trustees, have already been provided there. It is not easy for the onlooker, however, at once to see the relation of this work to the great charitable purposes of the Hospital or to appreciate the vital importance that chemical work of this kind has for the patients in the wards, and for their relief from pain and danger.

The physician in his healing art has constantly endeavoured to increase his powers of insight into the human body and its hidden machinery. For nearly two centuries and a half he has used the microscope to gain better powers of vision into the minute structure of the living body. For a hundred years he has used the stethoscope to improve his powers of hearing the sounds of disordered mechanism within the body. In the last generation science has made progress at a rate never known hitherto in the world's history, and has placed new weapons in the hands of the physician almost undreamed of before. In particular, the growth of biochemistry has already given him many new means of studying the body machinery—for the body is fundamentally a chemical machine—and has allowed him to trace some of the causes and results of disease at which hitherto he could only make guesses. The apparatus of a well equipped chemical laboratory has now become as essential to the daily work of the physician as the stethoscope in his pocket, or as his microscope and all the aids of bacteriology. Without chemical equipment the merciful daily work of the hospital cannot properly be done. Without it, moreover, we cannot hope to make progress and to improve our power of helping the sick.

Nowhere has this been shown more clearly than in the biochemical work which has already been done at St. Thomas's Hospital by Professor MacLean and his colleagues. I will give a very brief illustration of this. It was work done in the former laboratory which brought the British armies during the war the first clear light to guide

the treatment and disposal of the many thousands of men who suffered from trench nephritis, the kidney disease which was one of the gravest causes of the loss of man-power during the campaign in France and Flanders. It was this work, again, which pointed clearly to the modes of prevention of that disease which were brought into successful practice before the close of the war. That great work was based upon biochemical observations made by Dr. MacLean with apparatus brought from this hospital and similar to that seen to-day. It never returned to the hospital, for his little biochemical laboratory at Etaples was eventually destroyed by a German bomb—but not before it had done its work. The same line of investigation pursued here since the last period of the war has brought other great benefits to the country. It led to the establishment of a just and scientific system by which the Ministry of Pensions is guided in dealing with the results of disease or inefficiency of the kidney. The Ministry of Pensions has been able to show that, owing to this scientific contribution from St. Thomas's Hospital, better justice has been done to the ex-soldiers, while economies have been effected amounting to hundreds of thousands of pounds. The country in this way alone has probably already saved in money more than it has spent in medical research work of all kinds.

Still another development of the same work more recently has notably increased the safety with which certain kinds of surgical operations can be performed, and the small death roll of the operating theatres here has been made smaller still.

Even at this moment the biochemical laboratory is engaged in the necessary chemical work without which the new treatment of diabetes by insulin could not be used. In every week, patients in these wards suffering from that disease have been brought from the miseries of starvation and pain to comfort and to new hope. What is being done by the help of insulin now in this hospital would have seemed miraculous only a year ago. It has to be seen to be believed, and when seen it stirs the heart and imagination of every thoughtful man. This merciful work, like all the rest of the modern healing art of the physician or surgeon, has been based upon, and depends at every point upon, experiments made with animals. No nobler service has been given to mankind by the animal kingdom than by those creatures whose lives have been used, not for the food or the clothing or the amusements of men, but for the diminution of pain and disease both in man and in other animals. These experiments, done by humane men under the careful safeguards maintained under statute by the Home Office, are necessary not only in research work but in the everyday charitable work of the hospital. The work of the biochemical laboratory, and now in particular the use of insulin for the treatment of the sufferer from diabetes, is hampered by an artificial regulation that animal experiments may be done in the Medical College but not in the Hospital, although they are done directly for the hospital and although the hospital cannot do its work without them. The distinction between the Medical College and the Hospital in this matter is a mere pretence. It should be recognized as an unworthy pretence incompatible with the intellectual honesty of this place. It dishonours, moreover, the service which the animals have rendered, and are rendering now, to the noble work of charity within these walls.

Progressive work like that for which the new biochemical laboratory is designed cannot be done by the physician who is answering the calls of a busy professional practice. Medical science, like every other branch of science, can only be advanced and can only be effectively and fully taught by those giving their whole energies to it. The Medical Research Council, which is charged by the Government with the duty of promoting medical research work throughout the country, found from the beginning of its work ten years ago that little or no progress in research was possible under the existing hospital arrangements, and near the close of the war they joined eagerly with the Ministry of Health in pressing for the establishment, at some at least of the chief hospitals, of what are now called University Clinics or professorial "Units." These were commended in eloquent terms by His Majesty the King a fortnight ago, when he spoke of the munificent gift which has come recently to the support of the units at another hospital from the Rockefeller

Foundation of New York. Without liberal money help from outside, these new centres of accurate study and higher teaching in medicine cannot do effective work. The Government grants made to them from public funds are barely adequate for the support of the men engaged. It is upon the hospitals that the burden of providing the laboratories and equipment has fallen, and this at a time when their funds are strained to meet the immediate requirements of the sick. The existing buildings of St. Thomas's Hospital were designed before the growth of science had made the need for laboratory work imperative for the proper help of the afflicted, and the necessary changes involved costly structural alterations. It is this which has made the recent benefaction of the Dunn Trustees so timely and valuable—though indeed the unavoidable structural work has necessarily absorbed much of the money needed for the heavy expenses of research apparatus and materials. The provision of this biochemical laboratory, however, by the foresight and generosity of the Dunn Trustees, together with similar aid they have given at two other great hospitals, is the first benefaction from any private British source which has been offered to meet and reinforce the munificent help already given to the medical unit system in London from America.

In tending the sick and suffering we can show no effective mercy without knowledge, and this knowledge can only be gained by the steady pursuit of truth. In the intimate association here between the wards and the laboratory we can truly say, in those ancient words, that here indeed

"Mercy and Truth are met together."

#### Official Thanks.

The CHAIRMAN (Sir Arthur Stanley), in gratefully accepting the gift, said that the further surprise donation of £5,000 for the purchase of scientific instruments would be most welcome. The maintenance of the Hospital was covered by subscriptions and interest on invested funds, but the constant difficulty hitherto had been to meet the demand for new laboratories and equipment consequent upon the progress of science. He added that research in general had no better advocate than Sir Walter Fletcher, and to him as well as to the Dunn Trustees the Hospital tendered its most sincere thanks.

Sir CUTHBERT WALLACE, Dean of the Medical School, expressed the great indebtedness of the school for the assistance received.

The MARQUESS OF CAMBRIDGE then distributed the prizes and certificates.

## Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

### NURSES' REGISTRATION ACT.

#### The Proposed New Regulation.

A DEBATE took place in the House of Commons on June 13th as to the proposed regulation by the General Nursing Council to settle how far nurses should be admitted to the Register without examination. Under the Act of 1919 the General Nursing Council has power to frame regulations, but these have to be laid on the tables of the two Houses of Parliament, and either House can present what is technically known as a prayer to His Majesty for change or rejection of such proposal. In the present instance the Nursing Council intended to deal with the matter by inserting after Rule 9 (1) *a fresh regulation prescribing that where a nurse was, on November 1st, 1919 (the date of the Act), engaged in actual practice and had also been bona fide engaged in nursing prior to January 1st, 1900, it should be open to the Council to accept, in each case, evidence of knowledge and experience for the purpose of registration.*

Dr. Chapple moved to vary this by prescribing that a nurse who was in 1916 in practice should be eligible for registration subject to producing the following evidences of knowledge and experience:

- "(a) A certificate of good character;
- "(b) A certificate signed by a matron of a general hospital or an infirmary or by two medical men setting out that the applicant has been in attendance upon the sick in the capacity of a nurse for a period of not less than three years prior to the 1st November, 1919; and
- "(c) A certificate signed by a registered nurse and by two medical men, one of whom shall be on the staff of a general hospital, setting out that the applicant has adequate knowledge and experience of medical and surgical nursing, and is competent to attend upon the sick in the capacity of a nurse.

"Provided that the Council may require the applicant, as a condition precedent to registration, to present herself for special inquiry before a medical officer, or officers, appointed by the Council."

In supporting this Dr. Chapple urged that every Act of this kind which had been passed had made provision for those practising bona fide at the time of the passage of the Act. Dr. Salter, seconding the motion, said he had no desire to lower the standard of nursing education. He did not mind how narrow the portal of entry was made for the future, but he pleaded for justice and fairness for highly qualified women who did not fulfil all the technical requirements of the Rule of the Nursing Council.

The Minister of Health (Mr. Neville Chamberlain), in the course of his speech, remarked that controversies of this kind almost invariably arose when an effort was made to stabilize a profession which hitherto had had no general standard; but there was a difference between the cases of the nurses they were now considering and the cases which had been previously dealt with, such as the midwives and the dentists. Under those provisions people could not practise their profession at all unless they came on the Register. That was not so under the Nurses Act; there was nothing in it to prevent a nurse from practising even if not on the Register. He did not deny that some hardship was inflicted upon certain nurses. But Dr. Chapple's motion—proposing that nurses who could obtain a certificate signed by a registered nurse and two medical men should have the right of entry upon the Register—appeared to him to go a great deal too far. That took away from the Nursing Council the discretion given to it under the Rule which he (the Minister) had approved. It must be remembered that about 27,000 nurses had already applied for entry upon the Register. They had done so on the understanding that the conditions were those laid down by the Nursing Council. If it had been suggested to them that it was possible to bring in a large number of other nurses with no hospital training he was not sure that they would have applied for registration. The facts of the situation had to be faced.

Dr. Fremantle explained why he differed from some professional colleagues who were supporting the motion before the House. Had he had anything to do with the framing of the Act of 1919 he would probably have shared their view; but neither he nor they had any part in drawing up that Act. It would have been better to include everybody up to the time of the passing of the Act and let them go on as bona fide members of the profession: all these persons would then have been brought within the discipline of the profession. But the ground was cut away by the decision of Parliament. True, Parliament laid down that rules should be made for the introduction of the bona fide nurse, but it said that the conditions she must fulfil were to be such as seemed satisfactory to the Nursing Council. The Council had said it would be satisfied with certain conditions for bona fide nurses as long as they practised before 1900, and it was believed that it would extend the date to 1910. For that reason he had put down an amendment standing in his name extending the date to 1910.

On a division Dr. Chapple's motion was carried by 101 votes to 81. Dr. Fremantle's amendment and another in the name of Major Barnett were held by the Speaker to have been disposed of by the decision.

### Insurance Medical Service.

Mr. Chamberlain stated, on June 13th, in answer to Mr. Adamson, that he intended to propose the renewal of the National Health Insurance (Prolongation of Insurance) Act for the year 1924.

Lord E. Percy stated, in answer to Sir Kingsley Wood on June 14th, that the Government could not at this stage undertake that when a settlement had been reached with the doctors under the National Health Insurance scheme an opportunity would be given for the discussion of the agreement before it came into operation. But even if no express legislation was necessary, Parliament would have an early opportunity for reviewing the terms of the agreement next session on the Vote on Account.

Mr. Bruford, Dr. Watts, Mr. W. M. Adamson, Dr. Salter, and Mr. Leach addressed questions, on June 13th, to the Minister of Health regarding trade advertisements on the back of medical certificates required to be issued by doctors under the National Insurance Act, the point being made that the medical profession strongly objected to acting as advertisement distributing agents of any particular foods. Mr. Chamberlain said that he would consult the Stationery Office as to the possibility of securing other advertisements without loss to the revenue when the present contract terminated, if there should still be room for advertisements on the form. Dr. Salter asked whether the Minister appreciated the fact that a medical certificate issued by a doctor was a document of a very personal and intimate character, with the word "Confidential" across it, and whether, in these circumstances, any kind of advertisement on a document of that sort in the hands of a patient of the less educated class was taken as a personal recommendation from the doctor. Sir Henry Craik asked whether it was the case that the sum obtained at the Stationery Office for this advertisement on millions of forms was £135 a year. Mr. Chamberlain said that was so. He recognized that objections were taken and would try to have the matter altered as soon as the contract was ended. On another question by Commander Kenworthy, Sir William Joynton-Hicks said that the revenue from advertisements on the various medical certificates was estimated at £405 per annum (including £270 from Form Med. 40). Commander Kenworthy remarked they had just been given a different figure, but Sir W. Joynton-Hicks replied that he believed the question was a different one.

### Small-pox.

Sir W. Preston asked, on June 15th, how many cases of small-pox there had been in Gloucestershire in January, February, March, April, and May of this year; and whether any special steps had been taken to cope with the disease in the county.

Mr. Chamberlain replied that the number of cases of small-pox which had been notified in Gloucestershire, including the city of Gloucester, during these months had been as follows: January *nil*, February *nil*, March 8, April 25, and May 31. There was, however, evidence to show that many cases had occurred in the city of Gloucester during the last two months which had not been recognized as small-pox by the medical officer of health and had not been notified. Special visits had been paid by medical officers of the Ministry of Health to the districts in which the disease had occurred, in order to assist and advise the local authorities and their officers. In the case of Gloucester, two of these medical officers had, at the request of the local authority, assisted in the diagnosis of cases and in the organization of suitable measures to meet the emergency, and these officers discovered a number of cases which had been incorrectly diagnosed or overlooked. He had since caused a communication to be sent to the local authority recommending the several special steps which should be taken to deal with the outbreak, and he understood that effect was being given to these recommendations. In reply to a further question Mr. Chamberlain said that no official employed by the Gloucester medical officer to distemper houses where small-pox had occurred had himself contracted the disease.

Mr. Rhys Davies asked, on June 15th, whether, when the recruiting regulations requiring intending recruits to promise to be vaccinated was reintroduced in January, 1919, the War Office possessed information as to small-pox in the army; and, if so, why repeated requests for such information had been refused. Lieut.-Colonel Guinness said that the complete statistics which had been asked for from time to time were not then and were not yet available, but the Department possessed sufficient information to be satisfied that the reintroduction of the regulation was desirable from a military point of view.

Mr. Lee asked, on June 13th, whether the Minister of Health had seen an expression of opinion by the medical officer of health for Chesterfield that the outbreak of disease in Clowne, Bolsover, Ilkeston, and other places in Derbyshire, which had been notified as one of small-pox, was not due to that complaint, seeing that its effect had none of the usual characteristics of face disfigurement and that no deaths had occurred. Mr. Chamberlain assumed that the reference was to certain statements in the annual report of the medical officer of health for Chesterfield for the year 1922; but in that report the medical officer acknowledged that his view was shared by only a very small minority. When similar statements were made last year an expert committee was appointed by the then Minister of Health to examine certain patients in Chesterfield and elsewhere who had been notified as suffering from small-pox. This committee arrived at the conclusion that the disease was, in fact, small-pox of a mild type, a conclusion supported by subsequent investigation undertaken by medical officers of the Ministry.

Mr. Chamberlain has supplied the following information as to the number of cases of, and deaths from, small-pox in Japan during the years 1915-20:

	Cases.	Deaths.		Cases.	Deaths.
1915 ...	17 ...	3	1918 ...	1,469 ...	285
1916 ...	256 ...	48	1919 ...	4,056 ...	1,115
1917 ...	5,122 ...	1,153	1920 ...	3,167 ...	844

The notification of small-pox is compulsory in Japan when the disease is prevalent or threatens to prevail, and hospital isolation is practised if deemed necessary.

**"Patent Medicine" Duties.**—In committee on the Finance Bill, on June 12th, Mr. Neil McLean urged either that the Patent Medicine Duties should be repealed or that the addition imposed in 1915 should be taken off. The amount realized by the tax for Great Britain in 1914, before the imposition of the additional duty, was £360,377. In 1921-22 the net receipts from the duty were £1,328,448, and the figures of the current year were, he understood, about the same. Evidently there had been no greater consumption during the year, but since these articles were largely bought by people who imagined themselves to be unwell, and who were sometimes deluded by fanciful, alluring advertisements, he did not think that the Government, if it reduced the tax, would suffer a great loss of revenue. Mr. T. Williams also objected to the tax, and suggested that as drugs were now costing so much more than they did previous to the war doctors were not using them as they would have done if prices had remained normal. Sir W. Joynson-Hicks explained that this was not a tax upon medicine imported into the country, nor on medicines used in hospitals or prescribed by doctors, but on what everybody knew as "patent medicines." Although the tax had been doubled, the consumption had not in any way been reduced. Mr. Short spoke against the duty, but on a division the Clause was approved by 231 votes to 119.

**Opium Traffic.**—The Home Secretary informed Sir Walter de Frece, on June 12th, that the main results of the meeting of the Advisory Committee on the opium traffic at Geneva were (1) that an agreement was reached with the delegation from the United States which would, it was hoped, have the effect of securing the co-operation of that Government with the States which were members of the League in giving full effect to the International Convention of 1912, and (2) that the Advisory Committee decided to make a recommendation for the adoption by agreement between the Powers interested of measures for securing a more effective application of Part 2 of the Convention which related to the suppression of the use of opium for smoking and a limitation of the manufacture of morphine, heroin, and cocaine, and of the production for export of the raw material from which the drugs were made.

**Assisted Milk Supply.**—Having ascertained, on June 13th, from Mr. Chamberlain, that the form of application for assisted milk supply used by the Hertfordshire County Council was in use by

other authorities with the consent of the Ministry of Health, Mr. Rhys Davies put a lengthy question as to the character of this form. He conveyed that under it applicants were required to supply birth certificates in respect of children under 3 years of age for whom assistance was asked; that the application had to be accompanied by a medical certificate stating that, by reason of ill health, the applicant was in need of extra milk; and that a number of inquisitorial questions were included. Mr. Davies put it that the amount of milk supplied to mothers and babies in the Letchworth area had fallen from 6,660 pints for mothers and 5,901 pints for children in 1920 to 112 pints for mothers and 280 pints for children in 1922, and that this reduction had been accompanied by an increase in infant mortality from 43 per 1,000 in 1920 to 63 per 1,000 in 1922. The Minister of Health replied that one of the medical officers had been instructed to investigate the matter. Before taking any action it was necessary to ascertain whether the increased rate was really the result of the reduction in the milk supply.

**Lead Poisoning.**—Mr. A. Greenwood asked, on June 14th, whether the Home Secretary was aware that of the eight cases of lead poisoning among house painters and plumbers which came to the knowledge of the Home Office during April six were fatal; and whether the Minister would urge on the Government the importance of ratifying the White Lead Convention as recommended by the Norman Committee. Mr. Bridgeman said that the question was being carefully considered. On request he gave particulars as to the four workers in the china and earthenware industry reported in the May issue as stricken by lead poisoning:

**Case 1.**—Man, aged 51, glost placer, employed forty years (ten years in the dipping-house as a child and youth). Chronic lead poisoning—arterio-sclerosis.

**Case 2.**—Man, aged 62, dipper, employed thirty-three years. Chronic lead poisoning—nephritis.

**Case 3.**—Woman, aged 39, dipper, employed twenty years. Chronic lead poisoning—nephritis.

**Case 4.**—Woman, aged 32, aerographer, employed sixteen years. Chronic lead poisoning—nephritis.

**The Fire at Highbury Pensioners Hospital.**—Major Tryon, on June 14th, gave particulars of the distressing fatalities which had occurred through an outbreak of fire at the Ministry of Pensions Hospital, Highbury, Birmingham. The building was not owned by the Ministry, but was made available for its exclusive use by special arrangement with the Birmingham Pensions Committee, which was responsible for the administration. The fire began in an isolated open-air ward in the afternoon. It was at once observed by the orderly on duty, who attempted to deal with it and gave the alarm. The fire brigade arrived in five minutes. In the meantime the whole of the staff, and all patients who were fit to do so, endeavoured to put out the flames and to remove helpless patients. A gale of wind was, however, blowing at the time and the fire spread rapidly. The ward was an open-air hut of the most modern type. It was a wooden construction on a brick foundation with a galvanized iron roof. There were two exits, but that at the end where the fire started at once became inaccessible; the other had an opening of 9 feet wide through which two beds could be simultaneously removed. In the ward were nine full waterbuckets and two fire extinguishers. The number of patients there were fifteen, of whom only three could help themselves. Two lost their lives and two were seriously injured. Major Tryon expressed his sorrow at what had happened and promised full inquiry into all the circumstances, including the suitability of this type of building. He agreed with Mr. Macpherson that the hospital was regarded by medical experts as one of the most up-to-date in the world.

**Tuberculosis in Cattle.**—Mr. Adams asked, on June 18th, whether the Minister of Agriculture would reintroduce the Tuberculosis Order of 1914 or one similar whereby tuberculosis in cattle would be made a notifiable disease, and whether he would promote a bill to require all county authorities and the larger cities or combinations of smaller authorities to appoint whole-time veterinary officers for the inspection of cattle, particularly dairy herds, and the inspection of meat. Sir Robert Sanders said that unless and until he was assured that a majority of local authorities, including counties and cities, favoured the reintroduction of the Order of 1914, he did not see his way to reissue it in view of the expenditure involved. Section 1 of the Milk and Dairies (Amendment) Act, 1922, deferred until September 1st, 1925, the operation of Section 10 of the Milk and Dairies (Consolidation) Act, 1915, which contemplated appointment of veterinary inspectors by local authorities for purposes such as were suggested in the question.

**Infectious Diseases Notification.**—Mr. Scrimgeour asked, on June 18th, whether the Scottish Board of Health would direct the medical officers of health to record in their annual report the number of cases of small-pox and other infectious diseases notified from families living in houses or tenements containing one, two, or three rooms, and from houses containing four or more rooms. Dr. Elliot said that the Board was prepared to consult local authorities and their medical officers of health through their associations on this point, but not without such consultations to issue a direction.

**Medical Appointments.**—Mr. Becker asked, on June 13th, whether the attention of the Minister of Health had been called to the complaint of English medical men in that Wales, Scotland, and Ireland insisted upon having only men of their own nationality in their region, whereas in England many of the more lucrative appointments were held by other than Englishmen; and whether he would see that all doctors appointed by the Minister of Health for England should be English. Mr. Chamberlain replied that no general complaint of the kind named had reached the Ministry.

**Dangerous Drugs.**—Mr. Bridgeman stated, on June 13th, in answer to Captain Hay, that the number of factories licensed at the present time for the manufacture of morphine and heroin was two. The amount of morphine made in 1922 was 315,342 ounces, of which, however, 173,010 ounces were converted into codeine or heroin, leaving a net total of 142,332 ounces. The amount exported was 115,465 ounces. The amount of heroin made in 1922 was 31,673 ounces and the amount exported 25,911 ounces.

**Spahlinger Treatment for Tuberculosis.**—Mr. Chamberlain stated, on June 13th, in answer to Captain Reid, that owing to supplies of the complete serum and vaccine not being available, the opportunity for a trial of this method of treatment in this country had not yet arisen. He regretted it was so.

**Vivisection Inspectorate.**—Mr. Bridgeman, on June 14th, corrected an assertion by Colonel Sir Charles Burn that, following on the recommendation of the Royal Commission on Vivisection, four whole-time inspectors were appointed for Great Britain. The staff was increased to four, but of these only two were whole-time officers. The working of the present arrangement would be carefully watched, but in view of the financial situation he could not hold out any prospects of an increase in the inspectorate.

**Cannock Chase Hospital.**—Major Tryon informed Mr. W. M. Adamson, on June 14th, that owing to the decreasing requirements for hospital accommodation in the Midlands arrangements had been made for the gradual closing of the Pensions Hospital at Cannock Chase.

#### Answers in Brief.

The Mental Treatment Bill was read a third time in the House of Lords on June 19th, and will now go to the Commons.

Mr. Chamberlain states that the report of the Committee of Inquiry on Venereal Disease is under consideration, but he is unable as yet to state what action will be taken on the recommendations. On a further question he said he was advised that there was nothing in the existing law to prevent chemists from selling disinfectants for the purpose of the prevention of any venereal disease so long as they were not sold accompanied by any written or printed recommendations.

Sir W. Joynton-Hicks has promised on behalf of the Treasury that a deputation shall be received at an early date to discuss the possibility of exempting hospitals from legacy and succession duty.

## England and Wales.

### OPENING OF THE NEW BIRMINGHAM PATHOLOGICAL LABORATORIES AT HOLLYMOOR.

On June 16th the Minister of Health, in the presence of a representative gathering, inspected the new pathological laboratories established at Hollymoor Mental Hospital, near Birmingham, by the Joint Board of Research for Mental Disease. The laboratories consist of three large rooms in series, with small annexes, and an x-ray room. The rooms are well suited to the purpose and are equipped for all forms of pathological investigation. The equipment will be made more complete as funds permit, and, as in all probability the first research work performed in the laboratory will be on basal metabolism, a chamber for the purpose will shortly be erected. In addition to pure research, the laboratory will undertake the examination of specimens from any of the mental hospitals. The work is under the direction of Sir F. W. Mott, assisted by Dr. F. A. Pickworth.

After inspecting the laboratories, the company assembled in the Recreation Hall. Sir Gilbert Barling (chairman of the Joint Board of Research for Mental Disease) welcomed the Minister of Health, and explained that the Joint Board consists at present of an equal number of representatives of the University of Birmingham and the City Asylums Committee. The funds are provided largely by voluntary contributions, the mental authorities being prevented by existing regulations from contributing to any appreciable extent to the heavy expenditure. In this connexion he paid warm tribute to the generosity of the Feanay Trustees, and expressed the hope that new legislation would soon remove the present restrictions from mental authorities. In outlining the aims and objects of the Board, he said that the ideas before them were to stimulate research into mental diseases, and to secure for the patients in mental hospitals equal clinical advantages with those in the large voluntary hospitals.

Sir Frederick Mott recalled the fact that Mr. Joseph Chamberlain, when Colonial Secretary, founded the schools of tropical medicine, and trusted that the Minister of Health would take the same keen and practical interest in medical science. One of the considerations which determined the speaker's decision to undertake the directorship was the association of the scheme with the University. This ensured

breadth of outlook and all the advantages of freedom of discussion with other faculties. He would aim at stimulating the young men to study mental disease on a scientific pathological basis, and instanced the improvement in the standard of mental work which followed the institution, at his instigation, of the Diploma in Psychological Medicine by the University of Cambridge. Research meant time, patience, and criticism, and he hoped that it would not be hampered by too much routine work, which had a stultifying effect on research.

Dr. Hubert Bond (Commissioner of the Board of Control) welcomed the scheme, and said that it commended itself to his colleagues because of its personnel, the atmosphere of progress it created, and its association with the University. He expressed gratification at the presence of Mr. Neville Chamberlain, who, he said, by placing upon the proceedings his imprimatur, was helping to bring psychological medicine "within the fold."

Mr. Neville Chamberlain said that the duties of the Minister of Health were very varied: watching the activities of building rings, securing a pure milk supply, and so on; but he had come to the conclusion that that part of his work which was concerned with mental hospitals was by no means the most dangerous. The scheme marked the inauguration of a new form of co-operation which he warmly approved. He recalled Mr. Joseph Chamberlain's interest in scientific research, a tradition to which he said he intended to adhere. Mental affliction was now regarded not as a thing apart, but as one phase of disease, and this was a step in a rational attempt to find its causes. No one knew when their patient building would be rewarded by a great discovery. The joint action of the University and the Mental Hospitals Committee had opened the door to a real advance, and he congratulated them and Sir Frederick Mott, to whom he paid tribute. In conclusion he expressed his high confidence in the future of the work.

The Lord Mayor of Birmingham proposed a vote of thanks to Mr. Chamberlain. This was seconded by Councillor Miss Bartleet (chairman of the Asylums Committee), to whose activity the scheme owes so much. She called attention to the great help rendered by Sir Gilbert Barling, who had secured the co-operation of the University and hence the services of Sir Frederick Mott. The vote was carried with acclamation, and the proceedings terminated.

The laboratories are not yet in full working order, and are regarded by those responsible as only a beginning. It is hoped that eventually they will be moved to the University and be closely associated with its general pathological work. No general appeal is being made for funds, but many have given voluntary financial help. Sir Charles Hyde has made the munificent offer to the Joint Board of £250 a year for three years, the gift being made after the close of the meeting.

### SMALL-POX IN GLOUCESTER.

As reported in our parliamentary notes (p. 1069) the Minister of Health has made a serious announcement as to small-pox in the city and county of Gloucester. The notifications in March were 8, in April 25, and in May 31. But that is not all. There is, he stated, evidence to show that many cases have occurred in the city during the past two months which have not been recognized as small-pox by the medical officer of health and have not been notified. Special visits were made by medical officers of the Ministry, who discovered a number of cases which had been incorrectly diagnosed or overlooked, and the officers here, at the request of the local authority, assisted in diagnosis and in organization of suitable measures to meet the emergency. From the *Bristol Times* of June 7th we learn that the steps taken include the provision of increased hospital accommodation by utilizing capacious premises at Beechley, Chepstow, which had been in use for German prisoners of war. The Ministry has succeeded in obtaining agreement to this provision between various local authorities in West Gloucestershire. In addition to the county town, Westbury and Lydney, on the fringe of the Dean Forest coalfield, are mentioned, and the agreement includes Coleford Urban and Westdean Rural districts. Owing to the serious outlook in the city of Gloucester, cases are to be received from it at Beechley.

The latest official figures issued by the Registrar-General are for the week ending June 9th, and they record 35 notifications in the county, 26 of the 35 being in the city. We understand that Dr. W. H. Davison, Assistant Medical Officer of Health for Birmingham, has been given plenary powers by the Corporation of Gloucester to take charge of the epidemic and to control the staff for dealing with it. Meantime, as reported in the *Birmingham Post* of June 13th, twenty-seven practitioners of the city have met, and have published the following conclusions, with their signatures appended:

"That we, the undersigned medical men practising in Gloucester, are aware that a large number of cases of small-pox exist in the city. We urge the citizens to support the Health Authorities in their efforts to stamp out the outbreak, and we strongly advise that everybody, in his own interest and for the public welfare, be vaccinated or revaccinated."

From the *Birmingham Post* we learn that one practitioner, however, a well known antivaccinationist, has inserted in a local newspaper an advertisement containing the following:

"This city has been visited by two medical men from the Ministry of Health and one medical man from the Metropolitan Asylums Board. They have called upon a large number of persons who have been suffering from eruptions and, with one exception, they have declared the whole of these cases to be small-pox. The one exception was a child suffering from chicken-pox who occupied the same bedroom as the alleged case of small-pox. I saw them both. The supposed small-pox case was one of the mildest cases of chicken-pox I have ever seen. And yet your Health Committee squandered 50 guineas to fetch a man down from London to make that erroneous diagnosis. I have notified a large number of chicken-pox cases of my own, and I have seen other cases in company with medical colleagues, and I have no hesitation whatever in saying that these gentlemen from the Ministry of Health are entirely wrong in their conclusions. There have been a few cases of small-pox, but very, very few; some have been my own, but at the present time, judging from inquiries I have made, I do not believe there is a single case of small-pox in the city."

The Public Vaccinator, when interviewed on behalf of the *Birmingham Post*, stated that for some days people had been vaccinated at the rate of 300 to 400 a day, but lately there had been a falling off to 100 a day, a decline which he attributed to advertisements in the press.

Such, it appears, is the present position. As elsewhere in England the variola in Gloucestershire is of a mild type, and we have not heard of any fatal cases, though some severe attacks with serious complications or sequelae have been mentioned. Like mild infectious diseases of every sort, this strain of small-pox is more readily overlooked than the classical form of the malady, and there is on that account need for constant vigilance on the part of all concerned in the prevention of epidemic spread. Where diagnosis is difficult, there is all the more occasion to resort to the one measure, recent successful vaccination and revaccination, which, applied in circumstances like the present, can render diagnosis of less importance, by making the occurrence of small-pox an impossibility. Nowadays vaccination is largely a matter of individual option and every parent must take the responsibility of deciding for himself whether to protect his children or to leave them susceptible to attack. If he is wise he will protect them; if foolish, then his children will have to suffer for his folly.

#### LIVERPOOL ROYAL SOUTHERN HOSPITAL.

At the annual meeting of the Liverpool Royal Southern Hospital, on May 3rd, it was stated that the debt of the hospital to the bank had been reduced from £13,880 to £9,448, but the future of this institution was not free from anxiety, in spite of the extraordinary income from legacies that had come to the hospital in the past year. The contributions, for the first time, by the approved societies amounted to over £800. The treasurer suggested that the insurance companies might follow the good example of the approved societies, for they benefited directly or indirectly by the work of the hospitals. The new scheme of the Liverpool Local Voluntary Hospitals Committee, whereby the various trade societies would make a voluntary weekly contribution, was warmly welcomed. This plan, jointly with the efforts of the Hospital Saturday and Sunday Fund, should place the voluntary hospitals of the city on a sound financial basis and relieve the committees of their perennial

anxiety to meet expenditure. The need for a larger and better equipped electro-therapeutic and massage department has been recognized by the committee, and it is hoped that its construction and equipment, costing approximately £3,000, will be completed before the end of the year. In connexion with the lady almoner's department, a number of ladies have volunteered their services in alleviating the personal conditions of patients and their after-care, and an appeal was made for the establishment of an endowment fund, the interest from which could be used to provide relief immediately in necessitous cases.

## Scotland.

### INTERNATIONAL PHYSIOLOGICAL CONGRESS.

THE eleventh International Physiological Congress, which, as already announced, is to be held at Edinburgh on July 23rd to 27th, under the presidency of Professor Sir Edward Sharpey Schafer, F.R.S., will meet in three sections—general, chemical, and pharmacological—but on the opening day Professor J. J. R. Macleod, F.R.S., will deliver an address on insulin. Those desiring to enrol as members should apply and send the subscription (25s.) to the Assistant Secretary of the Congress, Department of Physiology, the University, Edinburgh.

### THE ADVANCE OF SURGERY.

An address on surgery, old and new, was given last week by Sir Montagu Cotterill, C.M.G., to the members of the Edinburgh Rotary Club. The lecturer stated that when he began medical study in 1869 at a hospital in the South of England, about one-third of those upon whom operations were performed died from the effects of the operation—and no wonder, considering the conditions that existed before the work of Pasteur and Lister. During the war, at Craigleith Hospital, he had operated on 1,538 soldiers, with only one death—a sufficient indication of the changes that had taken place in the intervening years.

### PUERPERAL MORBIDITY AND MORTALITY.

Last week (p. 1036) we announced the composition of the Departmental Committee appointed by the Scottish Board of Health to inquire into the incidence of puerperal morbidity and mortality, with special reference to its causes and possible remedies. The committee has begun its sittings and will welcome offers of evidence from medical practitioners; such evidence, we are asked to state, would be of special value where records have been kept over a period of years. Communications should be addressed in the first place to the secretary of the committee, Mr. C. L. Farmer, Scottish Board of Health, Edinburgh.

## Ireland.

### VITAL STATISTICS OF NORTHERN IRELAND.

DURING the quarter ending March 31st, 7,381 births were registered in Northern Ireland, this number being equivalent to a birth rate of 23 per 1,000 of the estimated population. The births registered comprised 3,777 boys and 3,604 girls. This rate was 0.8 below the rate for the corresponding quarter of 1922, and 0.1 below the average rate of the first quarters of the previous ten years. Illegitimate births numbered 311, being 4.2 per cent. of the total births registered during the quarter. The deaths registered during the same quarter numbered 5,112, representing an annual death rate of 16 per 1,000. Of the deaths registered, 2,472 were of males, 2,640 of females. This rate was 4.0 below the rate for the corresponding quarter of 1922, and 5.0 below the average rate for the first quarter of the previous ten years. Of the 5,112 deaths registered, 629, or 12.3 per cent., were of infants aged under one year; and 2,078, or 40.6 per cent., were of persons aged 65 years and upwards. There were 123 inquests reported to the registrars during the quarter, and 639 deaths (or 12.5 per cent. of the total deaths registered) were uncertified, there having been no medical attendant during the last illness. The urban mortality from

the principal epidemic diseases recorded during the quarter was equivalent to an annual rate of 0.9 per 1,000 of the population, the total rate from these diseases for the remainder of Northern Ireland being 0.3 per 1,000. In Belfast the mortality from the principal epidemic diseases was 0.8 per 1,000; of the 1,556 persons whose deaths were registered for Belfast during the quarter, 301 were of infants under one year, representing a mortality of 113.3 per 1,000 births registered; and of the deaths recorded for Belfast, 418, or 26.9 per cent., occurred in public institutions. The population of Northern Ireland in the middle of 1922 was estimated to be 1,262,000, inclusive of military. During the same period the births registered in England and Wales numbered 192,970, or 20.5 per 1,000, and the deaths numbered 124,720, or 13.3 per 1,000. The number of marriages registered in Northern Ireland during the last quarter of 1922 was 2,063, representing an annual rate of 6.4 per 1,000 of the estimated population. This rate was 0.6 above the rate for the corresponding quarter of 1921, and 0.2 below the average rate for the previous ten years. Of the total number of marriages, 548 were marriages of Roman Catholics and 1,515 related to persons belonging to all other denominations.

#### REPORT OF INTERNATIONAL RED CROSS ON IRISH INTERMENT CAMPS.

On June 2nd, in this column (p. 954), we published under this heading a communication from the International Red Cross Committee at Geneva with regard to internment camps in the Irish Free State. In reference to this matter we have received the following letter:

Sir,—I have read with surprise the report of the International Red Cross on Irish internment camps appearing in your issue of June 2nd (p. 954), having been one of the delegates sent by the Prisoners' Defence League to Geneva last November to lay a statement before the International Red Cross Committee on treatment of political prisoners in Free State prisons. There was no mention made in that statement of internment camps, where, in some cases, conditions are on the whole good.

The International Red Cross promised to send a Commission and to get into touch with the President of the Prisoners' Defence League, Mrs. Despard, immediately on their arrival in Ireland. After six months' delay, so far as I know, two members of the International Red Cross came to Dublin. They made no attempt to get in touch with Mrs. Despard—I only by chance learned that they had arrived and with two others succeeded in having one interview with them, during which the word "internment camp" was never mentioned. We told of more recent conditions in Maryborough, Mountjoy and Kilmainham. To my certain knowledge the Commission never visited Kilmainham or Mountjoy, nor as far as I know Maryborough.

There is abundant evidence that the representations of the Prisoners' Defence League are only too well founded, much of it in the form of sworn statements by prisoners. In this connection the statement of the Hon. Albina Brodrick in the *British Journal of Nursing*, May 26th, is interesting. There are also statements from Dr. Elsie Murphy, Miss Dorothy McArdle, B.A., of Alexandra College, Dublin, and many others.

These conditions prevailed while the International Red Cross delegates were in the city of Dublin, and if they had investigated those places of which definite complaints had been made, it would have been impossible to issue with truth such a report as has been issued by them.—Truly yours,

KATHLEEN LYNN, F.R.C.S.I.

## New South Wales.

[FROM OUR CORRESPONDENT.]

#### DIPLOMA OF PSYCHIATRY.

ON the recommendation of the Faculty of Medicine in the University of Sydney the Senate has decided to establish a Diploma in Psychiatry. A candidate must produce evidence (1) that he is a qualified practitioner registered by the New South Wales Medical Board; (2) that a period of not less than twelve months has elapsed since he obtained a registrable qualification in medicine, surgery, and obstetrics; (3) that after obtaining the registrable qualification he has been resident medical officer for six months in a mental hospital approved by the Senate, or has been in regular attendance at the rate of not less than six hours a week during term time in the wards of any similarly approved hospital devoted to the care and treatment of functional nervous and mental diseases for a period of not less than twelve months; (4) that after obtaining the registrable

qualification he has attended the following courses of lectures and demonstrations:

(a) Psychology, thirty-five hours; (b) Anatomy and physiology of the nervous system, thirty hours; (c) Neurology, twenty hours; (d) Pathology of the nervous system, including lectures and demonstrations, with special reference to microscopic anatomy, biochemical methods and the chemical examination and estimation of certain clinical symptoms; (e) Psychiatry, to include ten systematic lectures in advanced psychiatry and in addition five lectures in mental deficiency and ten clinical demonstrations in the wards of a mental hospital or psychiatric clinic, provided that candidates must have previously attended the courses of lectures in psychiatry delivered to medical students in the sixth year of the curriculum or an equivalent of such course. Candidates are required to pass written, clinical, and *viva roce* examinations in psychiatry and neurology, a written and a practical examination in psychology and in the anatomy and physiology of the nervous system, and a practical examination in pathology. The courses of instruction are to be given during two terms of each year as required.

Candidates who are unable to attend all the lectures and demonstrations in these two terms may take the remainder in subsequent terms, but all the courses must be completed and the candidate must present himself for examination within a period of six terms.

#### INSANITY IN NEW SOUTH WALES.

The annual report of the Inspector-General of the Insane for the year ended June 30th, 1922, shows that there were 7,997 insane persons under official cognizance during the year. This was an increase of 55 over the number for the preceding year; the proportion of insane to the general population is 1 in 267. The number of admissions was 1,477; of these, 1,236 were admitted for the first time. Natives of New South Wales formed 53.42 per cent. of the admissions. The number of persons recovered was 614, equal to a rate of 41.57 per cent. on the admissions and readmissions for the year. The number of those discharged improved was 167, a proportion to the admissions of 11.43 per cent. The recovery rate shows an increase of 3.93 per cent. compared with the recovery rate for the year 1920-21, and an increase of 2.02 per cent. on the average for the past ten years. Of the 606 deaths, 77 were due to general paralysis, 40 to inflammation and other diseases of the brain, 37 to epilepsy and convulsions, 34 to maniacal and melancholic exhaustion, and 26 to apoplexy and paralysis. Diseases of the heart and blood vessels caused 94 deaths, pulmonary tuberculosis 45, other diseases of the lung 50, decay and old age 36.

The Inspector-General again emphasizes the necessity for some amendment of the present Lunacy Act, inasmuch as this Act only contemplates the treatment in the mental hospitals of persons who are certifiable as insane, and no specific provision is made for persons in the incipient stages. An amending bill is now before the Minister which provides for the recognition of three classes of persons suffering from mental disorder according to the degree of restraint required for their care:

(a) Persons amenable to treatment, power of detention not being required as a necessary condition of their admission; such cases to be dealt with in the ordinary wards of a general hospital or in a special hospital. (b) Persons for whom detention is in their own interest. These would be treated in a special hospital. (c) Persons who from the nature of their complaint require compulsory detention, either for their own protection or for that of the public; they will continue to be provided for in the ordinary mental hospitals. Persons suffering from mental disorder to be admitted to a public hospital or special hospital are defined as those whose mental condition is not such as to render it necessary to grant a certificate of insanity in their case, either for their own protection or that of the public; those admitted to the special hospital will be admitted on their own request.

A special hospital of the nature to take patients of both classes—the Psychiatric Clinic at Broughton Hall—has been established, and is now admitting patients who voluntarily seek the assistance of the department. It is in charge of Dr. Evan Jones, who has associated with him as a consultant Sir John Macpherson, M.D., F.R.C.P. Edin., lately Commissioner in Lunacy for Scotland, and now Professor of Psychiatry in the University of Sydney. As psychiatry is a compulsory subject in the medical curriculum at the University of Sydney, this clinic will be of great value in the training of medical students.

#### MENTAL DEFECTIVES IN NEW SOUTH WALES.

Under the auspices of the Public Health Association of Australia a meeting was recently held to discuss the problem of the mental defective. Sir John Macpherson, Professor of Psychiatry in the University of Sydney, referred to the

system in vogue in Scotland of boarding out the mental defectives, who partook to a certain extent in the communal life of their respective parishes. Under this system they are far happier than they would be in institutions, and he urged that the institutions should be made, as far as possible, to embody the domestic idea. Dr. Eric Sinclair, the Inspector-General of the Insane in New South Wales, said there must be numbers of mentally defective persons in this State whose training was neglected, over whom no sufficient control was exercised, and whose wayward and irresponsible lives were productive of crime and much misery to themselves and their relatives. Only when these unfortunates committed some crime was attention directed to them, and such persons committed to prison repeatedly for crime not due to inherent vice but to a permanently defective mind, could not be improved by punitive sentences. This condition of things could only be ameliorated by devising some means of training them in discipline and in simple occupations. Such training could not be done at home, but the education authorities were in the best position for finding out these defectives and providing efficient means for their training and education. Dr. Ralph Noble advocated the establishment of such out-patient clinics as were to be found in New York and in Massachusetts as the most effective means to be used in the fight against feeble-mindedness in the community.

#### THE MATERNITY BONUS.

At a recent meeting of the National Council of Women a report on the maternity allowance was presented by two ladies who were members of the commission appointed to inquire into the working of the maternity allowance in New South Wales. They stated that the allowance is claimed by 98 per cent. of mothers, but unnecessary deaths continue to occur. In New South Wales statistics do not show that the money disbursed in the maternity bonus has had the slightest effect in minimizing maternal or infantile mortality. Dr. J. C. Windeyer, Lecturer in Obstetrics in the University of Sydney, gives the following as average conditions: "From 12 to 15 per cent. of pregnancies end in abortion; from 3 to 5 per cent. of women are delivered of stillborn children. At least 50 per cent. of stillbirths are preventable. First-year deaths represent 7 per cent. of births registered. . . . Neo-natal deaths are largely preventable." Between 1912 and 1922 the Federal Government has distributed some six and a half million pounds among 1,300,000 mothers. The report gave examples of other systems of assistance in operation in Europe and America, where it had been found that measures which provided for instruction in the hygiene of maternity and infancy through public health nurses, consultation centres, and other suitable methods were of much greater benefit to both the mothers and the State than the system of giving a maternity bonus, and some recommendations based on this information were made to the Council. These will be considered at a future meeting.

## Correspondence.

#### TOXIC SYMPTOMS FOLLOWING THE ALKALINE TREATMENT OF PEPTIC ULCER.

SIR,—In view of the fact that I have for several years been a strenuous advocate of the medical treatment of gastric and duodenal ulcer in preference to surgery, I think it only right to draw attention to the possibility of toxic symptoms arising as a result of using very large doses of alkalis.

Sippy, who was the first to recommend this treatment with the object of completely neutralizing the acid of the gastric juice, has not referred in any of his papers on the subject to the toxic symptoms which may result. In a recent paper from the Mayo Clinic Hardt and Rivers<sup>1</sup> describe the toxic symptoms which may develop in cases in which it is impossible to neutralize the acid completely. The patient is at first unduly introspective and nervous. He then complains of difficulty in taking his milk. After a time headache, nausea, and vomiting occur. The patient

becomes apathetic and drowsy, and in one of their cases death ensued. In every instance the urea in the blood became greatly increased, and albumin and casts appeared in the urine. In some there was evidence of kidney disease before the symptoms developed, and in the fatal case definite chronic nephritis was found.

I have met with three similar cases in private patients, though none in hospital, during the last three years. In one case the patient had only one kidney and this was affected with pyelitis. In the other two patients a moderate degree of pyloric obstruction was present and there was an extreme degree of hypersecretion. In one of these death occurred in spite of the early cessation of the alkaline treatment. The urea content of the blood was greatly increased in all three cases.

It is impossible at present to say what is the cause of the toxic manifestations. But it seems clear that no case in which the kidneys are diseased should be subjected to the full alkaline treatment, and the same is true when partial pyloric obstruction is present in spite of Sippy's advocacy of the treatment in such cases. If any suspicious symptoms develop, a blood-urea estimation should be made and the treatment discontinued until it is ascertained whether it is excessive; in that case the treatment should be modified.

For ulcers associated with renal disease treatment by diet, olive oil, and belladonna in the manner I have described, with only small doses of alkalis, may give sufficiently good results, but if pyloric obstruction is present, even in a mild degree, it is probably wise to recommend gastro-enterostomy without further delay.—I am, etc.,

New Lodge Clinic, Windsor Forest,  
June 17th.

ARTHUR F. HURST.

#### THE PREVENTION OF HEART DISEASE.

SIR,—In the JOURNAL for June 2nd Dr. Poynton and Dr. Moon point out the desirability of providing homes for the convalescence of cardiac cases, and say that as far as they are aware no such places are in existence in England.

I would like to call attention to the fact that, under the auspices of the Invalid Children's Aid Association, a home for patients convalescent from rheumatic affections of the heart who need prolonged rest and care under medical supervision was established three years ago at 14, Stonebridge Park, N.W. (the Edgar Lee Home). Twenty-four boys under 15 are taken, and since the home was opened 203 boys have passed through our hands with results which may be said to justify the experiment, in view of the improvement in their condition. An experienced matron and nurses are in residence; weekly visits are paid by myself, and Sir John Broadbent and Dr. Cotton act as honorary consultants. There is a large garden attached to the home where patients can sit out or take suitable exercise. An important feature is the provision of educational facilities. A certificated teacher approved by the Board of Education attends daily, and classes are held in a roomy and well ventilated schoolroom, which are much appreciated by the children. Patients are kept for several months if necessary, and are not discharged till convalescence is fully established.—I am, etc.,

London, N.W., June 13th.

J. ANDERSON SMITH.

#### DISEASED TONSILS AND HEART DISEASE.

SIR,—I wish to express my entire agreement with Dr. Herbert Tilley in his definitions of "diseased tonsils" (June 16th, p. 1038). Apart from the history of severe or repeated tonsillar infection, the evidence of such infection is better sought in the presence of enlarged glands behind the angle of the jaw than in the appearance of the tonsils themselves.

I expect to publish shortly a paper on the analysis of one hundred cases of rheumatic endocarditis in which definite tonsillar infection was present in 81 per cent. Enucleation was performed in thirty-six of these cases. The result of the operation was so beneficial in the majority that, in my opinion, the question to be solved is how late in the course of the endocardial disease can benefit be expected from the removal of the focus of infection.

The best results can never be obtained from the operation

<sup>1</sup> L. L. Hardt and A. B. Rivers, *Arch. Int. Med.*, xxxi, 171, 1923.

of tonsillectomy so long as the patient returns to the environment in which he first contracted rheumatic infection. The ideal treatment consists in the removal, first of the septic tonsils from the patient, and then of the patient from his old surroundings to the happy conditions described by Dr. A. P. Thomson in the same issue of your JOURNAL.—I am, etc.,

Norwich, June 17th.

HUBERT J. STARLING.

#### WHAT IS A "DISEASED" TONSIL?

SIR,—Mr. Stuart Carruthers's letter in your issue of June 9th (p. 995) recalls at least one other which dealt with the same subject—namely, that of "Clinic" (July 6th, 1921).

Mr. Carruthers calls for a "definition." Is it possible to make a general one, to order, in this way? And if so, of what practical use would that be? Perhaps that is why, as he states, one has never been forthcoming.

The real question is, surely, whether in such and such a case under consideration the tonsils can be held responsible for certain pathological symptoms.

There is obviously no difficulty in recognizing as "diseased" or "unhealthy" tonsils which are acutely infected, subject to malignant changes, or the invasion of serious chronic disorders. This class, however, is small. I think there should be no misgivings about pronouncing tonsils of the following types "diseased"—even if there should be no symptoms at the moment:

(a) Those which are grossly hypertrophied, causing obstruction. (There must be a limit to the enlargement which is not considered pathological.)

(b) Those associated with persistent enlargement of the glands behind the angle of the jaw in the absence of oral sepsis (tonsils, gums, etc.).

(c) Those, however small, from which can be expressed foul-smelling matter (although the crypts always contain micro-organisms, such contents cannot be passed as non-pathogenic—if "pus" is not a sign of disease here why should it be considered so in tooth sockets or accessory sinuses?).

(d) The tonsil "with a past"—frequent attacks of tonsillitis, "colds" always starting in the throat, past "quinsies"—although looking quiet and harmless when inspected.

These four types comprise by far the majority of cases with which we are concerned. What then remains? A comparatively small group of cases with local or general symptoms, which one has learnt by experience to associate with "diseased" tonsils, but with no definite macroscopic signs in the tonsils. Whether the latter are "diseased" or "healthy" is purely a relative question, and what may be producing symptoms in A would fail to do so in B. One cannot be dogmatic, in such cases—one cannot be "absolutely sure." As in other surgical problems, one can only arrive at a verdict in each individual case by considering all the evidence at hand in the light of personal experience, and that accumulated and recorded by others, unassisted by any "definitions."—I am, etc.,

Worcester, June 11th.

J. B. CAVENAGH.

SIR,—In the BRITISH MEDICAL JOURNAL of June 9th Dr. Carruthers suggests that a diseased tonsil is one which shows intracellular micro-organisms on section. But the lymphocytes in the tonsil are continually migrating through the epithelium, phagocytosing the bacteria in the crypts, and returning into the lymph nodules, where the bacteria are destroyed and some measure of immunity attained. Thus intracellular micro-organisms are probably always present in every tonsil after birth, though not often easy of demonstration. This constant ingestion of bacteria is most easily studied in certain other subepithelial lymphatic glands—namely, the vermiform appendix and Peyer's patches in the rabbit, where the Gram-positive nature of the organisms enables them to be easily traced for a long time after they have been ingested. Thousands of intracellular bacilli can be counted in one high-power field of the microscope in the lymphoid tissue of any healthy rabbit's appendix. I have collected the evidence in support of the above statements in *Immunity in Health: the Function of the Tonsils and other Subepithelial Lymphatic Glands in the Bodily Economy*.

The presence of intracellular organisms, therefore, may merely show that the tonsil is functioning normally.—I am, etc.,

London, June 16th.

KENELM H. DIGBY.

#### DEFECTIVE LIPOLYSIS IN DIABETES AND CANCER.

SIR,—The discoverers of insulin have shown that this substance not only has an effect on the blood sugar but also on the utilization of fat. This utilization of fat is defective in diabetes, and insulin markedly improves it and rapidly removes any lipaemia if present. This latter action is especially interesting to me because for many years various aspects of the fat-splitting action of the pancreas have been the object of research by myself and other workers in this laboratory.<sup>1</sup> The main outcome of this work has been to show that lipase in extracts of the pancreas consists of two components, one of which, following current nomenclature, is spoken of as the *coenzyme* and the other *inactive lipase*. The coenzyme when produced in the pancreas, or after injection, appears to be distributed by the blood to the tissues, activating the lipases there. We concluded further that this activating property is due to organic and inorganic phosphates. Whether the islets of Langerhans are responsible for the formation of the coenzyme or not appears uncertain. The same uncertainty is seen in De Witt's experimental work.<sup>2</sup>

My object in writing is to call the attention of workers to this aspect of the question, and more especially in relation to cancer. My experiments showed that tissue lipolysis is defective in cancer. I am convinced that increased tissue lipolysis is a factor in the defensive processes of the body, and this is particularly the case in cancer. Anything which increases this action in that disease should not be lost sight of.—I am, etc.,

J. A. SHAW-MACKENZIE, M.D.Lond.

#### HERPES ZOSTER WITH LOCALIZED MUSCULAR PARALYSIS.

SIR,—In his article in the BRITISH MEDICAL JOURNAL for June 9th (p. 970) Dr. C. Worster-Drought writes that in an extensive search he has been able to find very few recorded cases of paralysis accompanying or following herpes zoster of the trunk. On October 21st, 1915, I showed at the Dermatological Section of the Royal Society of Medicine a man, aged 64, in whom paralysis of the left upper extremity occurred on June 16th; it was later (about June 23rd) that an eruption of typical herpes zoster was first noticed. The eruption involved the left side of the head and neck, the left clavicular region and shoulder, and the upper front of the left side of the chest. The Wassermann reaction was positive. Antisyphilitic treatment was employed, and, whether owing to this treatment and faradization or not, the condition gradually considerably improved. Amongst cases not referred to by Dr. Worster-Drought are the following:

C. Handfield Jones (*Med. Times and Gazette*, 1882, i, p. 462) described the case of a man, aged 64, in whom herpes zoster of the left arm was followed by muscular wasting of the affected extremity.

Sir William Broadbent (BRITISH MEDICAL JOURNAL, October 27th, 1886, p. 460) narrated the case of a woman, aged 74, in whom herpes zoster in the distribution of branches of the brachial plexus was followed by partial paralysis in corresponding motor nerves.

In one of G. Waller's cases (abstract in BRITISH MEDICAL JOURNAL, 1885, ii, p. 560) right brachial herpes zoster was followed by paralysis of the right arm.

In a man, aged 35 (E. Schwimmer, *Die neuropathischen Dermatosen*, Vienna, 1883, p. 139), a blow on one shoulder was followed by herpes zoster of that region and then by sensory disturbance and incomplete paralysis of the arm.

In one of the cases recorded by E. F. Buzzard (*Brain*, 1902, xxv, p. 299) brachial herpes zoster was accompanied by paralysis of the deltoid muscle on the affected side.

S. Vere Pearson (*Trans. Clin. Soc., Lond.*, 1903, xxxvi, p. 268) reported the case of a painter, aged 52, who on getting up one morning noticed sharp, burning pain about the left arm and inability to move the upper part of the arm. On the following day an eruption of herpes zoster appeared on the left arm, which extended from the shoulder to the wrist. There was complete paralysis of the left deltoid and infraspinatus muscles, with some atrophy, and there was partial paralysis of the latissimus dorsi muscle. The herpes gradually healed and the affected muscles commenced slowly to regain power.

It was in a case of herpes zoster with motor symptoms that Magnus (quoted by A. Sunde, *Deut. med. Woch.*, 1913, xxxix, p. 849) found diplococci in the anterior horn of spinal grey matter and ordinary inflammatory changes in the spinal ganglia.

Souques and Mlle M. Henry (*Soc. de Neurol., Paris*, November 7th, 1919) showed a woman, in whom paralysis of the fifth and sixth cervical segments was followed by muscular paralysis of the deltoid, etc., having a radicular distribution.

A. Lemierre and P. Lantuejoul (*Soc. Méd. des Hôpitaux de Paris*, November 8th, 1918) described a case of cervical herpes zoster with motor troubles.

Bocca (*Soc. des Sciences Méd. de Lyon*, November 24th, 1920) communicated the case of a woman, aged 61, with herpes zoster of the left upper extremity followed by radicular paresis in that limb.

In the distribution of the paralysis Dr. Worster-Drought's case seems to differ from almost all others.—I am, etc.,

London, W., June 9th.

F. PARKES WEBER.

### THE VENEREAL DISEASE REPORT.

SIR,—I beg to inform you that an important and representative meeting of the Executive Committee of this Society was held yesterday under the chairmanship of Lord Willoughby de Broke, when Sir William Arbuthnot Lane, Sir Bryan Donkin, Sir James Porter, Mr. Basil Peto, M.P., Dr. Sequeira, and others were present.

The following resolution was proposed by me and seconded by Dr. Jane Lorimer Hawthorne (vice-chairman of the Women's Committee) and was carried unanimously:

"That the Executive Committee accepts the Trevethin Report as a document supporting the essentials of the policy of the Society for the Prevention of Venereal Disease, as defined in their policy pamphlet, and especially welcomes the recommendation 'that the law should be altered so as to permit properly qualified chemists to sell *ad hoc* disinfectants, provided such disinfectants are sold in a form approved, and with instructions for use approved, by some competent authority,' as set forth in Clause 14 of the Report."

—I am, etc.,

London, W.1, June 15th.

H. WANSEY BAXLY,

Hon. Sec., S.P.V.D.

SIR,—The report of Lord Trevethin's Committee has been read with interest and with qualified approval by many in the profession; but it is not easy for some of us to appreciate the difficulty that you and the Committee have found in determining which is the most suitable official body to approve the form of *ad hoc* disinfectants and to supervise their sale by qualified chemists.

For years past the Government has deputed the highly important task of propaganda work to the National Council for Combating Venereal Diseases, at whose disposal Government funds have been freely placed to enable them to carry out the work. Would it not be wise to entrust this other highly important task—the issue of disinfectants—to the Society for the Prevention of Venereal Disease, in whose ranks are to be found those who have devoted most time to the study of this difficult question? This surely is the most obvious and equitable way of burying the hatchet.—I am, etc.,

Carnwarth, Lanarkshire, June 18th.

ROBERT FORGAN.

### DIPHTHERIA ANTITOXIN ON SUSPICION.

SIR,—In connexion with the possible development of an anaphylactic reaction following the injection of antitoxic serum in previously injected persons, Dr. Sichel asks two pertinent questions, which, however, are difficult to answer categorically.

His first question—namely, What is the chance of any particular individual developing symptoms of anaphylaxis, if reinjected after the ten days' or so interval of safety?—is one of increasing importance by reason of the extensive use of prophylactic injections generally. The answer to this question is that every person injected must be regarded as

a law unto himself, since, in view of the fact that with the exception of an increased liability to serum disturbance evinced by asthmatic subjects, we really have no knowledge of any personal factor indicative of supersensitization. No predisposition has been shown in respect to either dosage, family, or sex, though I am inclined to think that age exerts some influence. I base this belief, however, in respect to age liability on observations on serum sickness as it occurs in persons primarily injected. Most of the really severe and accelerated reactions that I have witnessed have been in adults or older children, and partly on this account, and partly to avoid unnecessary sensitization, I never advise giving prophylactic injections of antiphtheritic serum to grown-up persons, if under medical observation.

In answer to Dr. Sichel's further question—How long does the liability to anaphylactic disturbance persist?—it may be asserted that expert opinion tends to the belief that after the lapse of two or three years the risk of anaphylaxis is very slight, though the issue is necessarily confused by the fact that idiosyncrasy may determine a severe reaction after a dose of serum, quite apart from previous sensitization.

Experience tends to show that the likelihood of serious anaphylactic symptoms occurring is much exaggerated, and it must be remembered, as Dr. Sichel points out, that an equally severe reaction may occur after a primary injection.—I am, etc.,

London, S.W., June 19th.

F. FOORD CAIGER.

### ETHER VERSUS CHLOROFORM.

SIR,—Dr. McNamara's attack upon the use of chloroform in England (June 9th, p. 996), where he says "death under anaesthesia is extremely common," carries no conviction to me. "Extremely common" is a loose phrase which, I believe, no statistics justify. During the war I anaesthetized hundreds of our wounded, and almost always used chloroform on a Skinner's mask; but there were no deaths.

Chloroform has the advantage of not irritating the bronchial tubes, of easily controlling movement, and of seldom causing after-sickness, if given with proper restraint. By starting slowly, keeping the pupil small, and, without touching the eyeball, keeping the palpebral reflex just absent, you can go on for hours with an average use of one ounce of chloroform per hour. Of this the patient respires but a small proportion. A few drops of ether occasionally are often helpful.

Ether as an anaesthetic requires a complicated apparatus, as it freezes on a mask, and evaporates uncertainly in consequence. It irritates the bronchi, necessitates a large quantity of anaesthetic, and causes after-sickness.

From what I have seen of the administration of an anaesthetic abroad I am not astonished that ether should be popular. Ether lets off the anaesthetist, but is often inconsiderate to the patient, and I doubt, if after-effects could be taken into account and tabulated, whether ether would not present the darker picture. My belief is that chloroform is the better anaesthetic in good hands, and ether the better in bad, and that deaths under anaesthesia are very rarely the direct fault of either anaesthetic.—I am, etc.,

Knowle, Topsham, Devon, June 11th.

D. W. SAMWAYS.

### THE DRUG HABIT.

SIR,—I have read the article by Dr. W. E. Dixon (March 31st, p. 543) with great interest, but in parts with great concern. That any scientific man should cite the findings of the Opium Commission of 1895 is amazing. I think one may fairly state that its general findings were contrary to the mass of evidence presented to it, and that among all except a very small minority its findings on the effect of opium smoking are utterly discredited.

So much so that the Medical Committee of the League of Nations, which is composed of experts on this subject from all countries, states "that medical use should be considered the only legitimate use, and that all non-medical use should be recognized as an abuse, and also that in the opinion of the doctors the use of opium as a stimulant could not be considered legitimate even in tropical countries."

This opinion would be endorsed without hesitation by the

medical men of China, who have had unrivalled opportunity of dealing with the vast number of opium smokers who have in the past years come to our hospitals.

To speak of an opium smoker as not forming a strong craving, and as being easily cured, and to add that "withdrawal symptoms are never observed," is simply not true. Where Dr. Dixon gets his information I do not know, but anyone who has been in charge, as I have been, of wards for the cure of opium addicts knows that the contrary is the truth. It is a rare thing for an opium smoker to pass through his cure without intense misery, especially manifesting itself in the form of diarrhoea, and the craving is so strong that a true smoker will do anything to obtain the drug.

I am sorry that Dr. Dixon should hint from a single abnormal case that the morphine habit can be acquired and given up without much inconvenience by a normal person. It may be argued that I am reading more into his words than he means to imply, but I have seen case after case where apparently normal persons, having acquired a painful disease, have taken to morphine injections for the relief of the pain, and have waked up after a few weeks to find themselves in the grip of a far worse disorder. It is true that those who have acquired the habit in this way are easier to cure than those who have taken to it simply for pleasure or vice, but it means on the part of anyone who is in the grip of the habit a severe struggle to get rid of it.—I am, etc.,

Peking Union Medical College,  
Peking, May 10th.

J. PRESTON MAXWELL.

#### OF EATING.

SIR,—Since the dentition of the race is every day regarded as a more and more important factor in its well-being, I may perhaps be allowed to suggest that the increasing prevalence of dental disease is largely due to the neglect of instinct. Commonly we attribute the retreat of the jaw, imperfect and crowded teeth, caries, and periodontitis and many intestinal disorders to the use of soft prepared foods. Modern cooking is doubtless a factor in poor dentition, but it occurred to me long ago that even with our common food mastication would be properly carried out if children's natural instincts were allowed full play.

Horace Fletcher showed that there was, or should be normally, a reflex preventing deglutition of solids. His remedy for ill health was to re-educate this destroyed or inhibited reflex by careful mastication. No doubt good was done by this perfectly correct observation, but the fact that re-education was committed to the higher cerebral centres militated against its general recognition. Such a relegation means attention and labour. It is entirely unnecessary, and this will be recognized when it is remembered that the invariable instinct of the child, as of the savage, is to fill the mouth and to keep it full during meals. This enforces continual mastication, as nothing solid can be swallowed with a full mouth. Unhappily it has become a doctrine that such a habit is dangerous. Polite mothers and nurses, even the mothers and nurses of the poor, do their best to destroy the only way in which food is rendered so liquid that it flows down the gullet without any effect at swallowing. Should anyone doubt this one trial will convince him of its truth. It may be objected that if it were generally adopted there would be an end of polite conversation at the dining table. I am not prepared to estimate the real value of this polite conversation, but I doubt if it can be set against decent dentition or decent health. In any case, if such conversation among adults is too valuable to be lost—and I have known occasions when this could be said of it—the chatter of children, which they would not indulge in unless wrongly trained, should not be allowed to interfere so greatly with proper exercise of the teeth and jaws as to prevent perfect late dentition. When this is established conversation cannot destroy it, and on every occasion when it is possible to eat in the instinctive manner properly trained people and adults will at once revert to nature instead of eating like cormorants or ravens with three bites and a concealed gulp.—I am, etc.,

London, N.W., June 7th.

MORLEY ROBERTS.

#### HOSPITAL STAFFS AND INCOME TAX.

SIR,—Ventilation of this subject in your columns would be interesting and valuable. The main question can be stated thus:

A member of the medical profession, mainly dependent on earned income, attends at a hospital for so many hours a week as one of the honorary staff. If he were a paid official, which he is not, he would be charged income tax on his salary. It seems to me that, in equity, he should be entitled to a deduction for the time spent in this public work. The difficulty is to assess the rate, as allowance must be made for experience gained, increased efficiency, and the age and experience of the member.

Before the war the out-of-pocket cost to the medical man of such work was not excessive, and then, as now, it was regarded as a privilege. At the present time, with the rate of income tax and the cost of living both high, the out-of-pocket cost is considerable. Allowable deductions at present compensate inadequately for the style of housing and service that such a man is obliged to keep up. In many provincial centres the public work is out of all proportion to private remuneration, and this tends to result in a lowering of standard as regards advanced and research work, there being no margin to pay for the clerical part of it. The factor of cost must deter some whose services in these and allied matters would be of use, both to the public and to the professed subjects, from venturing at all, and in the case of some already so engaged may cause them loss.

In the event of a sufficient body of opinion being expressed, and of some kind of flat rate deduction being suggested for day and night work, perhaps steps could be taken to bring the matter before the income tax authorities.—I am, etc.,

Aberdeen, June 16th.

G. H. COLT.

#### A PROTEST.

SIR,—In your issue of June 16th you published an article of mine relating to a case of foreign bodies in the stomach, and the very same evening an abstract of the article appeared in the lay press, giving my name, that of the hospital, and, to crown all, under sensational and objectionable headlines.

I would like, therefore, to take immediate opportunity of registering a strong protest against this freedom on the part of the newspapers to publish, without permission, any matter which appears in a medical journal; first, because, as in the present instance, the patient may read the account of same and run the grave risk of a relapse in her mental condition, and secondly, because there might arise in the minds of many people, both lay and professional, the erroneous impression that such publication had been permitted by the doctor in question for the purpose of self-advertisement.

I would further suggest that some steps should be taken to enable the Editor of the BRITISH MEDICAL JOURNAL to control the depredations of these sensation-loving and unthinking newspaper reporters, when they seek to cull cheap copy from its pages. Had I thought that such as the above would happen, my article would never have been sent for publication.—I am, etc.,

A. GEORGE BRAND.

Ayr, June 17th.

\*\* We sympathize with our correspondent and associate ourselves with his protest. But it is not easy to find a remedy. Matter published in the BRITISH MEDICAL JOURNAL is copyright, but the law of copyright is so ill defined that redress is difficult.

#### NURSES' REGISTRATION.

WE have received several letters from nurses calling in question the accuracy of some of the statements in Dr. Skene's letter published on June 9th (p. 997). The points raised seem to have been met in the discussion in the House of Commons, a report of which is published at page 1069.

## Obituary.

HENRY TROUTBECK, M.A., M.B., B.Ch.,

Medical Officer to Westminster School.

WE record with regret the death of Dr. Henry Troutbeck, of Ashley Gardens, Westminster, at the age of 57. About twelve years ago Dr. Troutbeck appears to have had slight symptoms of angina pectoris. On the morning of June 3rd last he seemed in perfect health; but on his returning from visiting patients he became very ill and had paroxysms of pain for nearly an hour. Recognizing that angina pectoris had reappeared, he directed his wife to give him injections of morphine and such other remedies as were at hand; but they were of no avail.

Henry Troutbeck was a son of the late Canon Troutbeck of Westminster; his brother, the late Mr. John Troutbeck, was for many years Coroner for Westminster. He was educated at Westminster School and Caius College, Cambridge, where he obtained honours in the Natural Sciences Tripos, and was for a short time a junior demonstrator in the University physiological laboratories. After studying at St. Bartholomew's Hospital he graduated M.B., B.Ch. in 1892, and obtained a post as house-physician. It was during his residence at St. Bartholomew's as house-physician that he produced a very clever series of caricatures of the hospital staff. He served next as house-surgeon at the East London Hospital for Children, Shadwell. After starting general practice in Ashley Gardens, Dr. Troutbeck became medical officer to Westminster School. He was a member of the Westminster and Holborn Division of the British Medical Association.

At the inquest Mr. Ingleby Oddie, the Coroner, commented upon the calmness and bravery of Dr. Troutbeck when he knew that he was dying, and described him as justly popular, and a kindly, efficient, and sympathetic medical man.

E. J. STEEGMANN, O.B.E., M.B., B.S.

DR. E. J. STEEGMANN, a distinguished worker in many departments of public health, passed away on June 8th. He came of an old Nottingham family, was educated at St. Mary's Hospital and at Durham University, and held resident posts at his own hospital and at the Brompton Hospital. After a short period of general practice he turned to public health work, which had always attracted him, and devoted himself to that field for the rest of his life. He held the post of Lecturer on Hygiene and Public Health at St. Mary's Hospital and for a time was medical officer of health for the Heston and Isleworth Urban District.

For ten years, from 1901, he was secretary to the Royal Commission on human and animal tuberculosis, which followed on Koch's startling pronouncement that infection of man by animal tuberculosis was negligible. Dr. Steegmann, who was a man of signal ability and administrative capacity, threw himself with great ardour into the work of the Commission, and I well remember the intense interest he took in the experimental investigations and the whole-hearted admiration he felt for the eminent men with whom he worked.

He was one of the earliest medical officers to join the R.N.V.R., in which at the time of his death he was Surgeon Commander. He went on active service in 1914 with the Fleet and afterwards did important special sanitary work for the Admiralty. It was on his advice that the system of Naval Sanitary Officers, which is now adopted at the large ports in this country, was introduced.

After the war he was employed in international medical work at the Ministry of Health, and later took a leading part in organizing the Section of Hygiene for the League of Nations.

In all, a record of public work of which any man might be proud, gallantly done in spite of ill health and almost lifelong pain. In public life Dr. Steegmann proved himself to be a man of great ability and enthusiasm with a marked power of impressing his views on others. In private life his friends will remember him as a bright, courageous spirit, whose loyal affection was always the same in spite of the lapse of time.

J. J. P.

## Universities and Colleges.

### UNIVERSITY OF CAMBRIDGE.

THE Professor of Anatomy has made the following appointments in the Anatomy Department: Senior Demonstrator, Dr. A. B. Appleton; Junior Demonstrators, Mr. N. G. Reid and Mr. A. Hopkinson; Additional Demonstrator, Mr. V. C. Pennell.

At a congregation held on June 16th the following medical degrees were conferred:

M.D.—G. W. Goodhart, G. W. Mitchell.  
B.Ch.—E. C. Curwen.

### QUEEN'S UNIVERSITY, BELFAST.

At a meeting of the Senate held on June 13th Dr. W. W. D. Thomson was appointed professor of medicine in the University, Dr. Andrew Fullerton professor of surgery, and Dr. Percival Orymble lecturer in operative surgery and applied anatomy. A resolution was adopted placing on record the Senate's high appreciation of the invaluable services rendered to the University by Professor Lindsay during his tenure of the chair of medicine from 1899 to 1923.

### ROYAL COLLEGE OF SURGEONS OF ENGLAND.

AN Ordinary Council was held on June 14th, 1923, when Sir Anthony Bowlby, President, was in the chair.

Mr. J. Howard Mummery, C.B.E., was introduced, and admitted a Fellow of the College.

#### Issue of Diplomas.

Diplomas of Fellowship were granted to the following twenty-four candidates found qualified at the recent examination:

W. Anderson, H. A. Brookes, A. G. Bryce, C. H. Carlton, G. R. E. Colquhoun, D. I. Currie, F. P. Fouché, G. J. Gillam, W. J. Lytle, N. Makar, P. J. Moir, J. W. G. Phillips, J. Mol. Pinkerton, J. E. Purves, S. D. Rhind, W. Salisbury, R. S. Scott, W. Shaw, N. R. Smith, G. F. Syms, D. R. Wheeler, E. R. Wheeler, R. L. Williams, S. H. Woods.

Licences in Dental Surgery were also granted to seventy-six candidates.

#### Examiners.

The following eight members of the Board of Examiners in Anatomy and Physiology for the Fellowship were elected for the ensuing year:

Anatomy.—J. Ernest Fraser, G. Gordon-Taylor, W. F. Haslam, William Wright. Physiology.—David de Souza, John Mellanby, Frankcon Roberts, A. Rendle Short.

The following were elected Examiners under the Conjoint Examining Board for the ensuing year:

Elementary Biology.—J. P. Hill, T. W. Shore. Anatomy.—Henry A. Harris, David Hepburn, John Basil Evans, H. E. Roaf. Midwifery.—Eard G. D. Robinson, Donald W. Roy. Pub. W. Andrews. Part II: Francis J. Hygiene.—George C. Low, H. B. G. Nov Surgery.—Part I: H. Willoughby Lyle Malcolm I. Hepburn. Psychological Med. . . . .

The resignation of Mr. F. F. Burghard from the Court of Examiners will take effect on the completion of the pass examination for the Membership in July. The vacancy on the Court thus occasioned will be filled up at the Ordinary Council on July 31st.

The vacancy caused by the expiration of Mr. N. G. Bennett's term of office on the Board of Examiners in Dental Surgery will be filled up at the Ordinary Council on July 31st.

The date fixed for the Ordinary Council following the Quarterly Council in July was Tuesday, July 31st.

The last day for sending in votes for the election to the College Council is July 5th, 2 p.m.

## The Services.

### OPERATIONS IN WAZIRISTAN.

THE names of the following medical officers have been brought to notice for distinguished service during the operations in Waziristan, April, 1921, to December, 1921, by His Excellency General Lord Rawlinson of Trent, in a dispatch dated May 24th, 1922:

Royal Army Medical Corps: Captain (acting Major) G. A. E. Argo, M.C., Captain (temporary Major) W. Frier, Colonel A. E. C. Keble, C.B., C.M.G., D.S.O., Captain (temporary Major) J. M. Mackenzie, M.C., Captain (acting Major) M. P. Power, M.C., Captain (acting Major) B. C. O. Sheridan, M.C.

Indian Medical Services: Temporary Captain P. P. Daruwalla, Captain (acting Major) P. A. Dargan, temporary Captain M. A. Mithavala, temporary Captain J. S. Pinto, Captain (acting Lieut.-Colonel) J. W. Van Reenan, Major (acting Lieut.-Colonel) W. D. Wright.

## Medical News.

THE Prince of Wales, President of Guy's Hospital, will open the new anatomy, biology, and physics department of the Medical School on Monday, July 2nd, at 3 p.m.

At a meeting of the Senate of Queen's University, Belfast, held on June 14th, it was agreed to confer the degree of LL.D. *honoris causa* on Major-General Sir R. Havelock Charles, G.C.V.O., K.C.S.I., Medical Adviser to the India Office and Sergeant-Surgeon to the King, in recognition of his public services to India and the Empire.

THE thirty-eighth annual meeting of the Caledonian Medical Society will be held in the Aberdeen Medico-Chirurgical Society's Hall, 29, King Street, Aberdeen, on Friday, June 23th, when Dr. David Rorie, D.S.O., will take the chair at 2.30 p.m. The annual dinner will take place on the same evening at the Palace Hotel, Aberdeen. This is the first occasion on which the annual meeting of the society is to be held in Aberdeen, and it is hoped to maintain, both as regards numbers and enthusiasm, the high level of the Stonehaven meeting in 1912, the only other occasion when the society met in the north-east of Scotland.

THE Mayor of Bath, Alderman Cedric Chivers, has assumed the responsibility for the expenses of a scientific research on the therapeutic properties of the Bath waters. The research will be carried out during the course of the summer in the Royal Mineral Water Hospital under the direction of Dr. Raimont of Oxford, assisted by Mr. G. L. Peskett, in co-operation with the medical staff of the hospital.

THE Council of Epsom College will shortly award several France pensions of £30 a year to medical men. Candidates must be not less than 55 years of age, and their income, independent of any allowance from the College, must not exceed £100 a year. The Council will also award one Grewcock pension of £50 a year. In this case there is no limitation as to age, but candidates must be legally qualified medical men who have retired from professional work, and who, in the opinion of the Council, are in need of the pension. There is the same income limit as in the case of France pensioners, and special consideration will be given to the claims of candidates having association with Worcestershire, Lincolnshire, or Carmarthenshire. Forms of application can be obtained from the secretary, Mr. J. B. Lamb, 49, Bedford Square, W.C.1.

SOME time ago we gave an account of the hospital established at Cardigan as a war memorial. It is staffed by practitioners in the county and Sir John Lynn-Thomas, who resides in the neighbourhood, is the director of the surgical clinic. The first annual meeting of the hospital was held recently, when it was reported that during the ten months for which it had actually been at work 167 cases had been treated; of these 88 were in-patients. Sixty-three operations were performed and 28 cases were submitted to x-ray examination for diagnostic purposes. The hospital when it opened had six beds, but it was soon found necessary to increase the number to ten and to add two cots. A vote of thanks to the staff was acknowledged by Sir John Lynn-Thomas.

DR. T. W. NAYLOR BARLOW, O.B.E., of Wallasey, has been elected president of the Society of Medical Officers of Health for the session 1923-24. He will be installed on Friday, October 19th, and will preside at the annual dinner of the society on the evening of the same day.

THE QUEEN has sent a donation of £50 to the Professional Classes Aid Council, 251, Brompton Road, S.W.3.

THE President of the Royal Society, Chairman of the General Board of the National Physical Laboratory, has issued invitations to visit the Laboratory, Teddington, on the afternoon of Tuesday, June 26th.

DR. A. H. G. BURTON, of the Middle Temple, and Dr. Charles Greer, of Gray's Inn, were called to the Bar on June 13th.

At the annual meeting of the governors of Queen Charlotte's Lying-in Hospital, London, Lord Howard de Walden referred to the serious financial position of the institution. There was a debt of £20,000, the hospital had had to deposit all its securities against the bank overdraft, and the committee to raise money on the security of the freehold. The number of patients seeking admission was greater than ever, and the accommodation in the hospital for post-graduate students, medical students, maternity nurses, and pupil midwives, who came to the hospital from all parts of the world, was quite inadequate for the demands made upon it. It was impossible to carry out the necessary extensions and alterations until the debt was paid off, and he made an earnest appeal for additional financial support.

A RECEPTION will be held at University College, London, on Saturday, July 7th, from 3.30 to 7 p.m., when the new anatomy building and the extensions of the physiology and engineering departments will be open to inspection. The secretary requests that old students of the college who have not recently communicated their addresses should send them to him.

THE KING has approved the appointment of the Honourable Dr. Alexander Campbell to be a member of the Legislative Council of the Colony of Newfoundland.

AN advanced course in oto-rhino-laryngology intended for specialists will be held at the Bordeaux Faculty of Medicine from July 23rd to August 4th under the direction of Professor Moure and Dr. Portmann. It will include operations, examination of patients, laboratory examinations and lectures. The fee of 153 francs is payable to the secretariat, Faculté de Médecine, Bordeaux.

A LECTURE on the stomach from the radiologist's standpoint will be delivered by Dr. G. E. Vilvandre in the Anatomical Theatre of the London Hospital Medical College on Thursday, June 28th, at 4.15 p.m. The lecture is intended for senior students of the hospital and to post-graduates, who are cordially invited.

APPLICATIONS for entry for the Savill Memorial prize (value £15) must be sent in to the Secretary of the West End Hospital for Nervous Diseases, 73, Welbeck Street, W.1, by July 16th. Post-graduate and undergraduate medical students who have visited the hospital during the year 1922-23 are eligible. A thesis on a neurological subject at the discretion of the candidate must be received at the hospital by October 1st.

THE Fellowship of Medicine has arranged for a special course in neurology at the West End Hospital for Nervous Diseases from June 25th to July 27th. There will be demonstrations each day in the out-patient department and lecture demonstrations dealing with the diagnosis and treatment of nervous disease will be given three times a week by members of the staff. A special course on diseases of children has been arranged at the Royal Waterloo Hospital from July 16th to August 4th. General refresher and special courses in cardiology, dermatology, and ophthalmology have also been arranged during July and August. Full particulars can be obtained on application to the Secretary, Fellowship of Medicine, 1, Wimpole Street, W.1.

THE University of Durham proposes to confer the degree of D.C.L. *honoris causa* upon Sir Anthony A. Bowly, K.C.B., K.C.M.G., K.C.V.O., President of the Royal College of Surgeons' Hospital, a Surgeon to St. Bartholomew's Hospital, and to the King. It is expected that Sir Anthony will receive the degree at the convocation on June 26th.

THE annual meeting of the Poor Law Medical Officers' Association will be held at the house of the Society of Medical Officers of Health, 1, Upper Montague Street, W.C.1, on Thursday, June 28th. Sir Arthur Newsholme, K.C.B., M.D., the president, will take the chair at 4.15 p.m. Poor Law medical officers are earnestly requested to attend.

COMMEMORATION DAY was celebrated at Livingstone College, Leyton, on June 13th, when a large assembly gathered in the grounds of the college, with Sir Leonard Rogers in the chair. The principal, Dr. Tom Jays, and the treasurer, Mr. L. R. Barclay, made statements on the work and the financial position of the college, which is not yet self-supporting. Sir Leonard Rogers referred to the excellent work the college does in training missionaries to look after their own health and to give medical aid to others in distant parts of the Empire where more skilled medical assistance was lacking.

THE David Syme Research Prize for 1923, presented to the University of Melbourne for research work in biology, chemistry, geology, and natural philosophy, has been awarded to Dr. Frank Longstaff Apperly, senior lecturer in pathology at the University. His paper dealt with the diagnosis and treatment of diseases of the stomach. Dr. Apperly was a Rhodes scholar in 1910 at Oxford. In acknowledging the honour he strongly advocated the establishment of an institute of research, where important problems that were purely Australian, such as hydatids and hookworm, might be thoroughly investigated.

DR. A. ROLLIER will hold a course of heliotherapy at Leysin from August 13th to 18th. Further information can be obtained from Dr. Rollier, Leysin-Village, Switzerland.

DR. DUBOIS has succeeded Professor Wertheimer in the chair of physiology at the Lille Faculty of Medicine.

MESSRS. BELL intend shortly to publish a book entitled *The Structure of the Atom* by Professor Andrade of Woolwich, and a new and enlarged edition of *X Rays and Crystal Structure* by Sir William Bragg and Professor W. L. Bragg.

## Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

The postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, Aitiology, Westrand, London; telephone, 2630, Gerrard.

2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate, Westrand, London; telephone, 2630, Gerrard.

3. MEDICAL SECRETARY, Medisecra, Westrand, London; telephone, 2630, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus, Dublin*; telephone, 4737, Dublin), and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: *Associate, Edinburgh*; telephone, 4361, Central).

### QUERIES AND ANSWERS.

#### SALICYLATE INJECTIONS FOR VARICOSE VEINS.

DR. W. A. MURRAY (British Hospital, Oporto) writes: I should be much obliged if any of your readers could give me particulars of the treatment of varicose veins by injection of sodium salicylate. The points on which I should like advice are: (1) Has the treatment proved successful? (2) What is the dose and technique of administration? (3) Are there any special dangers to be avoided—for example, thrombosis extending up the veins?

#### INCOME TAX.

"W. H. L."—(1) A and B have changed the ratio in which they share the partnership profits from two-thirds and one-third to half and half as from January 1st, 1923. (2) B bought a motor cycle in 1920 for £130 and sold it in 1923 for £62, buying a motor car in its place for £525. What is he "entitled to put down to this year's expenses"?

\* \* (1) We suggest that "W. H. L." should request the Inspector of taxes to let the firm have a statement setting out the computation of each partner's share of tax on the basis of the change on January 1st, 1923. Assuming that this is found to be correct, each partner should contribute towards the July tax (which is the second instalment of the total duty payable for the year to April 5th, 1923) the amount necessary to increase his January, 1923, payment to the total amount due from him according to the revised statement. ("£130-£62=£68 can be included in the expenses in computing the profits for 1923 for the purpose of the average amount assessable in subsequent years.

### LETTERS, NOTES, ETC.

#### SODIUM OR POTASSIUM SALTS.

DR. F. G. CAWSTON (Durban) writes: I do not consider that there is sufficient clinical evidence to support the contention that the sodium salt is preferable to the potassium where patients are being treated with intravenous antimony. In my own experience with these drugs I have found patients much more subject to muscular pains where the sodium salt is used, and, since I have adopted the procedure of using tartar emetic in doses ranging from 1/2 to 1½ grains dissolved in not more than 3 cubic centimetres of saline just before the injection, I have noted none of those unpleasant toxic effects which I sometimes observed when using distilled water or when injecting the sodium salt. I have not been able to note any more beneficial effect from the injection of 2 grains of the sodium preparation than 1½ grains of the potassium in several cases of bilharzia infection that I have treated, and in some patients suffering from extensive condylomatous conditions the experience was the same. In 1920 the Minister of Agriculture promised me that those methods of administering antimony which were being used with success in the treatment of bilharzia disease in Natal should be given a thorough trial in the treatment of cattle suffering from nagana in Zululand. Fortunately Mr. H. H. Curson, M.R.C.V.S., who had carried out a series of tests on fluke-infested sheep, using the freshly dissolved tartar emetic solution as I had demonstrated it to him, was placed in charge of the experimental station, and the treatment resulted, according to the Department of Agriculture, "in immediate success." Though I offered him all the sodium

preparation I had on hand, as I had hoped that cattle might be able to tolerate the drug better than human beings, he confined himself to the potassium salt, and we have yet to find a more economical and effective remedy for either nagana or bilharzia disease.

#### INTRAVENOUS ACRIFLAVINE FOR GONORRHOEA.

DR. M. W. BROWDY (London, W.) writes: In the Epitome of Current Medical Literature in the BRITISH MEDICAL JOURNAL (June 16th, 1923, para. 500) G. H. Wood is quoted as advocating intravenous injections of acriflavine in the treatment of acute gonorrhoea. I described this method of treatment in the Practitioner, October, 1921, with satisfactory results. I believe I was the first to suggest it.

#### METHYLATED SPIRIT DRINKING.

We observe that in his last annual report Dr. F. S. D. Hogg, medical superintendent of Dalrymple House, Rickmansworth, notes an increasing number of cases of methylated spirit drinking among his patients. He supposes that inebriates drink this disgusting fluid (alcohol "denatured" with 10 per cent. wood naphtha and 0.25 per cent. petroleum oil) because they are short of funds or are unable to buy potable spirits except during restricted hours of sale. Dr. Hogg has his own way of helping patients to overcome any temptation to indulge in secret draughts of methylated spirit. For the past twenty years such methylated spirit as has been used in the institution has been "doctored" with tartar emetic and marked "poison." He says—and we can well believe him—that it is very rare for a patient to sample this mixture, and he has never known one to try it twice. He accordingly suggests that all the methylated spirit sold to the public might well have this addition, which would add but a trifle to its cost. It has often surprised us that pharmacological advice is not sought in regard to the "denaturing" of alcohol.

#### MEDICAL GOLFING SOCIETY.

THE Medical Golfing Society's annual summer meeting was held at Addington Golf Club on June 14th. The meeting was a great success, over ninety members competing for the various prizes. As usual, all competitions were against bogy.

Mr. H. D. Gillies (+2) won the *Lancet* Challenge Cup and Memento for the best scratch return with 4 up; also the Henry Morris Challenge Cup and Society's Gold Medal for best handicap return with 2 up. His actual score was 73.

Other results were as follows:

CLASS I. (Handicap 9 and under.)		CLASS II. (Handicap 10 and over.)	
1st Prize.—Sir R. Cruise (2) 1 up. (Mr. H. D. Gillies was ineligible for this prize.)		1st Prize.	H'cap.
2nd Prize.	H'cap.	C. M. Hinds Howell ...	10
J. Swan ...	6	J. Cunningham ...	12
G. Dawson ...	4	N. B. Benjafield ...	16
Gordon Lane ...	9	H. L. Hatch ...	15
Sir K. Goadby ...	8	J. Clarke ...	14
(All square.)		(All square.)	
Best last nine holes.		Best last nine holes.	
Sir K. Goadby } All square.		J. E. Coulson ...	11
Gordon Lane }		L. Bathurst ...	11
		(1 up.)	

#### In the Foursome Sweepstakes.

1st Prize.	H'cap.
Bruce Hamilton ...	12
G. A. Sutherland ...	6
2nd Prize.	
{ Sir R. Cruise.	
{ Gordon Lane.	
{ O. R. Salisbury ...	16
{ O. H. Housden ...	18
{ J. S. H. Lewis ...	8
{ Murray Thomson ...	10

All ties will be played off in due course.

#### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 28, 29, 30, 31, and 34 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 32 and 33.

A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 279.

### SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Six lines and under	...	...	0 9 0
Each additional line	...	...	0 1 6
Whole single column (three columns to page)	...	...	7 10 0
Half single column	...	...	3 15 0
Half page	...	...	10 0 0
Whole page	...	...	20 0 0

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded. Advertisements should be delivered, addressed to the Manager, 429, Strand, London, W.C.2, not later than the first post on Tuesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive *poste restant* letters addressed either in initials or numbers.

## A British Medical Association Lecture.

## NOTES FROM PRACTICE.\*

BY

W. J. TYSON, M.D., F.R.C.P., F.R.C.S.,

HONORARY PHYSICIAN, ROYAL VICTORIA HOSPITAL, FOLKESTONE.

*Prognosis in Heart Disease.*

Just now there is reason to avoid going from one extreme to the other. Murmurs are not all innocuous, as some seem to imply, but vary in character, and also as to which valves are involved. What is important is this: How does the heart act? Are there any signs or symptoms? If there are not, then the less a patient knows about his heart the better it is for him. In my opinion the presystolic murmur ranks first in seriousness; after this the aortic (regurgitant); and the most favourable is the systolic mitral—all referring to the left side of the heart. Again, all these murmurs must be considered in conjunction with the state of the wall of the heart.

The sinus irregularity of children, associated with the respiration, which at one time produced so much mental anxiety among doctors and patients, need not disturb us. The extra-systoles, easily detected, are not prognostically bad; these are generally missed pulse beats, seen mostly in old people.

The effect of cardiac diseases is really to be gauged in its extent by how much the ventricular action is affected. The most important cardiac irregularity is auricular fibrillation. Its constant association with the presystolic murmur makes this latter of serious importance; it also occurs in the cardiac sclerotic changes of elderly people.

The very slow pulses of old people, often accompanied with insensibility, and even fits, which we have all seen, are now known to be due to heart-block, the condition, of course, varying with the amount of disease in the auricular bundle obstructing the stimuli from auricle to ventricle. In the young the heart disease is generally rheumatic in origin; although the prognosis is good, still this must depend on the ventricular efficiency, tested by physical exertion. In middle life and onwards cardiac disease is due to degenerative changes in the musculature of the heart.

Of all drugs digitalis holds its own, but after this ranks theocine-sodium acetate; both are most useful when auricular fibrillation is present. It is generally thought that the value of digitalis consists almost entirely in slowing of the pulse, the drug having no effect on the left ventricle, but only on the vagus nerve, affecting the supraventricular tissues.

*The Relief of the Right Heart.*

There is no doubt that the heart is more often auscultated than percussed—in other words, the valves are more thought of than the muscle; also, the left side receives more attention than the right. This probably is as it should be, but there are times when the right side of the heart, especially the auricle, demands our thought and skill. When we are dealing with diseases such as pneumonia, valvular or muscular disease of the left heart, it is well to examine by percussion the size of the right auricle. Now there is not much difficulty in detecting an enlarged right auricle; the normal dullness of one fingerbreadth to the right of the sternum in the fourth interspace is increased to two, or perhaps three, fingerbreadths; the ordinary finger percussion is quite sufficient for all practical purposes. When this enlargement is discovered, then local depletion by means of a few leeches—three to six—is decidedly valuable. I have seen cases where, after application of leeches, the distress has been almost at once relieved; it is then that the action of digitalis and strychnine can have full play, for it is bad treatment to begin with heart tonics before the heart congestion is relieved, and often, also, before the alimentary canal is purged.

\*Delivered at Carmarthen on Wednesday, April 11th, 1923, before the members of the South-West Wales Division.

*Treatment of Acute Diarrhoea in Children by Saline Injection.*

Acute summer diarrhoea in children is one of our greatest anxieties. I am not speaking of the comparatively mild cases which yield to ordinary remedies and dieting, but to those collapsed conditions in which sickness and constant diarrhoea are both present, and which are found mostly among the classes that live in poor and crowded thoroughfares. These cases, when possible, should be admitted as in-patients for hospital treatment; here alone can they be kept properly clean and fed, and in a thoroughly ventilated room. If we can manage to prolong life for a few days, recovery will frequently follow. It is often most difficult at first for the baby or child to keep down any food at all. It is in this condition that saline injections, given either by the skin or bowel, are of great and saving value. The injections must be given slowly and continuously.

*Pleuritic Effusion.*

When the right or left chest is three-fourths full of fluid or more, then aspirate or tap. I have seen two or three people die from simply sitting up in bed when one side of the chest was full. When the quantity of fluid is less than three-fourths there is no necessity for immediate action—in fact in a few days the fluid may not only diminish, but soon entirely disappear. There are two dangers in withdrawing the fluid—namely, a sudden acute congestion, or oedema of the compressed lung, producing an albuminous or serous expectoration in large quantity, resulting in serious obstructive breathing. The cases like this which I have seen have recovered, but fatal ones have been recorded. Again, the mere tapping or aspirating has resulted in immediate death. It is not wise to draw off the whole of the fluid, for the reason that when doing so syncopal attacks are apt to occur. The most common condition mistaken for an effusion is a chest tumour, which is generally malignant in character, but here the heart and other organs are not displaced.

Two other diseases may cause difficulty—namely, aneurysm of the thoracic aorta, and a hydatid cyst. It may be fatal to aspirate either. It is generally believed that the effusion is of a tuberculous origin; whether this be so or not, in my opinion a large proportion of these cases get well, and remain so. I do not remember seeing a serous effusion become purulent; when it is purulent it is so from the beginning. I know of no sign or symptom to distinguish between a purulent and a serous effusion—of course, one may make a shrewd guess. The temperature does not help us.

*The Mania following Pneumonia.*

I am not now referring to the ordinary delirium, or "delirium febrile," a delirium, as its name implies, which may come on in any case with high fever. Pneumonic delirium is not common, and it is often associated with the apical form. Perhaps one of the most interesting and practical points is that the delirium may be the first symptom noticeable in the disease—that is to say, the physician is called to see a case of delirium, and on examination of the lungs he discovers pneumonia. In young children this delirium has been mistaken for meningitis. The pneumonia is generally of the sthenic type and occurs generally in comparatively young people.

But the cases to which I wish particularly to call attention are those in which the mania follows the pneumonia. I have had the opportunity of seeing three of these cases, but the literature is exceedingly scanty. I think the reason of this scarcity is mainly because these cases occur in the hands of private practitioners and so do not get recorded. The following are the characteristic points in this form of pneumonia mania:

1. The pneumonia is of the sthenic or classical type.
2. The people affected are mostly of a neurotic temperament.
3. It generally occurs in youngish people under 40 years of age.
4. It is associated with great sleeplessness, and there seems great difficulty in the treatment of this symptom.
5. It is not essential that the disease be very acute or that much lung be involved—in fact, the amount of lung involved does not seem to bear any relation to the amount or length of stay of the mania.
6. It occurs after the crisis. The delirium, already mentioned, which occurs early in the disease, is as a rule a much more severe type of mania than that which follows the crisis.

7. The pathology, I suppose, is toxic, but I am unable to say why some people suffer in this way and others do not.

8. The prognosis of this mania is good; it should be looked upon as part of the pneumonia, and should not be especially treated as a case of mania *per se*. The question of asylum treatment need not be considered. I mention this point because in one of my cases the doctor in attendance considered the mania should be treated in an asylum.

9. *Treatment*.—Perhaps the most important thing in this trouble is to treat the sleeplessness. Food is the best hypnotic, but it may be necessary to give some paraldehyde or some other narcotic. The bowels should be attended to. A tactful, wise, and firm nurse is a necessity, and convalescence should be carried out in the country.

#### *On the Late Discovery of Physical Signs in Pneumonia.*

The signs to which I wish to draw attention are dullness on percussion, bronchial breathing, and bronchophony, which, in my opinion, not infrequently occur, or rather are discovered, comparatively late in the course of the disease. The following paragraphs occur in two standard works on medicine:

"Usually up to the third day after the chill the percussion note over the affected part becomes dull, the respiration of a blowing character. Bronchophony now makes its appearance."

"On the second day a dullness more or less appreciable reveals itself in the part originally affected, and there are also heard in that situation anomalous signs which become more and more decided, such as a fine and very equal crepitant r le, heard during respiration."

These paragraphs show the generally acknowledged time as to the appearance of the physical signs of pneumonia. From observation of cases of croupous pneumonia that have come under my care, I believe that the physical signs, such as dullness on percussion, bronchial breathing, and bronchophony, occur later in the disease than is generally supposed; or perhaps it would be more correct to say that there is a larger percentage of cases with the above signs lately discoverable than our reading or teaching has hitherto led us to suppose. What this percentage is I am not prepared to say. The authors already quoted say further on in their articles on pneumonia that the characteristic physical signs of the disease may escape detection from the inflammation being confined to the central situation of the lung. Probably this explanation may account for the lateness of the appearance of the aforementioned signs. Yet, allowing that this explanation is the true one, it is nevertheless just as important for the welfare of the patient to diagnose a central pneumonia early as it is a peripheral one, for the one is as dangerous in its prognosis as the other. If this dullness, bronchial breathing, and bronchophony are not infrequently noticed late—for all authors admit that these signs are occasionally either overlooked or lately discovered—then it becomes necessary to diagnose pneumonia by symptoms instead of by signs. One of the authors before quoted says that if the patient has had a chill, pain in the side, rusty sputa, and high temperature, there is scarcely any room for doubt about the diagnosis, and even in central pneumonia these symptoms are generally present. If there is one symptom which is pathognomonic of the disease it is the pulse-respiration ratio—it is often in the proportion of 2 to 1. I know of no disease in which this ratio is so low.

#### *Change of Type of Pneumonia.*

I should say from my own experience that the sthenic or classical type of pneumonia is not so frequently met with as formerly. The type of pneumonia seems to have changed in character. Pneumonia seems often to be of a less local form, spreading often, and the disease ends constantly by lysis rather than by a crisis.

#### *Abdominal Pain in Pneumonia.*

In some cases of pneumonia, especially in children, pain in the abdomen, which is referred, has been mistaken for peritonitis—for example, appendicitis—and the abdomen has been opened for this symptom. It is wise always to think of this fact, and when in doubt to examine the chest. On carefully examining the abdomen, although at first tender, this soon passes off, and the whole of the abdomen can be successfully palpated.

#### *Fresh-air Treatment of Acute Respiratory Diseases, with Special Reference to Pneumonia.*

The open-air treatment of phthisis is well established, but the treatment of the more acute affections of the lungs, such as pneumonia, bronchitis, asthma, by this method is not

well established. Oxygen is given, but there exists a good deal of doubt as to its efficacy—for the reason, perhaps, that it is too artificial in its manufacture, and, if of use, too intermittently given. Now, the natural atmosphere is always with us, and can be administered in large and constant quantities. May not the higher incidence of pneumonia in winter and spring be due, not so much to the cold weather, as to "the closer confinement of the populace indoors, in the stagnant air of living-rooms from which sunlight is excluded, and which tends to lower vitality and decrease resistance on the one hand, and to favour rapid multiplication and increased virulence of the specific poisons on the other"? (Anders.) Again, we have evidence that pneumonia is more prevalent in overcrowded districts and among the impoverished classes.

It seems to me that in a disease where nearly half of the breathing apparatus is out of gear it is hardly possible to have too much air, containing its full amount of oxygen. I treat these cases with free ventilation, or even on an open verandah exposed fully to the air. My experience is that pneumonic cases do better with this freedom of air rather than, as formerly, with a limited amount. I am not prepared to say that excessively damp air, or strong, cold east winds playing directly on the patient, is decidedly beneficial, but if the air is dry I doubt if the coldness is detrimental.

I should sum up the essential points in the treatment of pneumonia as (1) absolute rest; (2) appropriate feeding and stimulation; (3) sufficient, but light clothing; (4) sunshine, if possible; and (5) abundance of fresh air. The last point is the one most generally neglected, or perhaps forbidden by the patient and friends. I refer particularly to the more acute cases of the respiratory organs, but I have treated a fair number of subacute, and even chronic, cases, such as cases recovering from empyema, bronchiectasis, with or without purulent and offensive expectoration, etc., in open verandahs with the greatest success.

#### *Acute Intestinal Obstruction due to Thrombosis of the Superior Mesenteric Artery.*

The cases of the above have been more commonly reported abroad than in England. I have seen two cases. As they are rare and seldom diagnosed, the following points are interesting and useful to remember. The general symptoms and signs are very similar in character, whether the superior or the inferior mesenteric artery is involved. Certain differential points have been given; these do not seem of much value when practically considered, for in both intestinal obstruction is produced.

The first prominent symptom is abdominal pain, closely resembling an ordinary attack of colic. Nausea is frequent and arises fairly early. Vomiting follows, with a gradual change in the character of the vomit. Constipation is the rule, but diarrhoea has been often reported. Tension and tympanitic swelling of the abdomen are late signs indicating the advent of peritonitis. Extreme fetor of the stools, should there be diarrhoea, is of serious omen, and points to gangrene of the bowel having taken place. Profuse intestinal haemorrhage has also been recorded, and when meeting with this sign it is wise to bear in mind that embolus of the mesenteric artery may be the cause.

Prognosis is always most grave, but not absolutely fatal. Of course, this is better if only one branch of the artery is involved rather than several. If the main artery is occluded it is doubtful whether recovery has ever taken place. The greater the arterial obstruction the more severe the symptoms. As regards the source of the embolus, the left heart seems to be the most common one, and after this the abdominal aorta.

#### *Thrombosis of the Superior Mesenteric Vein.*

A few cases of this have been reported, giving rise to intestinal obstruction, the artery not being affected. Swelling of the bowel from infarcts occurred, and the tumour has been mistaken for one of malignant nature. Early abdominal section gives the only possible chance of recovery. I have not been able to find any recorded instance of recovery after delayed operation.

#### *The Intestinal Origin of Convulsions.*

In convulsions one must often look beyond the brain for the explanation and treatment. A boy, aged 2, was taken

almost suddenly with severe convulsions. I saw him soon after they had begun. They soon became almost continuous, and he appeared in a serious condition. On placing my hand on the abdomen I felt marked peristaltic action of the bowel. The convulsive attack was so tedious and violent in passing off that I gave some chloroform to check it. Some time later the bowels were opened four or five times, after which the convulsions ceased. There are many causes of convulsions in children, and intestinal irritation from undigested or ill-assorted food is among the most common.

#### *Indigestion.*

I know of no disease more difficult to diagnose than what is generally called indigestion. The difficulty mainly occurs after 50 years of age. Is the pain over the region of the stomach common indigestion—for example, hyperchlorhydria, or achylia gastrica, etc.—or has the patient a gastric or duodenal ulcer, or the beginning of malignant disease? I am not going to describe the textbook symptoms of the above; they are known to you.

The modern diagnostic methods of the examination by the x rays and bismuth meals, also the last method by fractional test meals, are both probably of more value in diagnosis than the common symptoms, but neither of them, in my opinion, can give a final definite opinion. Of course, where a "lump" can be felt, the consultant who is called in late in the disease may be the first to settle the dispute in question, but one should be anxious to know the trouble before the tumour is recognizable.

I was seeing a case in the country a few months back with a medical friend. We were speaking on the difficulty of diagnosing the cases I am mentioning, when he abruptly turned round and said, "I rarely allow a dyspeptic case to go on more than six months without recommending an abdominal exploration."

In looking back on my past experience I remember now many cases that it would have been better to have operated on, particularly gastric and duodenal ulcers, and malignant disease. Yet one must not forget that it is only comparatively recently that our surgeons have been fully equipped in all operative quickness and skill to deal successfully with these cases. Moynihans do not live in every town; still, they are becoming more common every day. Personally, where I can obtain this necessary surgeon, I feel more and more inclined to recommend this radical treatment of gastric ulcers and malignant disease in the comparatively early stage of stomach symptoms.

#### *Albuminuria.*

The ordinary textbook classification of Bright's disease—that is, acute Bright's disease, such as that which follows cold or scarlet fever, chronic tubular nephritis, or smooth kidney, whether large or small, or the granular and contracted kidney—does not by any means cover the cases of albuminuria which we meet with in private practice. I am not referring to those cases of cyclic or functional albuminuria which have often been described and which we know so well, nor to those conditions which follow temporarily specific fevers, nor to those associated with chronic congestive states of chest and abdominal organs. The cases that I am referring to occur in people who are for the most part pretty well; the albumin is almost constantly present, but not as a rule in large quantity.

I have seen a considerable number of albuminuric cases, some with hyaline casts and some without; they defy classification, and it is impossible often to prognose them; they occur at various ages between 30 and 70. Because you find albumin in the urine do not be in a hurry to class the case under one of the classical divisions of the disease. I am convinced that many of the patients live for years without ever having a granular kidney—certainly not a large white one.

I have lately described at the Royal Society of Medicine, and recorded in their *Transactions* of last year, a distinct class of albuminuric cases, which so far as I know have not been written upon before. A large quantity of albumin is present for many years, the quantity often amounting to absolute solidity on boiling. At times the albumin may

entirely disappear. Four of these cases have come under my notice, at ages ranging between 50 and 75. There was no oedema or dropsy. In two there were attacks of insensibility, and at this time the albumin was at its maximum in quantity. Dr. Mackenzie Wallis, of St. Bartholomew's Hospital, kindly examined the urine for me in one of these cases, in which the ratio of albumin to globulin was 2 to 1. The globulin when isolated behaved like serum-globulin, and was quite different from the type met with in functional albuminuria.

#### *Acute Glaucoma simulating a Bilious Attack or an Attack of Erysipelas.*

Glaucoma has been mistaken for three diseases—namely, cataract, erysipelas, and a bilious attack. The inflammatory condition of the eyelids and integuments of the face have at times been so severe in acute glaucoma that the case has been diagnosed as one of facial erysipelas; or again, the sickness has been so prominent a symptom that it has to a great extent masked the increased eye tension, so that the latter has been overlooked and gone untreated. Such cases show the importance of teaching the chief practical points in all the specialties. It is not necessary, nor even desirable, that all men should be able to do expert operations, for most cases can wait and be handed on to more skilled fingers. But cases like the above should always be diagnosed early, in order that they be properly placed. Every doctor should be a general practitioner in knowledge, although he need not be so in practice.

#### *The Value of Single Symptoms and Signs.*

In the diagnosis of medical and surgical cases one must not forget to put proportionate value on each symptom and sign; it is not the number of these that tell in making a diagnosis, but rather the quality of each one. One sign or symptom may count more in giving our final opinion than five or six others. One often hears men saying that the majority of the symptoms are in favour of such a disease, whereas the minority symptoms may be of much more total value. It happens not unfrequently that one symptom or sign may determine our view to the exclusion of all others. Two examples will suffice: in pneumonia the pulse-respiration ratio ranks probably highest of all the symptoms, and is almost pathognomonic of the disease. In acute appendicitis the pulse and respiration should rarely if ever be trusted, whereas rigidity ranks very high and may be the only sign.

#### *The Soporific Action of Mercury.*

I am not aware that the soporific action of mercury in the class of case about to be described is at all generally known. The cases in which I have found blue pill—for this is the form of mercury I am referring to—give such good soporific effects are rather difficult to describe, and must be given in a more or less general way. Many men would call them cases of biliousness, and for want of a better term I am contented to use it provisionally. The patients, who are usually over 40, complain of lassitude, loss of appetite, a general fullness of the abdomen, pains in the shoulder-joints, a want of clearness of thought, more or less dull pain in the head, not confined to one particular spot, irritability of the skin, and, above all, of sleeplessness at night. The tongue is generally of a whitish-brown colour, there is a nasty taste in the mouth, and the eyes are rather "thick." There may be many more symptoms and signs than the above, or few of them may be present, but when the symptom of sleeplessness is prominent, then the soporific action of blue pill followed by saline draughts is peculiarly brought out.

The symptoms I have detailed are principally found under the heading of "bilious dyspepsia," but there is this important clinical difference: whereas sex, sickness of food, and want of exercise play leading parts in producing this particular form of dyspepsia, the cases that I have in mind are found as often—if not more often—in women as in men, and where the plainest diet and fair amount of exercise have been taken.

There is little doubt that sea air has something to do with

this state of health; people who have come down to the sea-side after a long residence inland frequently develop, after a few days, all the symptoms described. I do not associate these cases with those which are commonly called "lithaemia," or the substitution of uric acid for urea as the final product of disintegration of albuminous substances within the body; in this last condition one finds the more remote symptoms of gout.

What is the exact action of mercury which brings about the happy result? I do not know, nor am I anxious to propose theories. Murchison supposed that mercury possessed a double action, for he says, whether or not the secretion of the bile was increased, more bile was certainly passed when the drug was being taken, and an eliminating action was brought about, so that less of the bile constituents were absorbed from the intestine than usually. Again, he supposed the albumin to be in some way more thoroughly disintegrated. In some such way the brain is "cleared." It is important for us to know empirically the use of a drug which will enable us to give a patient a good night's rest, whilst at the same time we are treating the origin of the trouble and apparently not giving ordinary soporific drugs.

#### *The Danger of putting Old People to Bed.*

Probably I shall be running atilt against someone's opinion when I say that I believe that many old people are sent to bed too early, and are kept too long in bed when they are convalescing. Of course, there are many obvious exceptions which will at once occur to you, and which I need not take up your time in mentioning.

I believe that we should be chary in advising old people to take to their beds when slightly ill. Some few years ago I was attending an old man of 80 with a slight attack of bronchitis, the like of which he had often suffered from before. A consultation was suggested, and the consultant called in advised my patient to go to bed. I remonstrated, but gave way to what I thought then was wiser advice than my own. The patient kept his bed for a week and then died. It may have been a case of *post hoc* and not *propter hoc*; still, my experience has since led me to believe that this man would have had a better chance of recovery if he had remained up during the daytime.

We must remember that the will power of old people is comparatively weak, and that bed to them is comfortable; then, when once in bed, after a few days the heart and muscular system lose tone. The effort to overcome the above is difficult, and sometimes impossible to obtain again. It often requires a good deal of courage to keep these old people from taking to their beds, for the patient often takes kindly to bed himself and the friends think you unkind in advising less rest.

My own belief, then, is that it is wise to keep old people about and with moderate exercise as long as possible.

#### *Final Remarks.*

I have finished.

I have often wondered, and at the same time regretted, why men who have been in practice many years do not record their experiences. Men who have been in general practice in the past have done great work. We think of Jenner, etc., and in modern times of Mackenzie.

Some years ago there was much more local record of cases made than there is to-day. In my own experience as Secretary of the East Kent District of the South-Eastern Branch of our Association, for six years we had regularly four meetings a year, with an average of four papers at each session, and with an average of twenty attendances. Things and times are changed. All the papers were written by our own members. Most of us who have been in practice for some years, whether hospital, private, or both, must have a vast experience well worth noting down. I have often said that young men write books, when they have little practice; old men, who know something, have little or no time. Personally I have seen in practice most of the rare diseases in medicine, many of which I have recorded.

We who live in villages and comparatively small towns see diseases often in their true perspective—the beginning, the middle, and the end of them.

## HERPES ZOSTER OPHTHALMICUS.

BY

SAMUEL LODGE, O.B.E., M.D.,

OPHTHALMIC SURGEON, ROYAL HALIFAX INFIRMARY;

AND

WILLIAM OLIVER LODGE, M.D., F.R.C.S.E.,  
D.O.M.S.,

ASSISTANT OPHTHALMIC SURGEON, BRADFORD ROYAL EYE AND EAR HOSPITAL.

THE eye has aptly been described as an elegant diminishing mirror of diseases of the body. Indeed, our ophthalmic experience of herpes zoster reflects so diffusely upon epidemiology, neurology, and dermatology that we can but select six arbitrary headings—etiology, pain, efflorescence, keratitis, complications, and treatment.

#### ETIOLOGY.

"In full fair tide let information flow—  
That evil is half cured whose cause we know."

Churchill: *Gotham*, Book 2, 652.

In our infirmary practice the incidence of herpes zoster is approximately 1 in 10,000, but in many clinics it is rarer—for example, Colonel Elliot estimated its relative incidence at Madras at 1 in 25,000.

In twenty private cases the average age at the time of attack was 55. We see the disease in children occasionally, but note that as a rule only elderly patients experience persistent pain, extensive scarring, or severe corneal ulceration. We are indebted to Dr. Henry Head for a letter confirming our inference that ophthalmic zona is more prevalent in early life than ophthalmic statistics denote.

"Herpes zoster in children," he writes, "is almost a negligible disease. Were it not that the mothers are frightened of the rash we should see very few cases in young persons. The elasticity of the ganglia and surrounding parts probably prevents the occurrence of severe forms of pain. Notoriously, herpes zoster wherever it occurs is much more severe in old people than in young. This is particularly the case when the rash lies over the forehead."

Some authors report a preponderance of male patients, and state that the right side is more often affected than the left; in our own series the proportions were equal in both respects. The cases were entirely sporadic. In one instance a man and his wife were affected, but fourteen years intervened between the two attacks. Most of those affected were in good health and were engaged in active mental or physical pursuits prior to some temporary fatigue or minor indisposition, upon which herpes supervened.

In a case which followed carbonic oxide poisoning Sattler first described infiltration, destruction, and degeneration in the Gasserian ganglion. Poulard distinguishes three varieties of trigeminal herpes according to the position of the causative lesion: (1) a neuritic form, affecting the peripheral branches of the ophthalmic division; (2) a rhizomeric form, implicating the Gasserian ganglion; and (3) a metameric form, in which the lesion is in the pontino-medullary nucleus of the fifth nerve. In this nucleus, according to Bing, the frontal region is represented most distally, the temples and eyelids in an intermediate position, and the nose and cheeks highest up. In one or two of our cases anomalous eruptions occurred, for example, on the buccal mucosa, in addition to the eruption of typical rhizomeric distribution.

Netter states that herpetiform eruptions appear in at least 1 per cent. of cases of encephalitis lethargica, and cites a case reported by Medea of Milan, in which encephalitis was accompanied by supra-orbital herpes, followed by paraesthesia of the affected area. Numerous instances of chicken-pox arising in remote farms and isolated villages within twenty-one days of a case of herpes zoster have been recorded.<sup>17</sup> Again, Head and Campbell point out that herpes zoster may justly be described, both on anatomical and pathological grounds, as acute posterior poliomyelitis. Probably the virus of shingles, widespread in an attenuated form, is liable to enhanced virulence, when epidemics arise, and is sometimes inconstant in its affinity for the small bipoplar ganglion cells, irritation of which results in the

herpetic eruption. The effects of such irritation are the same whether it be due to a specific virus, or to local inflammatory processes secondary to injury, tuberculosis, or new growth. Patients presenting herpetic eruptions should always, therefore, receive a careful examination.

#### PAIN.

" . . . and thus would be produced those paroxysms of shooting or flashing pains, which, in accordance with a well known physiological law, are referred to the periphery, although in reality due to a central cause."—Charcot: *Lectures on Diseases of the Nervous System*, Sigerson, 1877, 60.

In mild cases the early neuralgic pain is confined to one side of the head, but in severe and fulminating cases there is intense headache and vomiting. The meningeal branch of the ophthalmic division, which is given off before the nerve reaches the sphenoidal fissure, sends filaments to supply the tentorium: in the rare cases which simulate meningitis in their onset it is possible that the ganglion cells connected with this meningeal branch are implicated. Similarly, according to Chauffard, extension of the disease from the posterior root ganglia to the meninges in spinal zoster would account for the pains down the spine, girdle sensation, exaggerated knee-jerks, and lymphocytosis of the cerebro-spinal fluid which are observed from time to time.

A more typical manifestation is formation; our out-patients complain that the skin feels as though there were something "wick" (that is, alive) under it. Sometimes by rubbing the scalp they produce bald patches, comparable to the frayed sleeve and threadbare coat which proclaim the sufferer from shingles.

In proportion to the age of the patient and extent of the scarring, a type of pain is complained of which has much in common with that which, during the war, frequently complicated partial lesions of the median and internal popliteal nerves—causalgia; a scalding pain is felt in the palm of the hand or sole of the foot, and is increased to a maddening degree by the lightest touch. Causalgia has been attributed to compression of the nervi nervorum. Elderly convalescents from herpes zoster often compare the lancinating pains to the effect of a drop of hot oil, and are careful to avoid cold winds, which are apt to excite a paroxysm. Anaesthesia dolorosa, the duration of which was two years in the severest of our cases, is one of the gravest complications of the disease; Gowers speaks of suicide in despair. Happily cases of such extreme severity are rare.

#### EFFLORESCENCE.

"Diseased nature oftentimes breaks forth  
In strange eruptions."

King Henry IV, Pt. I, Act III, Sc. I.

The cutaneous manifestations make their appearance in the following order—hyperaesthesia, erythema, vesiculation, rupture of the vesicles, cicatrization, and hypaesthesia. Occasionally, according to Poulard, the eruption is haemorrhagic or gangrenous.

The rash usually appears three or four days after the onset of the pain, but this period is not constant; for example, one of our patients suffered from hemicrania for three weeks, and another from intense headache, for the relief of which morphine was required, for only forty-eight hours before the appearance of the rash.

It is sometimes possible, in the prodromal period, to map out the area subsequently affected by the rash by eliciting

a local increase in susceptibility to pain. According to Head and Campbell the eruption is due to intense irritation of ganglion cells which normally produce referred pain in response to afferent visceral impulses. In support of this theory it is urged that those dorsal ganglia are most affected which receive white rami from the sympathetic.

Fuchs records an old clinical observation that there is a striking elevation of the temperature of the skin upon the affected side, which not only is present when the inflammation is recent, but often lasts for a long time afterwards. This increase of temperature is presumably due to antidromic impulses passing from the ganglion, for physiologists

have proved by experiment that stimulation of the peripheral ends of divided sensory roots causes dilatation of the cutaneous vessels.

It has been shown that mustard does not produce its ordinary effect on the skin if it has previously been anaesthetized, nor if the nerves have been divided sufficiently long beforehand to allow them to degenerate.<sup>2</sup> It would be interesting to ascertain whether the eruption of shingles could be aborted by injection of an anaesthetic such as quinine and urea hydrochloride, the effect of which lasts for some days.

Extensive scarring after trigeminal ganglionitis becomes more common as age advances. The following case illustrates this tendency.

#### CASE I.

A medical student had been subject to attacks of herpes frontalis every summer since boyhood. More recently attacks had occurred twice a year, generally after examination. When he came under our observation, at the age of 20, he had for the first time reason to complain of residual scarring.

For the most part, our cases have borne out Hutchinson's rule, that when herpes zoster affects the nasal branch of the trigeminal the cornea is particularly liable to suffer. Poulard mentions the fact that the nasal mucosa is often swollen and hyperaemic during the attack, causing unilateral coryza.

A curious superstition is sometimes expressed—that when shingles meets in the middle line the result is inevitably fatal. Bilateral cases of herpes zoster ophthalmicus are

extremely rare. Greenwood of Boston, who reports a case, which showed the multiple scars of the skin along the course of both supra-orbital nerves, so characteristic of herpes, states that one eye was lost from glaucoma and the

other from panophthalmitis secondary to infected herpes corneae. "Il n'est règle qui ne faille."

#### KERATITIS.

"O loss of sight, of thee I most complain."

Milton: *Samson Agonistes*.

The frequency of corneal complications varies considerably in the experience of different ophthalmic surgeons. Out of 235 cases collected by Willbrand and Saenger the cornea was affected in 83. In rather more than half the cases in our series greyish streaks and opaque areas made their appearance as soon as the rash began to subside. In numerous instances there were vesicles, which ruptured on the surface, leaving superficial ulcers, which remained discrete or became confluent according to the severity of the attack. In one case the opacity was dendriform. Mild iritis accompanied the severer cases.

The current teaching is that herpes zoster corneae is only to be feared inasmuch as it tends to leave a permanent opacity. Thus, according to Mr. Foster Moore, "The ulcers

A typical case of herpes zoster ophthalmicus: Confluent ulcers on cornea

Diagram showing some of the connexions of the trigeminal nerve mentioned in the text.

never perforate and hypopyon does not arise. . . . recurrences never occur and both sides are never involved." The following case furnishes a notable exception to this generally accepted law.

## CASE II.

Male, aged 66. After severe hemicrania for three days an eruption appeared on the right side, which the patient, who had resided in Jamaica, compared to confluent small-pox. The nasal branch was affected. Severe corneal ulceration ensued, with accompanying iritis. The eye was covered with a dressing and treated with atropine and an antiseptic lotion.

At the beginning of the second week, as a result of a consultation with Mr. Teale, paracentesis and syndectomy were performed, without an anaesthetic.

Improvement was only temporary, ulceration continued, and panophthalmitis set in. After consultation with the late Sir Jonathan Hutchinson enucleation was recommended. Enucleation was accomplished without resort to any anaesthetic, no pain being felt.

There was considerable scarring, and the patient complained of fulgurating pains and of a constant sensation—"as though someone had put a plug in his eye and broken it off." Large doses of quinine afforded relief, but on one occasion, after 70 grains in three days, toxic labyrinthitis developed and prevented further exhibition of the drug. The anaesthesia dolorosa lasted for two years.

Anaesthesia of the cornea may persist for months. On rare occasions we have detected a difference between the sensibility of the nasal and temporal halves of the cornea. Clinically there seems little doubt that the neuro-paralytic factor has an important bearing on the course of herpetic ulceration of the cornea, although Turner and Ferrier, by experimental division of the fifth nerve, its root and branches, with protection of the eye from injury, reached the conclusion that keratitis from disease or injury of the trigeminus was the result of irritation rather than paralysis.

## COMPLICATIONS.

"It is by no means enough to spend all our pains upon one object."—Horace: *Satires*, Book II, 4.

The following case was complicated by sympathetic irritation.

## CASE III.

Male, aged 58. Right herpes zoster ophthalmicus—eruption extending to the tip of the nose. No corneal nor ophthalmoscopic changes detected on repeated examination. Extreme photophobia and lacrymation of the left eye, lasting several months.

Four years later, the patient having suffered an embolism of the right retinal artery, it was ascertained that he was still unable to distinguish between the blunt and sharp ends of a pin on the right side. The left eye was no longer irritable.

The late Sir Jonathan Hutchinson wrote of this patient as follows:

"I have repeatedly known the other eye in cases of herpes to be somewhat irritable, but I do not think I have ever seen a case which approached yours in severity. Have you tried arsenic? It is, I believe, the most efficient remedy for herpetic after-pain. I know a gentleman who suffers from frequently repeated attacks of herpes on the right eyelid, and the attacks are always attended by lacrymation and irritability of the unaffected eye."

Herpetic inflammation of the Gasserian ganglion does not prevent the secretion of tears by the lacrymal gland; the secretory fibres come from the facial trunk, via the great superficial petrosal nerve, sphenopalatine ganglion, and temporo-malar branch of the superior maxillary nerve, which communicates with the lacrymal. Oversecretion by the lacrymal gland of the opposite side furnishes an interesting problem in neurology.

Glaucoma, which complicated three of the twenty cases, occurs in two forms, the treatment of which is essentially different. The first variety is to all appearances idiopathic. There is generally some indication of predisposition to the disease—for example, glaucoma in the other eye previously. It is, in our experience, usually subacute, and tends to occur during convalescence from herpes zoster ophthalmicus, which can only be regarded as an exciting cause. The onset of glaucoma is possibly connected with loss of the normal periods of contraction of the pupil which accompany sleep. An alternative explanation is as follows:

According to Priestley Smith's theory of glaucoma the vitreous is secreted by the pars plana of the ciliary body and the aqueous by the ciliary processes. Senile degeneration affecting the two zones unequally results, it is conjectured, in a relative excess of fluid in the vitreous and displacement of the lens forward. Acceleration of some

such obscure process may be responsible for the somewhat frequent conjunction of herpes zoster ophthalmicus and glaucoma. The following is an illustrative case.

## CASE IV.

Woman, aged 56, convalescent from right herpes zoster ophthalmicus. Cornea unaffected. Subacute glaucoma on the same side. (The left eye had been operated on for glaucoma nine years previously.) Right iridectomy. The patient remained under observation for six years, during which time the refraction altered from  $1\frac{1}{2}$  dioptries of hypermetropia to 2 dioptries of myopia, with a low degree of inverse astigmatism. When last examined the vision with glasses was R. 6/10, L. 6/60.

Symptomatic hypertension, as certain American authors describe it, may generally be recognized by the presence of punctate deposits on Descemet's membrane or other signs of irido-cyclitis. Secondary glaucoma of this type yields promptly to the use of atropine. The interference with filtration must be attributed to changes in the aqueous.

Herpetic lesions of the choroid, retina,<sup>20</sup> and optic nerve<sup>9</sup> have been reported. Circumscribed nodules on the sclera of reddish colour,<sup>19</sup> the centre of which resembles a limpid vesicle, surrounded by injected vessels, have been observed about a fortnight after the corneal disturbances had declared themselves.<sup>16</sup> Facial palsy and paralysis of the extrinsic and intrinsic muscles of the eye<sup>1</sup> are among the rarer complications of herpes zoster ophthalmicus.

## TREATMENT.

Isabel: Alas! what poor ability's in me  
To do him good.

Lucio: Assay the power you have.

*Measure for Measure*, Act I, Sc. 5.

Like other exanthemata, herpes zoster runs its course, albeit at times a painful and protracted one. In elderly subjects, morphine is often indispensable in the early stages; but the danger attending its use in a painful affection which may last for two years is manifest. For one of our patients Gowers recommended the following prescription, which gave relief:

R. Caffeinae citratis	} ... .. gr. v
Sodii iodidi	
Sodii salicylatis	
Salicini	
Phenazoni	... .. gr. x

Misce. Fiat pulvis. Mitte in chartulam. Sig.: One paper to be taken every four hours as required.

There is a general prejudice against the use of arsenic, originating in Hutchinson's statement that herpes zoster may actually be caused by arsenic taken medicinally; hence the special interest of his letter quoted above.

Locally, we recommend dusting powders until the vesicles rupture, when cocaine or orthoform ointment is appreciated. In the later stages painting with ichthyol in glycerine, or massage with any simple ointment, is beneficial; hot fomentations should be avoided, as the skin is anaesthetic, and burns are readily produced. Paroleine is a suitable instillation for the conjunctival sac. The intra-ocular tension should be estimated at regular intervals and ocular complications treated as they arise.

Since encountering the case described above which resulted in panophthalmitis, we have several times resorted to suture of the lids. Sir John Tweedy observes that "in very severe cases immediate and permanent relief may be obtained by paring the edges of the lids and suturing them together. Not only does the pain at once abate, but the ulcerative process is checked and repair takes place." We have verified this observation. In elderly patients continuous application of a pad and bandage is apt to produce entropion, retention of secretion, and superficial dermatitis, and the cornea is at the mercy, for so many hours at a time, of any micro-organisms present in the conjunctival sac. Median tarsorrhaphy, on the other hand, provides a natural dressing with adequate drainage. We make a shallow incision along the grey line of the lids, and, introducing three sutures, bring the clefts so formed into apposition. Union is firm on the third day, and the cornea may be inspected by gently separating the outer or inner third of the palpebral margins. The central united portion is divided when corneal sensibility returns—after a period of eleven months in a recent case. The process of healing is

slow and relapses are apt to occur if the lids are separated too soon. Ultimate transparency of the cornea depends largely on complete protection of the delicate corneal surface and freedom from infection.

Median tarsorrhaphy lightly closes the eye as in sleep, compelling it to "hibernate" until its reflex protective mechanism is restored.

## THE TREATMENT OF CHRONIC MALARIA.

BY

T. STORIE DIXSON, M.B., C.M.,

HONORARY CONSULTING PHYSICIAN TO THE SYDNEY HOSPITAL, AND LADY EDELYNE HOSPITAL FOR INFANTS, PRESIDENT OF THE NEW SOUTH WALES BOARD OF MEDICAL REGISTRATION.

QUININE has been long, and still is, recognized as the chief drug for use in malaria, but there is no general agreement as to the best method of administration, and this is my excuse for discussing some results of my experience in its use.

## 1. Physical Form of Administration.

Sugar-coated pills of quinine are very unsatisfactory, and I have known them, when containing quinine hydrochloride only, cause violent gastric trouble in malaria, and pills so coated are often passed through the bowel undissolved. Even uncoated pills may be so densely compressed, if made of the sparingly soluble sulphate, that a like result may follow; but, on the other hand, if made of the hydrochloride they may dissolve in the act of swallowing so as to give an intensely bitter taste. If taken in 10 to 15 grain doses, whether in this form or as wafers, or in easily soluble capsules, gastric irritation is sometimes set up; this is especially liable to be the case if only a mouthful of water be taken. This result is due to the quinine acting in great concentration on a limited area of the stomach. These troubles can be avoided by administering the quinine in uncoated pill form, using an excipient affording enough cohesion both to prevent it dissolving during the act of swallowing, and to slow down solution in the stomach sufficiently to avoid undue concentration when at least 2 ounces of water are taken with it.

## 2. Chemical Composition of the Dose.

Unfortunately, for reasons of cheapness, the sulphate has often been the chief salt used, though it has otherwise manifest disadvantages as compared with the hydrochloride, which is soluble 1 in 36 or so of water, is neutral, and in solution less liable to get mouldy. To give quinine sulphate, which is soluble 1 in 800 or so of water, in a mixture to which nearly a minim of dilute sulphuric acid or aromatic sulphuric acid is needed for each grain to secure its solution, is unsatisfactory, especially where large doses, such as 15 grains, are given. The taste is very disagreeable, the acidity is prejudicial to the teeth, and on reaching the stomach both its chemical action and the foreign nature of the mineral acid cause further local and afterwards even systemic trouble. Clinically quinine hydrochloride is better tolerated. Whereas in the case of children pills cannot be used, the sparingly soluble and so less bitter sulphate can be given with syrupy or mucilaginous but non-acid menstrua; the tannate might be better still

## 3. Route of Administration.

The oral route has in general most advantages, and even where gastric disturbance might be feared adoption of the rules suggested in this paper overcomes it. In severe acute forms the intravenous route would, of course, be the correct one.

Kenneth Mackay<sup>1</sup> found that blood films become negative earlier under oral administration than under either intramuscular or subcutaneous administration, and that four-hourly observations upon the asexual benign tertian cycle appear to show that quinine has an immediate effect upon the malarial parasite—not only upon the young sporulating merozoite but also the intracorporeal stage.

## 4. Time of Administration.

Marchiafava and Bignami have shown that quinine acts in all phases of the life of the malarial parasite and that therefore it is unnecessary to wait for any specified period. Giemsen and Schlaumann found that if quinine were given with the meals traces of it were not found for over two hours, but, given fasting, in twenty to thirty minutes. Kerner demonstrated that, given by the mouth, the hydrochloride is found in traces in fifteen minutes, after the quinine in alkaloidal form in twenty-five to thirty minutes, and that its excretion continued with a meal; whilst Mariani showed that the maximum elimination of quinine in a man's urine occurred between the sixth and twelfth hours if given after food, but between the third and sixth hours if given before it. Castellani and Chambers<sup>2</sup> say: "With regard to mild quartan and tertian fever, in many cases we give the drug three times a day without regard to the conditions of parasitic life, and this method is apparently not less successful" (than giving the drug four hours before sporulation of the parasite is due).

The following scheme, adapted from MacGilchrist,<sup>3</sup> will give some idea of the rapidity of absorption and excretion of quinine after various methods of administering it.

This takes no account of the effects of gastro-intestinal disorders, whether due to malaria or quinine itself or to other causes, in diminishing or in increasing the energy or rapidity of action of a dose, but, so far as my experience goes, by adopting the methods to be subsequently described these are to a great extent negligible.

Hele's experiments<sup>4</sup> proved that "In active malaria the excretion rate after oral quinine no doubt varies, according to the condition of the alimentary tract, but high fever is not incompatible with rapid absorption and the rapid attainment of the maximum excretion rate, more rapid than after intramuscular therapy." He found no decrease in quinine excretion during continuous administration by the mouth, but that the greater part of the excreted quinine is excreted within twenty-four hours of the last dose, though traces persist for another twenty-four or forty-eight hours. There was no great fall in the quinine excretion till the twelfth hour after a dose by the mouth, till the eighteenth hour after intramuscular injection, and, following the immediate rise, fall, and re-rise in the first half-hour, till the twelfth hour after intravenous injection.

MacGilchrist suggests that a rapid and energetic absorption of quinine is best obtained by giving a salt of it during fasting, then when sporulation is regular to give it two or three hours before the paroxysm, fasting; but where sporulation is irregular to give less soluble forms soon after meals. It is generally agreed that even if a certain amount is absorbed from the stomach, as some assume, the greatest amount is absorbed in the duodenum and practically none (when the drug is given orally) in the large intestine. In practice I prescribe it to be taken an hour before meals and

5. *Frequency of Dose.*

If 3 or 4 grains be adopted as a dose, and 16 grains as needful daily, it means that four or five doses a day must be given. For a full-sized adult this implies an amount just bordering on one sufficient to cause nervous symptoms, varying with the patient—symptoms which I always try to avoid. This will effect a fairly continuous, yet mild, quininization of the patient's system, with the idea of steadily lowering the vitality of the plasmodia till they become unable to reproduce their kind—just the opposite of the *therapia sterilisans magna*, or knock-out blow. It is this great evenness and persistence of treatment that I venture to think affords this, and one which might be labelled "*therapia sterilisans perstans*." The doses should be given as far as possible at equal intervals, and therefore one should be given during the night, if possible, or at least the last thing at night, and another the first thing in the morning.

6. *Coincident Treatment.*

This consists in most cases of preliminary treatment with an aperient, mostly calomel. In view of the action of the latter in causing "bilious" motions, whether due to lessening catarrh in the region of the duodenum, etc., by acting as an antiseptic, or otherwise, the possibility of its aiding indirectly the absorption of quinine is evident in view of MacGilchrist's experiments. He found that the alkaloid quinine in the crystalline form is soluble 1 in 625 of blood serum (that is, three times as soluble as in water), but is soluble 1 in 183 of bile (that is, about nine times as soluble as in water). Against this it is often assumed that the alkaline secretions of the liver, pancreas, and intestines precipitate the quinine, though, as MacGilchrist showed, quinine glycocholate is soluble in excess of bile. There may be in addition to the antiseptic and characteristic aperient action of calomel another due to its increasing the mucous secretions in the bile ducts of the liver (as occurs with the salivary and intestinal secretions), and so removing the blocking by the malaria-thickened bile. In some cases of persistent headaches in patients affected with malaria calomel acts very quickly and thus I have not needed the help of acetyl-salicylic acid, gelsemium, etc., which at best act symptomatically.

I may now refer to some prescriptions in which small doses of quinine are alleged to be effective.

1. *Warburg's Tincture* is a very complicated mixture containing some fifteen ingredients. It contains in each half-ounce 4 grains of quinine sulphate, and as only two doses were to be given, in all only 8 grains were administered. But with each dose there are given 6 grains of aloes—that is, within half an hour, 12 in all—a rather severe treatment. In view of the readiness with which a chill seems to bring on an attack of malarial fever the diaphoretics contained in the tincture are of possible value; they may be expected also to act beneficially as gastro-intestinal antiseptics. The alcohol is evidently a powerful solvent medium, and beyond that its action need not specially concern us. This preparation has been abandoned since the aperient action, at least in some cases, must be rather strong; hence the aloes, if desired, is omitted in the various preparations supplied commercially, thus, perhaps, removing the soul of the efficiency ascribed to it. The complicated form makes it expensive, many of the ingredients are practically unobtainable, and their effects are unknown; it is said to depress the heart and has an appalling taste.

2. *Huxham's Tincture* was the forerunner of the compound tincture of cinchona, the composition of which has varied since its first introduction. The dose was 1 to 4 fluid drachms. Originally it was made with pale, but is now made with red, cinchona bark; the other constituents being orange peel and serpentary and saffron (now omitted). The serpentary in small doses acts as an aromatic bitter, diaphoretic and diuretic; in larger doses as an emetic and aperient. The full dose of half a fluid ounce, containing 10 per cent. cinchona bark, would perhaps mean  $1\frac{1}{2}$  grains of mixed cinchona alkaloid. At four doses a day this amounts to 6 grains of cinchona alkaloids with some possible help from antiseptics and diaphoretic or mildly aperient agents. The present official dose of the compound tincture of cinchona is only half to one fluid drachm.

3. E. T. Simpson (Civil Surgeon of Oudh, India) recommends in all acute cases where diarrhoea is not present:

Magnesiæ sulphas	...	...	...	...	dr. ij
Liq. ammoniæ acetatis	...	...	...	...	℥. oz. j
Quininæ sulphas	...	...	...	...	gr. xv
Aquam camphoræ	...	...	...	...	℥. ad fl. oz. viij

Sig.: One ounce every four hours.

He claims that 90 per cent. of cases recover under this treatment. He employs a somewhat similar prescription for chronic tertian.

4. Finally, there is Forbes Leslie's recommendation of calomel only.

*Method Recommended.*

The foregoing will make clear the principle—namely, the more or less continuous coincident administration of an

aperient, preferably calomel—upon which I base the method which I have for many years adopted and which is as follows:

1. Give a small dose of calomel at once, 1 grain, perhaps repeated in an hour or so; this single dose is to be administered each night at bedtime. I prefer the pill form as less liable than that of a powder to cause mercurialism in the mouth. This should be followed early next morning by a saline aperient. This will help release of bile into the duodenum and by its antiseptic and aperient action without irritation cleanse the bowels. The continual administration of calomel, in doses insufficient to risk distinct mercurialization, is to my mind extremely, indeed I think essentially, important; though in certain circumstances a stronger dosage for the purpose of thinning the thickened bile might be desirable. The rapidity, however, with which the calomel aids quinine indicates a local gastro-intestinal action rather than one due to absorption.

2. Give the quinine in 3 or 4 grain doses according to the size and strength of the (adult) patient, as a pill; the small dose and form avoid irritation of the stomach.

3. Give the hydrochloride; this is in order to secure rapid absorption with minimum of gastric irritation.

4. Give the doses an hour or more before meals, and at bedtime; this is in order to secure rapid absorption.

5. Give with each dose 3 or 4 ounces of water; the amount of fluid, by diluting the quinine freely, prevents disturbance of the stomach and encourages rapid removal from it.

6. Continue the treatment for two months.

I have never failed in this way rapidly to relieve urgent symptoms; generally there is no attack or at most only a slight one in the first week of treatment, none afterwards in my experience. Those few cases which I have followed a year or two after the treatment have been free from attacks and have felt unusually well as compared with their general condition between the attacks before treatment. But, no more with this, perhaps, than with other treatments can one promise an absolute cure. I claim, then—

1. That the method is in no sense unpleasant, except as regards taking the salines, though even these might be replaced by other aperients.

2. That it is easily carried out, being very simple. The patient can go on with his work, not needing to go into hospital.

3. That the drugs are easily obtained, are portable, and keep well.

4. That if the result is not perfect it at least is produced more rapidly than by the ordinary routine, and in general is much more effective.

5. That there is no risk whatever of permanent disorders of the nerves due to quinine, for, indeed, the slightest symptoms of such disorders are taken as the indication for lessening the dose.

Although my experience is limited to chronic cases it is quite possible that the principles of this treatment are adaptable at least in some measure to acute cases.

## THE AUTOGENOUS PEG GRAFT IN CERTAIN FRACTURES OF THE FEMUR.

BY

WALTER MERCER, F.R.C.S. EDIN.,  
EDINBURGH.

FROM a study of the end-results of simple fractures of the shaft of the femur it would appear that in spite of a great variety of methods of treatment there is still scope for one which will ensure a more perfect end-result.

The disabilities resulting from fracture of the shaft are from two main causes—bad alignment and knee-joint trouble.

*Faulty Alignment.*

The shortening is maintained by the pull of the muscles irritated by the bony ends and by the distension of the fascial planes with hæmorrhage and exudate. This is usually considerable at first, and attempts at manual reduction frequently fail. Oblique fractures make the retention of the position very difficult. The usual procedure is to

attempt manipulation if there is marked shortening, and if retention is difficult extension is applied to the femur by one of the various methods.

The extraordinarily careful adjustment of the line of pull and the delicate nature of the means of retention of the fragments mean constant watching and attention; in civil hospitals the surgeon has not the constant stream of such cases that were seen in military hospitals, and minor defects result. Manipulation followed by traction with a considerable weight frequently fails to overcome the muscles, so that shortening and overriding persists, and when reduction is successful and retention is attempted by extension the presence of the necessary apparatus makes it difficult to carry on the movements of the joints and the massage which are so useful to the injured limb.

#### *Limitation of Knee Movements.*

The commonest cause of the limitation of movement of the knee is the long-continued immobilization, as was so evident in many of our soldiers returned from German prisoner-of-war hospitals, where they had not been looked after. It is said that immobilization will not limit the movements of a healthy joint. This may be so, but it allows tendons and muscles to undergo fibrosis and shortening, and the end-result is the same—a limitation in the extent of joint movement. This fibrosis is due in many cases to the actual wounding of the quadriceps by the bony fragments. When healing takes place fibrous tissue forms; this limits the relaxation of the muscle and also tacks it down to the fracture. Actual adhesions in the joint are rarely considerable enough to prevent their being gradually broken down, nor is any capsular shortening ever very troublesome.

We should aim at some method by which complete reduction of the deformity is obtained and retained with some degree of certainty and yet without any cumbersome appliance that will prevent active movements and massage to the affected parts. An autogenous intramedullary peg bone graft as here described fulfils these conditions. This graft of live bone ensures alignment in a good position and maintains fixation while the osteogenetic functions produce a greater amount of internal callus, and the patient is allowed a greater freedom of movement at an earlier date. The peg stimulates bone production, and this new bone fills up between the peg and the parent bone till a solid mass is produced. This increases in strength according to the demand put upon it, and it is of great importance to get movements started early so that the new tissue may be "taught" its function. It is not contended that the peg is a permanence, as with complete bony union the shaft generally resumes its normal shape and a complete medullary cavity is reproduced. This is even produced when a long gap of 4 to 5 inches in the forearm bones is filled with the anterior surface of the tibia. It takes some years to produce, but it is the eventual result.

The essential feature of every case is that there is no wound of the skin that might lead to sepsis in the operative field, hence it is practically only in a simple fracture that the method can be used.

In many oblique fractures where both reduction and retention are difficult and where external immobilization is necessary afterwards to retain the position an autogenous peg graft would make the after-treatment easier and the end-result better. It would also be the operation of choice in that class of fracture in which reduction cannot be secured otherwise than by open operation. The obstacle to reduction would appear to be either the pull of strong muscles irritated by the fragments or oedema expanding and so shortening the fascia.

#### *Mode of Using a Peg Graft.*

If operative treatment is deemed essential it is necessary to wait only until any shock has disappeared. It is better to give the operative field a very complete preparation; this is usually begun two days before the operation, and after the usual shaving, washing with spirit, soap, and lysol, spirit is applied and then 1/2 per cent. picric acid; this is found to be less irritating to the skin than iodine and equally

effective. The skin of the same leg over the crest of the tibia is prepared equally carefully.

The fracture is exposed by an incision 5 to 7 inches long over its lateral aspect. It is a matter of choice whether sterile towels should be clipped round the wound, but where there is any doubt about the skin the towels should certainly be used. The blood clot, including that in the marrow cavity, is cleared away as freely as possible. Traction is applied to the limb by a second assistant, and the deformity is reduced by the levering aid of a strong file and Lane's T-shaped lever with serrated edges. It is essential to obtain this preliminary reduction so as to stretch the muscles and make the reduction easier when putting in the graft. The leg is now adducted at the site of fracture and the ends protruded from the wound so that the medullary cavity may be prepared. The size of this is increased in its transverse axis by the reamer attached to the Albee saw. The actual calibre is not increased in all directions as the peg graft to be introduced is flattened rather than round. This reaming is done to a greater length in one of the fragments, that length being the same as the graft to be cut. The length in the other fragment need only be half the length of the graft.

The peg graft is cut from the anterior surface of the tibia and should be about 4 to 5 inches long, unless the fracture is oblique, when a greater length is necessary. The breadth should be just less than the already measured breadth of the marrow cavity it has to fit. The periosteum is now stripped from the graft, as this fibrous tissue element prevents union of its underlying bone. A shallow saw cut is made at the mid-point of the graft so that its correct position may be ascertained when fitted.

The graft is now inserted into the upper fragment to practically its full extent; it should not be gripped too tightly by the femur, but should be so loose as to be easily extracted by a pair of Kocher's artery forceps which are clipped on to the terminal 1/8 inch of the graft, which is allowed to protrude. The lower fragment is now got into position by traction on the foot and by leverage, but the thickness of a strong file—about 3/8 inch—is interposed between the bony ends, so that a gap of that amount is left between the bone fragments through which the Kocher's artery forceps are used to "tease" down the graft into position. This is recognized to be correct when the saw cut in the middle of the graft is seen, and then the file is carefully removed while traction is applied. The traction being removed, accurate reduction is obtained and retained by the peg graft. The muscles and fascia are stitched with interrupted catgut and the skin with interrupted silkworm gut. No drainage is necessary, but the stitches are not put in too closely so that the effused blood can get away easily.

Although I used a complete plaster case in some of my earlier cases I do not now consider this necessary, as with ordinary care of a good nursing staff there is little to fear. The leg is accordingly bandaged firmly on a double inclined plane and the plane fixed to the foot of the bed. About the end of the second week the bandage is removed from the leg and the knee extended and some gentle massage given. This is continued once daily right on and the movements gradually increased. By the end of six weeks the splint may be removed and active movements increased by this freedom. Consolidation of the callus is frequently quickened by ionization with calcium salts, while the faradic current to the quadriceps is extremely useful in developing a muscle slightly wasted by disuse. The patient should be taught frequently to contract his quadriceps even though not getting great movement with this contraction, to preclude any possibility of it adhering to callus. He is up on crutches at the end of two months and can get home. In three months a walking calliper is applied and used for other three months, by which time the patient should be saying good-bye to the surgeon. The method is so simple and reasonable that it seems necessary to add the history of only one typical case:

K. B., aged 23, as a result of a motor cycling accident, was admitted to my care on May 23rd, 1921, with a simple fracture of the lower third of the right femur presenting the usual signs, but

no crepitus could be made out. There was over 3 inches of shortening. X-ray examination showed a transverse fracture at the junction of the lower and middle thirds with about 3 inches overriding of fragments. The leg was put on a double inclined plane, and on May 24th, under a general anaesthetic, was pulled out as far as possible, counter-extension being maintained by a roller towel round the perineum. Pearson's ice-tong calliper was applied and the patient put back to bed; x-ray examination showed that there was still 2 inches of shortening.

On June 5th a further attempt was made under chloroform to correct the displacement of the lower fragments and the leg was put on an inclined plane. This attempt was also unsuccessful, as shown by x rays; 45 lb. weight extension was now put on the Pearson calliper with a roller towel round the perineum to the head of the bed. X rays still showed the fracture to be in an unsatisfactory position, and the shortening not reduced after forty-eight hours of this weight. It was accordingly decided to operate on the fracture.

#### Operation.

On June 11th an incision was made along the lateral aspect of the leg, exposing the site of fracture. There was a considerable amount of blood clot and bruising of muscle at this level. By means of traction on the leg and leverage with a heavy file between the ends it was seen to be possible to get the fragments in good position. Retention, however, appeared difficult, and I decided to introduce an intramedullary peg bone graft. An incision was made over the tibia on the same side, and a piece of the anterior surface of the tibia about 6 inches long by 3/4 inch broad was removed by Albee's electric saw. The graft was slightly sharpened at both ends and the electric reamer used for slightly widening the medulla of both femoral fragments. The graft was then inserted into the two fragments and their position was found to be easily retained by this means. The wounds were then closed with catgut and silkworm gut without drainage; the leg was applied to a Miles's double inclined plane.

Recovery from the operation was uninterrupted and the stitches were taken out on the thirteenth day; knee movements were started at the end of the first week. The inclined plane was left off on the twenty-first day, he was up on the twenty-eighth day, and out on the fifty-second day. No shortening resulted.

The radiogram of the femur taken about two months after the operation showed perfect alignment with complete osseous union and a considerable amount of callus around the fracture. The knee- and ankle-joint movements rapidly improved, the full extension of the knee being the last movement to come, but all were perfect on his discharge, and he now walks without a limp and is able to run and play strenuous games without any difficulty.

#### Conclusions.

1. The method by autoplasmic peg graft is superior to all other operative measures in that it retains the alignment of the fracture and helps to form new bone, so ensuring union at an earlier date and allowing early active and passive movement.

2. Though requiring a certain skill with the electric saw it is by no means a difficult operation.

3. The peg is eventually absorbed from the marrow cavity, leaving the shaft in the normal condition.

4. It obviates any limitation of knee movements as the joint is moved from the tenth to the twelfth day.

5. The results achieved warrant its much wider application.

## LARYNGEAL INTUBATION IN ANAESTHETICS.

BY

STANLEY ROWBOTHAM,

ANAESTHETIST, THE QUEEN'S HOSPITAL FOR FACIAL AND JAW INJURIES,  
SIDCUP; HONORARY ANAESTHETIST, THE CANCER HOSPITAL AND  
THE SEAMEN'S HOSPITAL, GREENWICH.

THE method of laryngeal intubation to be described is offered (1) as an alternative, and (2) in some cases as a very necessary adjunct, to intratracheal insufflation where this method of anaesthesia is indicated.

Intubation for the administration of the anaesthetic, when the operation is in the region of the mouth or jaw, is usually performed by means of a Kühn's tube. The indirect method of intubation, however, is not generally so easy nor so certain as that of passing a tube through the glottis by direct vision; moreover, the tube supplied by instrument makers in this country seems to offer a very considerable resistance to free respiration.

The technique of intubation to be described is no more

difficult and takes no longer than that for passing a tracheal catheter. The following advantages may be claimed for it:

(a) It completely shuts off the air passages so that no blood or mucus can enter.

(b) It enables gas and oxygen almost entirely to be administered, and, as most operations in this region do not require very great relaxation, the patient can be kept in a lighter zone of anaesthesia without fear of respiratory obstruction, the glottic sphincter being entirely out of action.

(c) A soft rubber tube is used which does not injure the cords.

In combination with a tracheal catheter—

(d) To obtain expiration entirely free from all obstruction some form of return airway is usually necessary with intratracheal insufflation. This especially applies to cases where the surgeon is working on the lower jaw.

(e) It prevents bubbling of blood from hindering the surgeon when the operation is in the mouth or nose. In the latter case a post-nasal sponge is unnecessary.

The tube used is of rubber, rather a cheap quality being

FIG. 1.—Three illustrations showing method of cutting tube to slide along catheter.

preferable because it is not so soft and compressible. The walls are not more than 2 mm. thick. The size varies with the patient and also with its mode of use, a larger size, of course, being necessary if the patient is to breathe backwards and forwards through it, than if it is merely to be used as a return airway, the entering stream of air being supplied by way of a tracheal catheter. Tubes approximating numbers 22 to 32 French catheter sizes are most generally useful, and the length should be about 8 inches, so as to carry the end well into the trachea. When the tube is to be passed through the nose, its end is cut away in a sloping manner to facilitate its passage through the nose, and a small hole is punched half an inch from the end

FIG. 2.—Two illustrations showing directing rod and method of hooking up tube.

to receive the hooked end of the directing rod. When used as a return airway with a catheter passed through the mouth, a tube is cut as in Fig. 1, and the end turned round to form a loop; this slides down the catheter after it has been passed into the trachea, and so is guided through the cords.

The directing rod is a straight metal rod curved slightly upwards and forked at the distal end. The inner prong of the fork is turned upwards and a little outwards so as easily to enter the hole in the tube when catching it up in the pharynx. The outer prong is cut short (Fig. 2).

The direct laryngoscope is used for intubation. When intubating by way of the mouth, the directing rod is hooked into the hole in the distal end of the tube, which is cut as for passage through the nose. The two are held together and passed by the side of the speculum. The upward bend on the directing rod enables the tube to be more easily directed between the cords. As soon as the thin end of the tube has passed into the glottis it is pushed on alone, and the directing rod gently withdrawn.

After intubation, the tube is connected with a gas-bag by means of a metal angle piece, a short length of one-inch-bore rubber tubing, and the usual three-way stopcock, the mask having been removed. A flat angle piece curving straight down to the chin has proved very useful for intranasal operations; it does not get in the operator's way if it is held to the chin by a piece of adhesive plaster (Fig. 3).

FIG. 3.—Flat metal angle piece.

When administering gas and oxygen by this method it is advisable to keep up a small *plus* pressure (3 to 5 mm. Hg) in the bag. This is easily effected by suitable adjustment of the stopcock. Ether or chloroform can, of course, be administered by using a Shipway's three-bottle apparatus in connexion with the intubation tube. Before removing the tube it is advisable thoroughly to cleanse the pharynx and mouth of all mucus and blood.

When the operation is within the mouth a double intubation may be performed as follows: A catheter is passed down one side of the nose and the return airway tube down the other (a piece of tubing with a natural curve should be chosen and passed with its concavity towards the floor of the nose). The laryngoscope is now passed through the mouth and the tube and catheter viewed in the pharynx. After having passed the catheter into the trachea (BRITISH MEDICAL JOURNAL, October 16th, 1920) the hooked end of the directing rod, turned so that it curves towards the tube, is passed down into the eye at the end. By rotating the rod through a quarter-circle so that it now turns upwards, a secure hold of the tube is obtained, and it is easily directed between the cords.

The advantages of this method over the simple pharyngeal return airway previously described are that bubbling of blood is entirely avoided without packing the pharynx, and that if the lower jaw is pushed back, as often happens during intra-oral operations, the airway is not in the least obstructed.

## CHANCER REDUX.

BY

P. C. P. INGRAM, M.B., B.S.LOND.,

HONORARY PHYSICIAN FOR DISEASES OF THE SKIN AND MEDICAL OFFICER IN CHARGE, VENEREAL DISEASE CLINICS, ROYAL GWENT HOSPITAL, NEWPORT, MON.

CHANCER redux is a condition which excited a good deal of interest among syphilologists of a past generation, but little appears to have been heard of it in recent years, though Wilfrid Fox<sup>1</sup> has drawn attention to the fact that it may be mistaken for the primary lesion; it has therefore been thought worth while to record the following cases from the venereal diseases clinic of the Royal Gwent Hospital, Newport, as further illustration of a condition which appears to be of importance both in diagnosis and prognosis.

### CASE I.

A man, aged 25, first attended the clinic on August 15th, 1921. There was no history of previous infection. Exposure ten weeks previously; sore first noticed ten days ago. He had a slightly indurated sore on the ventral surface of the glans penis and the inguinal glands were enlarged; there were no other signs. General condition good. The *Spirochaeta pallida* was found in the sore by dark-ground method. The Wassermann reaction was weakly positive. Treatment was commenced forthwith (on dark-ground diagnosis) and an intravenous injection of novarsenobillon and an intramuscular injection of mercury given. In the ensuing eight weeks he received a total of 4.8 grams of the former and 8 grains of the latter. The sore was healed in a fortnight, and a Wassermann test done on October 28th was completely negative. He then took potassium iodide, 10 grains by mouth thrice daily, for six weeks.

On January 6th, 1922, he attended and stated that a sore had broken out a week previously. He emphatically denied re-exposure and said that eight days previously he had had an attack of vomiting, after which he had become somewhat jaundiced. He now had a small non-indurated sore on the inner surface of the prepuce—that is, not at the same place as the original chancre. This sore, on dark-ground examination, showed numerous *Spirochaeta pallida*, and the blood gave a strongly positive Wassermann reaction. As the urine contained some bile, salvarsan was withheld and he was given intramuscular injections of mercury only, 1 grain at weekly intervals. The sore was quite healed by February 1st, and no

other lesions developed; the jaundice quickly disappeared, but the Wassermann reaction was still strongly positive on February 15th. Treatment was resumed, and he had eight ram at weekly intervals. He stayed away the month of June, and on his return on July 19th his blood was slightly positive only. He took liq. hydrarg. perchlor. dr. 1 with potass. iodid. gr. 10 in mixture by the mouth for two months, but in spite of this his blood relapsed, and on September 29th was back to markedly positive. He had two more injections of novarsenobillon and mercury, but then stayed away from the clinic and has not attended since.

This case, I think, must be considered a relapse and not a reinfection, though, in view of the fact that he had what might be termed more than a maximum tolerant dose of novarsenobillon, such a clinical as well as serological relapse is unusual. With a sore not more than eight to ten days old (he was attending the clinic at the time it developed), the Wassermann reaction was strongly positive, and in spite of treatment his blood has not remained permanently negative since.

### CASE II.

A man, aged 21, first attended on April 13th, 1921, with a history of exposure three weeks previously and soreness of his penis for one week. He had phimosis with a profuse discharge. No *Spirochaeta pallida* but numerous *refringens* found; no gonococci; no ulcer could be felt beneath the prepuce—probably because it was too early. The Wassermann reaction was slightly positive. He was given 0.45 gram of novarsenobillon and 1 grain of mercury. Blood taken the week following was strongly positive. Seven more injections were given at weekly intervals to July 21st; he then stayed away until August 10th. He was then free from active signs, the prepuce could be easily retracted and the sore was quite gone, no scar being visible. The Wassermann reaction was completely negative. He was given potassium iodide 10 grains t.i.d. On August 24th he reported a slight soreness at the margin of the meatus; this was thought to be a simple balanitis and he was ordered to resume local treatment (hydrogen peroxide), but a week later there was a definitely ulcerated area and *Spirochaeta pallida* was found in the serum obtained from it. He did not attend the clinic again for a week, and the blood taken then was found to be strongly positive. He was given a second course of novarsenobillon and mercury injections. Within a fortnight the sore was quite healed and no further signs developed. Injections of the two drugs were given at weekly intervals up to October 23rd, and on the 30th of that month his blood was completely negative. He took potassium iodide for six weeks and then stayed away. He came again to the clinic on February 15th, 1922, and was found to be free from active signs and the Wassermann reaction was completely negative. A month later the blood, taken a week after a provocative dose of novarsenobillon, was still negative. He had no further treatment, and a like result was obtained in the following June and November.

This patient, like the first, emphatically denied re-exposure, and the strongly positive Wassermann reaction so early in the stage of the second sore makes it probable that his statement is correct, though it is not quite so conclusive as in the first patient, where the sore was a little older, though certainly not more than three weeks, and probably only two, when the blood test was done. It is unfortunate that blood was not taken on August 31st, the day spirochaetes were found in the sore, and when one considers the way the disease cleared up, both clinically and serologically, one is not quite so certain that this was not a reinfection.

But should either of these cases be called chancre redux? Hutchinson's<sup>2</sup> original description laid stress on the fact that the sore is almost invariably located exactly on the site of the former chancre. The first of these does not fulfil that criterion; the second possibly does if we do not regard it as a reinfection.

The point on which I would lay stress is that these cases may, if a full bacteriological as well as clinical examination be not done, be taken for reinfections, and that, unlike the latter, their prognosis from the point of view of a permanent cure is much more unfavourable—as witness the first case, who is still uncured, in spite of eighteen months' treatment on most modern lines.

More recently a patient came to the clinic showing what I would consider a classical redux chancre.

### CASE III.

A man, aged 32, attended on January 10th, 1923. He gave a history of a chancre six years ago, and some months' treatment for it by mercury only. Beyond some sores on his head he does not appear to have noticed much in the way of secondary signs, and he had been quite free from symptoms for over four years, until his present trouble began. He had a gummatous ulcer on his palate, and, on what he says he is sure is the site of his primary sore, was a definite red indurated area which, though now dry, he said had been weeping recently. The Wassermann reaction was strongly positive; the site of the chancre was too dry to get any

material for examination by dark ground. He was put on novarsenobenzol and mercury injections; the induration and ulcer quickly became much less and disappeared in the course of about three weeks.

## MEDIASTINAL GROWTH WITH VENOUS THROMBOSIS.

BY

J. A. MacLAREN, M.D., Ch.B.

The following case is of interest owing to the difficulty in arriving at a definite diagnosis.

In August, 1922, a medical man began to suffer from general malaise, shortness of breath, and cyanosis of ears and nose; x-ray examination was negative.

In October, when I was called in, there was complete thrombosis of the brachial veins and partial of the external jugulars; the face was puffy and congested, and the arms enormously swollen. The superficial veins of the thorax and abdomen were engorged. The respirations were quickened and shallow; the heart apex was outside the nipple line, and the liver two inches below the costal margin. The pulse was regular, varying between 70 and 80 a minute; there was no heart murmur, and the chest was clear except for slight dullness and diminished air entry at the right base behind. A sputum test was negative for tubercle bacilli; there was no history of syphilis, but there was a history of previous thrombosis of the right leg following enteric fever and malaria some thirty years ago. Treatment consisted in iodides and podophyllum internally, with fomentations to arms and support to arms and head. The oedema and hardness of veins gradually cleared up, and the heart and liver became normal in size. The chest dullness, however, did not disappear, and later the left base behind also became dull; there were no adventitious sounds except for a few occasional coarse crepitations. The extreme bases appeared to be clear and resonant and breath sounds were audible near the spinal column. The dull patches varied in position and extent from day to day, and were influenced by dry cupping. The patient's temperature never rose above normal, and he had no discomfort apart from slight shortness of breath, sleeplessness, and some flatulence.

In February, 1923, oedema began to reappear in the arms, and later in the right leg, and the heart sounds became muffled. There was then no appreciable dullness in the front of the chest. On the chance of there being a septic focus present I now inoculated him with antisepsis vaccine (P. D. and Co.), with the result that the oedema rapidly began to disappear and the chest dullness diminished. After the third weekly dose everything cleared up except a small patch of dullness in the right axillary line of the chest. Improvement in his condition continued till the beginning of April, when suddenly cough became troublesome, cyanosis began to return, and the heart sounds became weak. At this time there was some slight dullness to percussion over the middle of the front of the chest. The patient now lost weight and daily became weaker and more cyanosed, though he stated that he felt really better in himself except for the cough. Cyanosis increased, oedema of both legs set in, he suffered from orthopnoea, and died suddenly after getting into bed on April 19th.

Post-mortem examination revealed a soft growth, cheesy and breaking down in parts, adherent to the manubrium sterni. It extended down to the pericardium and surrounded the large vessels at the base of the heart. The apices of the lungs, especially on the right side, were involved, and on cutting into the lung substance secondary deposits could be seen studded throughout both lungs. Microscopically the growth showed all the characteristics of round-celled sarcoma.

The points I wish to emphasize are: (1) X-ray examination showed no evidence of new growth. (2) Until the last week or two of the illness there was no dullness over the anterior mediastinum. (3) The dull patches behind varied daily in size and position, and were influenced by dry cupping. (4) The antisepsis vaccine produced immense temporary relief, causing the dull patches, the cyanosis, and oedema to disappear. (5) What relation, if any, had the new growth to the thrombosis? Finally, I draw attention to this point: "In all cases of venous thrombosis affecting the upper portion of the body the existence of a mediastinal new growth should be borne in mind in spite of the want of direct evidence."

## Memoranda:

### MEDICAL, SURGICAL, OBSTETRICAL.

#### ACUTE PUERPERAL INVERSION OF THE UTERUS.

The case here recorded is of interest on account of the serious condition of the patient when admitted to hospital, and the rapidity with which recovery followed the treatment adopted.

Mrs. M. W., aged 29, was admitted to Victoria Hospital, Southend, on April 16th, suffering from complete inversion of the uterus, following labour, which had occurred an hour previous to admission.

She had been under the care of a midwife, who stated that labour had been normal but somewhat precipitate. As the placenta did not come away after half an hour she expressed it, and the "placenta and uterus came down together." The placenta was then removed. She also said that she had not pulled upon the cord, which was normal in length and was not twisted round the child. The haemorrhage was slight. Two years previously the patient had a normal labour, in which the placenta had been retained for an hour after the birth of the child.

On admission the patient was unconscious and pulseless, and in a condition of extreme shock. The shock was treated and consciousness returned in an hour, when the pulse could first be felt. The patient was lightly anaesthetized and Dr. Cleveland Smith succeeded in replacing the uterus by steady pressure for about ten minutes. Pituitrin was given intramuscularly and the uterus douched; it contracted immediately and there was no haemorrhage. For about three days following reposition she had a swinging temperature and an offensive vaginal discharge. This cleared up with douches and she was discharged from hospital three weeks later in perfect health.

The points of interest in this case were the extreme gravity of the shock, the slight amount of haemorrhage, the rapid contraction of the uterus after reposition, and the good results which followed upon early reposition with removal of the placenta as a preliminary.

I am indebted to Dr. Cleveland Smith for permission to publish this case.

ROBERT R. FOOTE, M.R.C.S., L.R.C.P.Lond.

Southend-on-Sea.

#### IDIOSYNCRASY TO MERCURY.

Miss K., aged 26, came to me complaining of a painful eye condition. On examination the lids were seen to be oedematous with small pearl-like blebs on the skin surface; there was a good deal of injection of the conjunctivae, with similar blebs on them. She complained of excessive watering of the eye, blurred vision, and photophobia. On the posterior surface of the auricle and skin adjoining were erythematous pearl-like blebs. All down one side of the neck over the distribution of the fibres of the trapezius was a distinct shotty erythema.

The case appeared a puzzle until I went into the question of occupation. The patient had lately engaged herself as a dental nurse, and I ascertained that she had been clearing up amalgam fillings, and had touched some globules of mercury. Evidently she had rubbed her eye with the finely divided metallic mercury, and set up slight mercurial poisoning. She had some slight watering of the mouth, and the parotid was very tender.

Evidently the case was one of special idiosyncrasy to mercury, and I congratulated myself that I had not ordered her a mercurial ointment as treatment for the conjunctivitis.

After using a weak solution of potassium permanganate and some cocaine drops for the eye, the rash and other symptoms disappeared in a week.

Bath.

FELIX MEINÉ, M.B., Ch.B.Edin.

In 1922 there were 386 cases of typhus in Germany as compared with 533 in 1921. Almost all of the cases occurred among immigrants and refugees.

According to the *Journal Officiel* the number of marriages in France during 1922 was 383,220, or 73,000 less than in 1921 and 240,000 less than in 1920. The number of divorces was 27,684, or 4,873 less than in 1921 and 1,472 less than in 1920. The excess of births over deaths has diminished on the whole, but was higher in 1921 in nine departments—namely, Pas-de-Calais, Lozère, Corrèze, Ardèche, Saône-et-Loire, Haute-Savoie, Indre, Ain, Aube.

## CLINICAL AND SCIENTIFIC PROCEEDINGS.

CAPE OF GOOD HOPE—WESTERN PROVINCE  
BRANCH.

A MEETING of the Cape of Good Hope (Western Province) Branch was held in Cape Town on May 25th, when the President, Dr. C. M. MURRAY, presided, and thirty-five members were present.

*Caesarean Section.*

Sir EDMOND S. STEVENSON read a paper on Caesarean section. He dwelt on the danger of the scar rupturing at a subsequent confinement, and spoke at length on the difficulties of sterilizing a woman at the time of section. The indications which he laid down for Caesarean section were accidental haemorrhage, eclampsia, and placenta praevia. As regards operation he favoured the lower uterine segment scar. Professor E. C. CRICHTON congratulated Sir Edmond Stevenson on his courage and spirit in contributing a paper in spite of his advanced years. The paper gave a true account of the operation of thirty years ago, but ideas had changed materially, and the indications laid down by Sir Edmond were no longer accepted in their entirety. He agreed as to the great importance of placing swabs in the abdomen before opening the uterus. Dr. C. W. COMRIE-SHARP described his own technique. Dr. D. H. WESSELS agreed with Professor Crichton regarding the indications for operation. Contracted pelvis was rare in Cape Town. He thought that if placenta praevia was seen late, Caesarean section might be considered. He thought the personality and lengthy experience of the speaker had lent tremendous interest to a paper which had shown very clearly how much the conception of this operation had changed. Mr. C. C. ELLIOTT remarked how rarely Caesarean section was carried out in South Africa; in a very large experience he had only performed the operation three times. Sir EDMOND STEVENSON replied to the discussion, and the PRESIDENT thanked him on behalf of the Branch for his contribution.

*Care of the Pregnant Woman.*

Dr. C. W. COMRIE-SHARP read a paper on the care of the pregnant woman. He gave an entertaining historical review of the origin of conception, and detailed many of the weird beliefs still held by native races in South Africa. He then detailed modern advances in the manner of dealing with the pregnant woman, and dwelt on the methods and teaching of Ballantyne, the father of the new gynaecology. Dr. R. LANCE IMPEY emphasized the importance of ante-natal care, and suggested that the reduction of high infantile mortality turned on the better education of the medical student and the rigid prosecution of modern methods of ante-natal supervision. He discussed the great advances made in dealing with syphilis *in utero*. Professor CRICHTON, Dr. D. H. WESSELS, Dr. SIMPSON WELLS, and Mr. A. REITH FRASER also discussed the paper.

*Treatment of Genital Prolapse.*

Dr. R. LANCE IMPEY read a paper on the treatment of genital prolapse. In a brief review of the anatomy and physiology of the pelvis, he showed how the pelvic viscera were kept in position by three sets of forces—namely, intra-abdominal pressure, the pelvic diaphragm, and the parametric tissues; the great importance of the last was emphasized. He gave his personal experience—gained while working at the Royal Infirmary, Edinburgh, St. Mary's Hospital, Manchester, and the Michigan University Hospital, U.S.A.—of the three best known types of operation. In his opinion the essential points when operating were (1) to shorten the elongated parametric tissues, (2) to repair the pelvic floor, and (3) to keep the uterus anteverted. Vaginal plastic surgery gave the best results, and abdominal intervention was unnecessary. The operation introduced by Fothergill was described and illustrated by means of diagrams. He strongly recommended this operation for general use. Dr. D. H. WESSELS entirely agreed

with everything Dr. Lance Impey had said. He had himself adopted Fothergill's operation, and deprecated opening the abdomen for genital prolapse. Professor E. C. CRICHTON also spoke.

## Reports of Societies.

## THE LARYNGOLOGICAL SUMMER MEETING.

THE summer meeting of the Section of Laryngology of the Royal Society of Medicine was held—for the first time outside London—at Manchester Royal Infirmary on Friday and Saturday, June 15th and 16th, and was extraordinarily successful. The President, Mr. C. A. PARKER, was in the chair, and over sixty laryngologists were present from some thirty different centres, including London, Manchester, Edinburgh, Glasgow, Dublin, Belfast, Newcastle-on-Tyne, Leeds, Sheffield, Harrogate, Blackpool, Liverpool, Stoke-on-Trent, Birmingham, Leicester, Nottingham, Norwich, Reading, Cardiff, Bristol, Worcester, Bournemouth, and Brisbane.

The meeting was opened by the PRESIDENT on Friday morning, when Dr. DOUGLAS GUTHRIE (Edinburgh) read a paper on chronic hyperplasia of the upper jaw and its relationship to other osseous tumours.

*Chronic Hyperplasia of the Upper Jaw.*

Dr. Guthrie described two cases, a girl aged 16 and a boy aged 4, both of whom presented a uniform, painless enlargement of one upper jaw, due to the exuberant growth of soft cancellous bone. The alveolus was greatly thickened on the affected side and the maxillary antrum almost obliterated. A number of lantern slides were shown to illustrate the osseous tumours of the upper jaw which might bear some relation to chronic hyperplasia. Leontiasis ossea, for example, was, he said, a name somewhat loosely applied to any bony enlargement of the facial bones and might commence as a hyperplasia of one maxilla, but as a rule the lesions were multiple. The tropical disease known as goundou, or symmetrical exostoses of the nasal processes of the maxilla, appeared to be the result of some infective condition within the nose. Unilateral hypertrophy of the face—the strange congenital anomaly described by Greig and others—was an enlargement of normal tissues, without hyperplasia, and might possibly be caused by localized meningitis or neuritis during intrauterine life. The pathogenesis of these osseous enlargements was worthy of further study. In the museum of the Royal College of Surgeons, London, there were, said Dr. Guthrie, three specimens of chronic hyperplasia of the upper jaw. One, from a woman aged 35, whose right upper jaw had been the seat of a painless enlargement for ten years, was described by Christopher Heath in his classical work. The jaw consisted of a uniform mass of porous bone and the antrum was much reduced in size. Another specimen was a jaw excised by Lord Lister, and the third has been described in detail by Sir Frank Colyer. A complete account of the disease was given by Westmacott at the International Medical Congress of 1913; he described eight cases, all of whom, save one, were females. The cause of the hyperplasia was unknown. It appeared to bear no relation to syphilis or tubercle, or to maxillary antral suppuration. The microscopic appearances suggested a reversion to the embryonic type of bone and presented a striking similarity to otosclerosis. Mr. G. J. Jenkins had recently demonstrated a relationship between otosclerosis and osteitis deformans, and it seemed probable, suggested Dr. Guthrie, that a similar relationship existed in the present instance, although it could not be concluded that two diseases were pathogenically identical even when the histological appearances seemed indistinguishable. The paper was discussed by Mr. F. H. WESTMACOTT, and by Mr. T. B. LAYTON, who described a similar condition found in chimpanzees.

*Diseases of the Thyroid Gland.*

Mr. F. HOLT DIGGLE (Manchester) discussed (1) the incidence of laryngeal paralysis in benign diseases of the thyroid gland, and (2) the effects of thyroid enlargements on the shape and position of the trachea. After quoting other

published figures as to the incidence of laryngeal paralysis, Mr. Diggle stated that of 34 cases which he had examined during the last eighteen months, 7 presented laryngeal or tracheal complications. Of these, one was an adductor paralysis in a case of exophthalmic goitre. In the six remaining cases, three were due to tracheal compression, one to the involvement of the right recurrent nerve in a perithyroid inflammation, one, a woman aged 43, with a large goitre, suffered from attacks of spasmodic dyspnoea associated with adductor spasm, and lastly, there was one case of hoarseness in a child. Mr. Diggle remarked that in the majority of cases the paralysis was unilateral and was more generally associated with intrathoracic or substernal goitres, and that by reason of the anatomical position of the recurrent nerves in the neck it was unusual to obtain vocal cord paresis without tracheal compression. Laryngeal paralysis occurred, however, in retro-oesophageal or retro-pharyngeal extensions of the thyroid gland. Referring to the involvement of the nerve in perithyroid adhesions, a case was quoted of a lady, aged 60, who had a right abductor paralysis due to haemorrhage into a cystic goitre. It was interesting to note that two months later (no operation having been performed) the paralysis had completely recovered. Radiograms were shown illustrating the bilateral or scabbard compression of the trachea in cases of parenchymatous goitres occurring in young adolescents. Mr. Diggle pointed out that it was essential in these cases to remove more than one lobe of the thyroid in order to prevent dyspnoea from subsequent tracheal displacement. The paper was discussed by Mr. TILLEY and Mr. SMURTHWAITE.

#### *Malignant Disease of the Upper Jaw.*

Mr. MUSGRAVE WOODMAN (Birmingham) gave a lantern demonstration illustrating the surgery and pathology of malignant disease of the upper jaw, in the course of which thirty-two coloured lantern slides were shown. He divided the growths of the upper jaw into intrinsic and extrinsic, and pointed out that, whether they arose from the air sinuses or from the outer walls of the jaw or tissues covering it, they sought and entered the antrum as the site of election. In the latter group of extrinsic growths, slides were shown illustrating epitheliomata and spheroidal-celled carcinomata arising in the palate and alveolus. Similarly squamous-celled carcinomata and rodent ulcer growing from the skin and various types of sarcomata growing from the base of the skull, including giant-celled sarcoma, were demonstrated. The endothelial sarcoma was considered the typical growth arising intrinsically from the air cells. Sections under low and high power were given of the normal ethmoid bone showing the air cells with their endothelial lining and bony walls. The series of slides showed transition from the normal structure to that of an endothelioma with typical vacuolated cells. Considerable emphasis was laid on the varied microscopical appearance shown by sections taken from various parts of the same tumour. Coloured slides were also shown of three operation cases: the first was a sarcoma of the base of the skull, which on exposure bled so seriously that the operation had to be abandoned. It was pointed out that the source of this haemorrhage was mainly the vertebral artery, and that ligation of the external carotid would not have checked the haemorrhage. The second was an extensive rodent ulcer of the face, which had become epitheliomatous and had destroyed the eye. This was excised completely and a photograph was exhibited showing that the operation area became eventually completely covered by epithelium. The third was a case of extensive recurrent endothelioma with secondary nodules in the region of the eye, the whole eye, together with the upper jaw, having to be excised. The growth was found to be adherent to the dura mater, where it was destroyed by diathermy. The patient made a good recovery, but suffered from considerable headache, which was probably due to increased meningeal pressure. These cases were shown to illustrate the wide scope of operative treatment in the region of the upper jaw, and the necessity of approaching each case with an open mind and of modifying the operation to suit the individual case and to deal with its complications. The demonstration was discussed by Mr. WILKINSON, and by Mr. SYME, who said that he had not found radium of much benefit in such growths.

#### *The Lingual Tonsil.*

Mr. J. ARNOLD JONES (Manchester) said that he had found that troublesome symptoms, such as an irritable cough, arose, particularly in neurotic women leading sedentary lives, from certain conditions of the lingual tonsil. He had obtained good results by local treatment with the cauterizer or silver nitrate and by giving ovarian extract internally. Mr. WILLIAM HILL, Dr. WATSON-WILLIAMS, Sir WILLIAM MILLIGAN, Mr. H. TILLEY, and other speakers deprecated the part played by the lingual tonsil in causing the symptoms described, and suggested that treatment of the neuroses alone would have given equally good results.

#### *Large Foreign Bodies in the Gullet.*

Dr. D. R. PATERSON (Cardiff) discussed the problem of the treatment of large foreign bodies impacted in the gullet. Sir WILLIAM MILLIGAN pointed out the value, in some cases, of the open operation, in place of attempting to remove the obstruction *per vias naturales*, and was supported by Mr. WILLIAM HILL. Mr. MUSGRAVE WOODMAN, while supporting the employment of the open operation, emphasized the danger of infection spreading to the mediastinum. Mr. LAYTON raised the point of whether removal of an impacted foreign body was an "urgent" operation, or whether it was justifiable to wait. It was generally agreed that waiting was quite justifiable in most cases; Mr. WESTMACOTT indicated, however, that copper coins should be attacked at once, as they quickly ulcerated.

#### *After-Treatment of Maxillary Antrum Empyema.*

Mr. LINDLEY SEWELL (Manchester) read a clinical note on the after-treatment of empyema of the maxillary antrum (Denker's operation). He detailed the steps of the operation and stated that he had obtained excellent results by discontinuing irrigations after operating. Mr. MUSGRAVE WOODMAN promised to try the effect of discontinuing irrigations; in performing the operation he thought it best not to cut but to crack the inferior turbinate and push it upwards to obtain free access. Mr. LAYTON had found physiological saline the best irrigation; Mr. GRAHAM BROWN gave the results of his large experience of antrum suppurations in Queensland; and Sir WILLIAM MILLIGAN, Mr. BANKS-DAVIS, Mr. WRIGHT, and Dr. GUTHRIE also took part in the discussion.

#### *Evolution of the Nasal Sinuses.*

Mr. J. F. O'MALLEY (London) read an interesting paper on the comparative anatomy of the nasal cavities and sinuses, and their evolution in relation to function.

#### *Exhibition and Discussion of Cases.*

After an excellent luncheon in the Medical Board Room of the Infirmary, given by the local committee to the visiting members of the Section, there was a demonstration and discussion of laryngological cases in the Throat and Ear Out-patients' Department. The cases were fifty-three in number, and elaborate arrangements had been made to facilitate examination by the members. Sir WILLIAM MILLIGAN showed a case of sarcoma of the left tonsil, successfully treated with radium; a case of epithelioma of the soft palate and left anterior faucial pillar, which had been and was again about to be diathermized; a case of epithelioma of the right vocal cord, successfully treated by laryngo-fissure and removal of the cord; a case of suppurative labyrinthitis successfully treated, so far as static symptoms were concerned, by extirpation of the left labyrinth; and (with Mr. F. WRIGLEY) a case, successfully operated upon, of orbital cellulitis complicated by invasion of the frontal sinus and osteomyelitis of the frontal bone, and a case of sarcoma of the right tonsil and faucial region treated by diathermy and external application of radium. Mr. F. H. WESTMACOTT showed, for diagnosis and suggestions, two cases of chronic oedema of the orbit, several cases of laryngeal growths, and a case of ulceration of the soft palate and left tonsil; he also showed several cases of laryngeal growths successfully treated by removal under suspension laryngoscopy. Dr. KNOWLES RENSCHAW showed, for diagnosis, a case, possibly following injury twelve years previously, presenting a large, smooth tumour more than half filling the pharynx. Mr. J. ARNOLD JONES showed, among other cases, an extensive condition of tuberculosis of

the nose, pharynx, and larynx. Mr. LINDLEY SEWELL showed a case of epithelioma of the anterior pillar of the fauces and base of the tongue, treated by diathermy, and a case of lupus of the anterior end of the inferior turbinate, treated by electro-cautery puncture. Other cases were shown by Mr. FRANK WRIGLEY, Mr. A. A. SMALLEY, Mr. G. E. ARCHER, Mr. F. HOLT DIGGLE, and Dr. DAVID THOMSON.

#### Demonstrations.

On Saturday morning Dr. P. WATSON-WILLIAMS (Bristol) demonstrated his method of diagnostic bacteriological exploration of the nasal sinuses. This method, in brief, consists in attaching to a syringe a cannula suitable for entering the suspected sinus and sucking up the discharge, which is then placed in a sterile bottle and submitted to bacteriological investigation; it is usually helpful to inject a small quantity of sterile water into the particular sinus and then suck it back with the contained discharge. In adults the procedure is carried out under local anaesthesia (20 per cent. cocaine), but in children general anaesthesia is used.

Dr. IRWIN MOORE (London) demonstrated his method of reducing or destroying hypertrophied or diseased tonsils by means of the "London paste" of Morell Mackenzie—caustic soda and slaked lime. The paste is applied to the tonsils with a special applicator, under local anaesthesia (10 per cent. cocaine); this procedure, carried out once a week for about four to six weeks, causes a rapid reduction of the tonsillar tissue right down to the capsule. It is recommended only for cases in which operation is contra-indicated or persistently refused.

In the new X-Ray Department of the Infirmary—which was greatly admired—Dr. MORISON (Manchester) gave a demonstration of radiograms illustrating "cardiospasm," and initiated a discussion on the subject, in which Mr. WILLIAM HILL and others joined. Dr. TWING showed x-ray photographs of normal and diseased mastoids; and Dr. ANDERSON demonstrated methods of treating by x rays malignant conditions of the throat.

In the Radium Institute, Nelson Street, Dr. A. BURROWS exhibited interesting cases, and demonstrated methods of the application of radium.

Sir WILLIAM MILLIGAN performed a number of operations, including radical mastoid and skin grafting, acute mastoid (blood-clot method), and enucleation of tonsils; and Mr. F. H. WESTMACOTT carried out operative procedures with the aid of suspension laryngoscopy.

#### Annual Dinner.

The annual dinner of the Section of Laryngology was held on Friday evening at the Clarendon Club, with Mr. C. A. PARKER, President, in the chair. The toast of the Section of Laryngology was proposed by Sir HENRY MIERS, Vice-Chancellor of Manchester University, and the PRESIDENT—who had discovered that he was an old school-fellow of the Vice-Chancellor—replied. The health of the guests was proposed in felicitous phrase by Sir WILLIAM MILLIGAN, and Dr. C. H. MELLAND replied. Mr. LINDLEY SEWELL, who acted with great success as local secretary of the meeting, told some of his inimitable Lancashire (and fishing) stories; and Mr. LAYTON and Mr. O'MALLEY, secretaries of the Section, were also called upon to speak.

### GYNAECOLOGICAL CASES AND SPECIMENS.

A MEETING of the North of England Obstetrical and Gynaecological Society was held at Leeds on May 25th, when Professor E. O. CROFT showed a specimen of axial rotation of the right Fallopian tube and ovary.

The ovary was enlarged by a small cyst; it was removed from a patient 36 years of age, whose fourth child was born eight years before. Menstruation did not return after weaning the baby; a year later part of an enlarged thyroid was removed. After three years' amenorrhoea she had one very slight show of blood followed by a normal pregnancy and labour; menstruation has not reappeared. For some months she has had irregular labour-like pains, some difficulty in micturition and defaecation, but no bleeding. On March 12th an irregular, rounded, soft lump in the pouch of Douglas displaced the uterus forwards. Professor Croft remarked on the rarity of the extreme rotation of a tubal swelling—probably inflammatory or hydrosalpinx—and the mechanism of rotation of

such a small swelling with a relatively broad pedicle; on the amenorrhoea which existed from the fourth child eight years ago, probably associated with the enlarged thyroid and its subsequent removal and observed that the amenorrhoea was not associated with sterility.

Mr. R. A. HENDRY showed a hydatidiform mole with considerable epithelial overgrowth, suggesting the possibility of chorion-epithelioma.

The patient was 30 years of age, had had two children, the last six years ago. Menstruation ceased in October, 1922. Vomiting began during the second month and became severe. There had been occasional shows since December, and a fortnight's bleeding preceded the passage of hydatidiform mole on February 17th. The uterus was about one inch above the umbilicus; no data as to the rapidity of uterine enlargement were obtainable. The patient was transferred to Liverpool Royal Infirmary, where, after anterior hysterotomy, the uterine contents were cleared out and the cavity explored digitally. Sections of the mole showed an unusually active growth of both syncytium and Langhans's layer, suggestive of chorion-epithelioma. Since the abortion she has had three menstrual periods, the first two at intervals of four weeks, the last after two weeks' interval—the ovaries were then slightly enlarged. She had now gone three weeks without bleeding and the ovarian enlargement had disappeared.

Mr. A. GOUGH showed a fibroid uterus removed by abdominal pan-hysterectomy combined with colporrhaphy.

The patient was 46 years old, and had prolapsus uteri since her only confinement nine years before. For several years menstruation had been increasing. On examination, the cervix was prominent, and the uterus formed a firm, globular mass almost filling the pelvis. At the operation a quadrilateral colporrhaphy incision was made and vaginal hysterectomy begun; the uterus could not be brought down and was removed through an abdominal incision, and the vaginal repair was then completed.

Dr. J. W. BRIDE described a case of obstructed labour due to carcinoma of the bladder.

The patient was aged 49, had had seven normal labours, and was admitted, eight and a half months pregnant, to St. Mary's Hospital, Manchester, with a growth from the bladder projecting into the vagina. She had been an in-patient at the Manchester Royal Infirmary about a year previously, when the bladder growth was recognized as a carcinoma; it was operable, but the patient declined operation. Labour was obstructed by a hard indurated mass, the size of a Tangerine orange, firmly adherent to the pelvic arch. A living child, 6 lb. 14 oz. in weight, was removed by Caesarean section, but maternal death ensued from exhaustion.

Mr. J. ST. GEORGE WILSON showed a hydatidiform mole with unusual features.

The patient, a 3-gravida, was 25 years old; her last child was born in July, 1921; menses ceased on March 16th, 1922; and the baby was weaned in May at the onset of morning sickness. In January, 1923, a month overdue, there was two days' bleeding; on January 30th, on examination the uterus corresponded to a sixteen weeks' gestation, and alternately contracted and relaxed. On February 26th, as the uterine condition was unchanged, three bougies were inserted; on March 2nd the mole was expelled with few pains and little bleeding. The mole consisted of a pyriform mass of vesicles with an incomplete decidua covering; section disclosed an amniotic sac containing a 12 mm. embryo.

Professor CROFT reported the after-history of a multipara aged 38 years, who consulted the late Mr. Wright in October, 1897.

A gradually increasing sore had existed for about eighteen months. On examination a raised oval growth, about 2.3 inch in its longest diameter, was seen on the inner aspect of the right labium majus. There was no history nor other evidence of syphilis. Mr. Wright removed the growth freely, but did not remove any glands from the groins. The growth was examined by Mr. J. E. Taylor and also by the late Mr. Targett, and the appearances were those of typical squamous epithelioma. A year later the patient had some uterine haemorrhage—probably an early abortion—a small polyp was removed and curetting was performed. In 1902, five years after the operation, the inguinal glands were enlarged, and the patient came under the care of Professor Croft, who cleared the glands away. The patient was not seen again until February, 1923, twenty-six years after the primary operation. She was now 64 and came with various neurotic complaints, including some pain in the right side of the pelvis. A thorough pelvic examination revealed no evidence at all of any physical disease and, except for the scars, both the vulva and the groins were normal. The facts of the case are all carefully noted in the hospital records, and the pathological report was as reliable as it could be.

A POST-GRADUATE course on orthopaedics will be held under the direction of Dr. F. Calot, at Berck-Plage, Pas-de-Calais, from August 6th to 13th. The subjects will include non-pulmonary tuberculosis, congenital and acquired deformities, the treatment of fractures, etc. Demonstrations will be given in English and Spanish, and the fee is 150 francs. The number of places is limited, and early application should be made to Dr. Fouchet, Institut Calot, Berck-Plage, Pas-de-Calais, France, or 69, Quai d'Orsay, Paris.

## Reviews.

### PSEUDO-APPENDICITIS.

THE general belief that all pains in the right iliac fossa are due to appendicular disease shows little sign of abating. There is no doubt that the public are very greatly to blame for this. The man in the street has learned that if you have appendicitis you have pains in the right iliac fossa. Unfortunately he believes the converse to be equally true: pains in the right iliac fossa must, he thinks, be due to appendicitis. The general practitioner and the surgeon who try to disillusion the chronic sufferer often get but small thanks for their trouble. In a small, but exceptionally clearly expressed book<sup>1</sup> TH. DE MARTEL and ED. ANTOINE have a tilt at this windmill. They concern themselves with the symptomatology, diagnosis, and treatment of "the painful syndromes of the mobile caecum and proximal colon." They point out that colonic mobility may give rise to no trouble, and may to that extent be considered normal. They regard the troublesome cases as failures of compensation. We have long been taught that it is the uncompensated heart which is the truly diseased heart, and so, according to these authors, is it with the colon. The book has the advantage of being written by a surgeon and by a physician in collaboration. Great stress is laid on medical treatment, details of which are given, and the authors very rightly say that no surgical treatment is successful unless aided by careful and intelligent attention to diet, bowel action, and general hygiene. They believe that all the pains which arise from the supposed abnormalities of the colon are mechanical in origin, being chiefly due to back pressure and dilatation of the caecum. There is a good account of the acute crises which are apt to arise, the chief point in differential diagnosis being the sudden and early relief of the pain (one to three hours) by the release of gas from the distended caecum. They point out that abnormal caecal mobility, caecal ptosis, ptosis of the hepatic flexure, ptosis of the whole proximal colon, Jackson's pericolic membrane, and the "shot-gun" hepatic flexure have a common symptomatology and that it is usually impossible accurately to distinguish the one from the other by the clinical history alone or by examination without x ray.

M. de Martel has little faith in caeco-plication or in any of the fixation operations. He performs, nine times out of ten, a short-circuiting followed by a greater or lesser colectomy at a later date, but only if the occasion demands it. Section of bands, dissection of veils, and fixations have not given him such good results. As regards operation, a very healthy conservatism is maintained, and he insists on the necessity for a very wide abdominal exposure if any real good is to be done.

The book should make a wide appeal. It is easy to read, it is well arranged, and the few illustrations are very clear.

### TWO BOOKS ON CANCER.

ALTHOUGH the public are well aware of the frequency of cancer, and appear often to have an exaggerated idea of its painfulness, they are not so well informed of the nature of malignant disease as of certain other diseases, such as typhoid, dysentery, or anthrax, which are really rarer. This want of knowledge is often betrayed by the questions asked in conversation, and has lately been reflected by the inaccurate information contained in the correspondence of the press. To remedy this defect Dr. C. E. WALKER has written a popular book entitled *Theories and Problems of Cancer*,<sup>2</sup> in which he presents the modern orthodox views as to the origin and spread of cancer in such a way as to render the information intelligible to the ordinary reader. The book is largely a reproduction of a series of articles written for *Science Progress* in 1912, but in its present form

contains also an account of the advances made in subsequent years, notably the experimental production of cancer in animals. The difficulties of addressing an audience unfamiliar with the technical vocabulary of pathology have been overcome by simple methods of expression, but, thanks to the careful choice of language, the book has not lost in accuracy. Though not by any means easy reading, it could be followed without the assistance of a scientific dictionary by a person of average education. The book correctly represents accepted teaching concerning the development of malignant disease, but is saved from being "dry" by references to the author's own researches which afford a personal touch. After reviewing the many experiments in treatment which have been tried at different times, Dr. Walker states that "the only conclusion to be arrived at is that at the present time the only means available which affords any reasonable chance for the patient is complete removal by a surgical operation." Under surgical treatment he includes also the action of agents such as x rays or radium, which kill the cells of the malignant growth instead of removing them.

Quite another opinion is aggressively advocated by Dr. JOHN SHAW in his recent book *Cancer: Fallacy, Theory, and Fact*.<sup>3</sup> Dr. Shaw has a poor opinion of cancer research, and declares that experiments on animals have led to lamentably fallacious results. Misled, as he thinks, by the teaching of research workers, surgeons have embarked on extensive operations which, he argues, have had the double effect of increasing the mortality from cancer and actively spreading the disease. He holds that cancer is a preventable disease and a curable disease; the former object is to be achieved by obedience to certain hygienic laws, and the latter can be assured by medical treatment. The methods of treatment he most relies on are the application of the constant current, radiant heat, pressure, injections of oxygen, external remedies, and animal extracts, such as that of the thyroid gland. The author defends his conclusions by a detailed account of about forty cases of cancer affecting different organs of the body successfully treated by such tranquil therapeutics.

Thus these two books lead to diametrically opposite conclusions, but were they to fall into the hands only of those readers for whom they were intended there would be no cause for misgiving as to the influence they may exert. Dr. Walker's excellent exposition of the cancer problem is carefully prepared for non-medical readers, and it is to be hoped that it will have a wide circulation. Dr. Shaw's controversial opuscle has for its object the enlightenment of the medical profession, and the restraint of what he has persuaded himself is the barbarous practice of surgeons. We trust it will have a wide circulation amongst them, but, such is the perversity of human nature, we shall probably find the laity will become much better acquainted with the fruit of the tree of knowledge intended for their medical brethren than with that provided for themselves.

### HAEMORRHAGIC JAUNDICE.

THE valuable monograph on the morbid anatomy of spirochaetosis icterohaemorrhagica,<sup>4</sup> by Dr. RENJIRO KANEKO, professor at the medical clinic at the University of Fukuoka, Japan, is the outcome of his wish to make known to European readers investigations which had previously been published mainly in Japanese literature. The book is divided into three parts. The first contains a review of the literature up to the time of the discovery of the *Spirochaeta icterohaemorrhagiae* by Inada and Ino in 1915, when only 30 cases had been described in Europe and 7 in Japan. Apart from icterus and haemorrhages, the chief lesions described by the earlier writers were inflammatory or degenerative changes in the liver and kidneys and enlargement of the spleen. The second part contains an account of Professor Kaneko's own elaborate investigations, which were based on 42 cases, of which a clinical and

<sup>4</sup> Ueber die pathologische Anatomie der Spirochaetosis icterohaemorrhagica Inada (Heidische Krankheit). By Professor Dr. Renjiro Kaneko. Vienna, Leipzig, Munich: Rikola. 1922. (Roy. 8vo, pp. 181; 8 plates.)

anatomical study was made and the diagnosis confirmed by finding the causal organism. The third part is a critical review of the literature which has appeared since the discovery of the *Spirochaeta icterohaemorrhagiae* in February, 1915, and the writer's first article on the morbid anatomy of the disease in the same year.

In addition to the generalized jaundice, numerous small haemorrhages, severe renal disease, and degeneration of the skeletal muscles described by other writers, Professor Kaneko emphasizes the diagnostic importance of the following pathological features: (1) obstruction in the bile capillaries without mechanical obstruction in the large bile ducts; (2) inflammatory and degenerative changes in the heart muscle and in the nerve cells and fibres; (3) certain negative findings, such as the absence of the so-called infective spleen, fatty degeneration, and severe extensive necrosis and suppuration.

The work contains a bibliography, and is illustrated by microphotographs, some of them in colours.

#### ELEMENTS OF TUBERCULOSIS THERAPEUTICS.

THE French volume on the treatment of pulmonary tuberculosis<sup>5</sup> is one of a series of monographs on treatment, written primarily for the general practitioner. With this end in view practically all discussion of the various problems presented by the disease is omitted; the scientific side is completely suppressed, and just a plain, straightforward account of the conduct of a case is provided. As in every book, there are one or two subjects upon which the author lays particular emphasis—subjects making an individual appeal to the author himself. Such subjects are climatology and the treatment of haemoptysis. Practising at Cambo, a pleasant little health resort in the foothills of the Pyrenees, he naturally is impressed with the importance of the different types of atmospheric and environmental conditions in the treatment of his patients, and is, therefore, careful to give a fairly liberal account of the more popular places of resort for tuberculosis patients, and to indicate the type of case for which each is suited. With regard to haemoptysis his main contribution has to do with the different modes of treatment to be applied to the patient, depending on whether the blood pressure is above or below normal. In the latter case the usual remedies are recited—rest, bandaging of the limbs, calcium lactate, posterior lobe of the pituitary, etc.—but in the former case he recommends the intramuscular injection of emetine, which he regards as of the greatest value in lowering the systolic pressure and diminishing the haemorrhage from the lungs. The remainder of the book calls for little comment. A considerable amount of space is devoted to drug treatment and to the use of serums—more than is usual in an English manual. Artificial pneumothorax is dealt with very fully, and the treatment of pulmonary tuberculosis in infancy, old age, pregnancy, and diabetes is carefully considered. To those who care for a simple, clear, somewhat empirical description of the treatment of disease we would recommend this book unhesitatingly.

#### DIATHERMY.

IN a volume entitled *Diathermie et Diathermothérapie*<sup>6</sup> Professor BORDIER has written on the physics, electro-technics, and therapeutics of diathermy. The principles on which high frequency and diathermy currents are generated, the various types of apparatus which produce these currents, the physical and physiological properties of diathermy, are described in the first three parts of the book. The fourth part deals with the various methods of performing the operation of coagulation by diathermy. In the fifth part the tumours and infective granulomata of different regions which may with advantage be treated by diathermic coagulation are considered. The author describes his methods and results and those of other workers. Medical diathermy is considered in a similar way in the

fifth part. Methods of applying diathermy are described, and the author then states, under the headings of the different systems of the body, the diseases for which diathermy is a valuable method of treatment.

The advantages of diathermy for the destruction of malignant growths are well known to many English workers, but Professor Bordier also recommends this form of treatment for other morbid conditions for which, in this country, it has been less widely used. Among these may be mentioned haemorrhoids, lupus (certain forms), rhinophyma, and enlargement of the prostate. Professor Bordier has used diathermy for the cauterization of external and internal haemorrhoids for ten years; his patients were not confined to bed after the operation, and no post-operative accidents are mentioned. He recommends diathermy for the treatment of rhinophyma; the operation, he says, can be performed without loss of blood. For enlargement of the prostate he advises a wider trial of diathermy for the purpose of cauterization of the gland where it narrows the channel, so making a wider outlet for the passage of the urine. He quotes the work of Luys, who has had considerable experience in the method. The patients were treated under local anaesthesia and were not confined to bed after the operation.

In the section on medical diathermy some interesting reports are given of this form of treatment on chronic gastritis accompanied by alteration in the degree of acidity of the contents of the stomach. Test meals were given before and after a course of diathermy and the analyses showed a return to normal; the patients were relieved of their symptoms.

Professor Bordier has evidently had a wide experience of diathermy, and his results will be read with interest by English specialists. He admits that French workers have had less experience in the treatment of malignant growths by diathermy than English laryngologists. He freely quotes the work of English authors, and some of the tables and illustrations in an English work on diathermy are reproduced.

The volume under review contains a large quantity of useful information. It is clearly written and well illustrated.

#### A USEFUL GUIDE.

THE neophyte, fresh from the schools, proud in the possession of full knowledge of the books and of cases carefully selected to demonstrate the exactness of medical science, has many a fall when he bursts his bonds and spreads his wings in the free air of general practice. In this atmosphere one attribute counts more than all others, and that is—experience; and however well he has been taught, and with whatever diligence and zeal he has studied, this the fledgling cannot have.

It is to anticipate for him some of the pitfalls and the gins of general practice that Dr. A. CAMPBELL STARK has compiled a little book which he styles *An Index to General Practice*.<sup>7</sup> In an admirable and all too short preface and introduction Dr. Stark explains that he writes solely from the point of view of a general practitioner, and seeks an apology for the book in "the curious fact that although a large majority of medical students go into general practice, no attempt is made during their curriculum to train them for their special work." He further regrets that "experience of general practice is not an indispensable qualification for election to a hospital staff"; that "writers of textbooks, and others who cater for the needs of the medical profession, have little for the general practitioner, and he is left to work out his own salvation." Probably Dr. Stark would agree that in the working out of his salvation lies the practitioner's true source of strength. No man can be a success in practice without first "going through the mill," and it is good for the young practitioner that the way is hard, for thus his character is moulded, and thus, out of necessity, he acquires those weapons with which his hospital training does not equip him.

There is, nevertheless, every reason for complaining that he is not sufficiently warned of the kind of thing

<sup>5</sup> *Le Traitement de la Tuberculose Pulmonaire en Clientèle*. By C. Colbert. Comment Guérir? Bibliothèque des Praticiens. Paris: A. Maloine et Fils. 1923. (52 by 74, pp. 291; 12 figures. Fr. 10.)

<sup>6</sup> *Diathermie et Diathermothérapie*. By Dr. H. Bordier, Professeur Agrégé à la Faculté de Médecine de Lyon. Paris: J. B. Baillière et Fils. 1922. (Post 8vo, pp. 512; 157 figures. Fr. 30.)

<sup>7</sup> *An Index to General Practice*. By A. Campbell Stark, M.B. and B.S.Lond., L.S.A.Eng., Ph.C. London: Baillière, Tindall, and Cox. 1923. (Cr. 8vo, pp. x + 181. 5s. net.)

MR. J. ALBAN ANDREWS, M.C., F.R.C.S. (Resident Surgical Officer, St. Peter's Hospital for Stone), has had made for him by Mr. J. H. Montagu (69, New Bond Street, W.1) a box to carry apparatus for ureteral catheterization and pyelography in compact form, and sterilized for immediate use. The advantage claimed for it is that, apart from its portability, the contents are available with a minimum of handling when it is required to pass a ureteral catheter or introduce a pyelographic medium. The box is of the flat oval pattern introduced by Mr. Swift Joly for holding ureteral catheters. In the lid is a series of six clips, arranged round the margin, for holding spare ureteral catheters, and one or two phospho-bronze stiletts useful in clearing a blocked catheter; in addition, two clips in the centre hold a pair of forceps for manipulating the catheters, etc. In the base, fixed round the margin, is a series of eight racks, with a hinged clip attached to each; by means of these racks four ureteral catheters can be coiled within the box, each lying in a separate compartment of a given rack. A triangular container, with perforated sides, and a detachable wire-mesh lid holding cotton-wool soaked in a strong solution of formalin, is so placed that when the four catheters are in position their proximal ends can be fitted to four fixed, tapered, hollow needles projecting from its base. Formalin vapour passes from the container, by way of these needles, into the lumen of the catheters; this is accelerated by warming the closed box; in this way the inner and outer surfaces of the catheters are both exposed to the action of the vapour. To ensure efficient sterilization care must be taken that the lumen of each catheter is quite clear, and that the exposure to the vapour is made for not less than twelve hours. Within the racks is a central oval space fitted with clips holding a 10 c.cm. all-glass syringe, a 5 c.cm. Record syringe, four single needles fitting both the 5 c.cm. and 10 c.cm. syringes, and three double needles. A catheter can be readily extracted, without disturbing those adjacent, by detaching its proximal ends from the fixed tapered needle with the forceps, and then withdrawing it smoothly from the racks.

# NINETY-FIRST ANNUAL MEETING of the British Medical Association, PORTSMOUTH, 1923.

## OLD PORTSMOUTH AND PORTSEA.\*

"Strange enchantments of the past  
And memories of the days of old."

PORTSMOUTH is not all harbour and dockyard. If visitors to the Annual Meeting have a few minutes to spare after their attendance at the scientific Sections, and if the festivities of Southsea do not prove too alluring, or the Trades Exhibition at the Naval Barracks too attractive, there are a few relics of the drowsy past worth seeking out in old Portsmouth and Portsea. It will be interesting to wander for a space in the streets and places where Byng, Vernon, Anson, Hawke, Kempenfelt, Rodney, Keppel, Howe, Nelson, and scores of other famous officers were wont to walk and work and play. We may perhaps be able to recall to our memories forgotten facts, and repicture the places we see with the doings of the good old days. What yarns we might hear from the old "Blue Posts," the "Star and Garter," and the "George" could their walls but speak; what might not High Street, Broad Street, and Point tell us! Boys as midshipmites came quite young and fresh to Portsmouth; like Peter Simple, they stayed at the "Blue Posts," and then for the rest of their careers would be frequent visitors. As they climbed the service ladder the "Blue Posts" would be forsaken for the "Parade Coffee House," and finally the "Crown" and the "George" would be their temporary resting places. Their sojourns in old Portsmouth would be full of fun and adventure. Even young Nelson wrote:

"Yesterday I was riding a blackguard horse that ran away with me at Common (Portsea), carried me round all the works into Portsmouth by the London Gates, through the town and out at the gate that leads to Common, where there was a waggon in the road, which is so very narrow that a horse could barely pass. To save my leg and perhaps my life I was obliged to throw myself from the horse, which I did with great agility, but unluckily upon hard stones, which have hurt my legs and back, but done no other mischief. It was a thousand to one I had not been killed."

Little of old Portsmouth is left, and to find it the visitor must penetrate behind the modern frontages into some of the back streets, grubby and picturesque, but no longer the highways they used to be. Here and there he will find an old house—even a partly wooden house or two. The oldest portions of the town are or were at Point, on either side of Broad Street and around the Camber. There, in narrow and twisting lanes, old houses may be found with sixteenth and seventeenth century dates carved on their beams, mostly built of red brick and roofed with red tiles, here and there shingle fronted or more rarely half timbered. But the modern medical officer of health and the sanitary authorities have been at work, and have cleared away the old and antique that was pleasant to look on but dangerous and unhealthy to live in. Perhaps the oldest street of all is (or was, for now most of it is cleared away) East Street, running from Broad Street to the

Camber, and the oldest public house, the "Shoveller's Arms," is still here, and was kept not many years ago by a family whose predecessors were there in the days of Nelson.

The neighbourhood of Point, which was outside the old town wall, has always been notorious. It was called Spice Island, but for what reason no one knows. The Camber remains the commercial harbour of Portsmouth, but there is nothing at the dockside indicative of prosperity. Portsmouth is naval first—everything gives place to the requirements of the navy—and commerce goes elsewhere. Here by the Quay is an old red brick building that once held all the food stores for the navy! In it was the biscuit bakery which was once visited by George III. A story is told that he set the fashion of munching biscuits in the streets, for he was observed eating a specimen in the roadway after visiting the naval bakehouse. After the Crimean War the old Cavalry Barracks at Gosport were taken over and converted into the present Victualling Yard.

From Point starts the floating bridge that connects Portsmouth with Gosport. From "the Bridge" when crossing a fine view of the harbour and dockyard is obtained. Haslar Hospital is also seen, and Haslar Creek, the home of the submarines. Many yachts and all kinds of naval craft may be seen at anchor or moving about the waters. Alas! the old *Triton*, that once rode so proudly in midstream, is now in dry dock undergoing repair. Here in the Royal Dockyard she may be visited, and for many long years may she remain the cynosure of the navy.

Right at the very end of Broad Street, opposite the ferry landing stage, is the "Star and Garter" hotel, which is perhaps the most interesting of all Portsmouth's inns.

It has more historic associations than any other of the old houses. Here the very room and the bed is shown in which in their time have slept Howe, St. Vincent, Nelson, and Franklin. It is related that Lady Franklin, after the great arctic explorer had been given up for lost, used to come here year after year on a sacred pilgrimage. In the common room or naval snuggery one can in imagination picture the old seamen recounting their yarns and telling how things should have been done had they had their way. William IV, when Duke of Clarence, regularly occupied a room here from the window of which is obtained a fine view of the harbour with its varying interests. Louis Philippe, when an exile, was here a great deal. Dickens and Thackeray were frequent visitors. It is of interest to note that the third of the trinity of novelists, Sir Walter Scott, also visited Portsmouth in 1831. The deeds of the house date back to the time of Queen Mary, and the landlord still pays capon money to the corporation.

About half-way between the above house and the High Street is the site of the "Two Blue Posts," built in 1613, and once the chief posting house in the borough. The old house was destroyed by fire on May 7th, 1670. A new house has been built here since. The "Two Blue Posts" is frequently alluded to in Marryat's novels. It is recorded

FIG. 1.—The Round Tower.

\* Previous articles on Portsmouth and Southsea and neighbourhood have appeared in the BRITISH MEDICAL JOURNAL of December 9th, 1922, p. 1137; January 13th, 1923, p. 77; February 10th, 1923, p. 253; June 2nd, 1923,

that on one of the old window panes was scratched the following inscription:

"This is the Blue Postesses  
Where midshipmen leave their chestesses  
Call for tea and toastesses  
And forget to pay for their breakfastesses."

In the old days there was a large porch over the front door supported on two big columns which were painted a bright blue colour.

On the opposite side of the road is a narrow opening called Bathing Lane, leading to a spot now known as Bath Square, interesting for its connexion with sea bathing. The fashion of going to the seaside for holidays set in about the middle of the eighteenth century. Sea bathing, although not unknown before, was made popular by the propaganda of a certain Dr. Richard Russell in 1753, with the result that many people, as the old rhymester says—

"Rushed seaward to be cur'd like  
tongues  
By dipping into brine."

Portsmouth, not to be left behind in the fashion, provided visitors "facilities for washing" in Bathing House Square. Not far from here the Hot Walls, in front of the "Saluting Battery," was a famous place for bathing and playing for many generations of old Portsmouthians.

A little further east a reading room and pump room, with conveniences for bathing, was established in 1816 near the site of the Clarence Pier. This has gone, as well as the old-fashioned horse machines with a big hood over the scaward door, and the hoop-skirted "nymphs" who ducked children willy-nilly beneath the salt sea waves. Now there are corporation chalets and tents on the beach, and the Swimming Club, between the Clarence Pier and the Castle, has a good diving board; another is in use at the popular bathing site to the east of Southsea pier.

Proceeding from Bath Square to the Round Tower we shall find between the tower and Broad Street a railed-off space called Capstan Square. Here stood the apparatus for "taughtening the mightie chaine of yron" used in war time, from the days of Henry VIII till 1813, for the defence of the harbour mouth. At low tides some of the links of the chain may be seen in the shingle. The Round Tower was built early in the fifteenth century, as well as a similar one on the opposite side of the harbour mouth. Cannon were then coming into general use, and were placed on these platforms to defend the harbour. Near here, running from Broad Street, is a twisting passage that leads to the Sally Port; in the old days it was the spot for taking boat to Spithead; in Mr. Gow's picture in the Royal Exchange Nelson is represented as embarking from this spot. Access to the sea is now obtained from the King's Stairs, nearer Southsea, close to the old Victoria Pier. The Square Tower, which is here on the conspicuous, was once the garrison magazine. It has on its land face a bust of Charles I, set up to commemorate his safe return from his travels in search of a wife. When

Lord Viscount Wimbeldon was governor of Portsmouth he issued an order that all persons were to doff their hats to the King's image—an order the inhabitants treated with scorn and derision.

We are now at the bottom of High Street. Before exploring it we will go back to some of the grubby streets. But first, looking up the High Street on our left hand, we shall see two plaques on adjacent houses—one on the house of Admiral Anson and one on the birthplace of George Meredith. On the right-hand side, at the corner of Grand Parade, is the York and Pier Hotel—the old Parade Coffee House. The Coffee House was patronized by the captains of the old navy. Here in red breeches, three-cornered hats, and pigtails they sat on benches outside the house smoking their long nines. Here in 1729 they had an "early club" which met at 4 a.m.

Fig. 2.—Sally Port.

till he was fourteen and was then sent to Germany to complete his education. Not much is known of his early life. He is said to have threatened to haunt anyone who attempted to write his biography. There is a reference to Portsmouth in *Erra Harrington*.

In Oyster Street, the favourite resort of the Guernsey onion men when they visit Portsmouth, there is a small disused chapel, now utilized by the foreign egg business, in which John Wesley often preached, and on the opposite side of the way is the house in which he lodged. Another chapel in which Wesley used to preach stands at the corner of Warblington Street and Nobbs Lane. John Wesley came to Portsmouth in July, 1753. He records in his journal of the crowds that thronged to hear him—

"So civil a people I never saw before in any seaport town in England. I preached in an open part of the Common adjoining the new chapel of St. George's. The congregation was large and well behaved, not one scoffer did I see, nor one trifler."

Now we turn out of the narrow street into the broader and more picturesque Street of Saint Thomas, which is just a quarter of a mile long. In it are one or two sixteenth century houses known as "garrison houses." These were built low so that they should not overtop the fortifications or interfere with the sighting of the guns. No. 78 will interest lovers of Dickens. Here Mr. Vincent Crummles had his quarters. "Mr. Crummles lived (on mutton and onion sauce) at the house of one Bulph, a pilot, who sported a boat-green door with brass knocker, brass plate, and

Fig. 3.—John Pound's House, Highbury Street.

brass handle." At the upper end of the street is a Baptist chapel which claims to be the oldest Nonconformist place of worship in Portsmouth. John Sicklemore preached here in 1642. Near it is Palliser House, noted for its connexion with the trial of Admiral Keppel. The house has a round bay supported on columns. Another house is plaqued, "In 1801 Sir Frederick Madden was born here."

Running across St. Thomas's Street is Highbury Street. From 1214 till quite recently it was called St. Mary's Street. On the north side of this street is a fine house, No. 8, now called Curzon House, with a plaque on its front; here lived Admiral Lord Howe, the victor of the Glorious First of June, 1794. On the south side of the street No. 78 is a little wooden house with a tiny workshop. This is the house of John Pounds, the founder of ragged schools.

Pounds was born in 1766 and was apprenticed as a shipwright in the Dockyard. Here he met with an accident which crippled him for life. He then took to cobbling and worked and lived in this little house. His brother had a deformed son whom John took great care of, and no doubt the devotion he lavished on his unfortunate nephew initiated in him the care and pity he lavished on the uncared for youngsters that ran and played about the narrow lanes and alleys round his shop. Whilst toiling in his little shop he found time to teach them the rudiments of the three R's. Too poor to buy books for his unkempt scholars, he picked advertisement bills from the walls and with scraps of newspapers made them into primers. He was very fond of birds, and often expressed the wish that he might die like one—just drop off his perch. His wish was gratified. He died suddenly on January 1st, 1839, aged 72 years. He called at the house of Mr. Edward Carter in High Street and dropped dead whilst waiting in the hall. A monument to his honour is erected in the burial ground of the Unitarian chapel in High Street.

(To be concluded.)

## Nova et Vetera.

### AIX EN SAVOIE.

It seems as though a spring gushing out of the earth has a fascination for even the most primitive peoples, who are apt to attribute its presence to mysterious agencies and to credit its waters with special virtues, even when they do not contain medicinal solids in solution in quantities enough to produce striking effects on the human body. When in addition the spring is hot it is likely to be still more renowned, for a copious supply of hot water obtainable without any effort or expense must have been an inestimable boon during the long ages before "Bath h. & c." became a household term. The Romans, who had long acquired the art and the means of heating large quantities of water, nevertheless seized eagerly on hot springs wherever they found them and used them for the supply of their public baths. At Bath, at Aix, at Baden, and elsewhere the remains of *Thermae* testify to the estimation in which such springs were held, and the ruins are evidence of the elaborate constructions of which they were the occasion.

Whatever may be the real therapeutic value of "the waters," their presence has always attracted the sick, and the flow of visitors to them may be compared to the religious pilgrimages, which even yet survive, some presenting the double attraction of the Saint and of his or her holy well.

The well known springs of Aix in Savoy are no exception to the rule, and M. Gabriel Perouse has done well in his book on the old days of Aix-les-Bains to tell the story of the rise and vicissitudes of this famous watering place.<sup>1</sup> He has found evidence that the Gauls or Allobroges had made use of the hot springs before the Romans came upon the scene, and the foundations of the massive constructions of the latter leave no doubt as to the importance of this bathing place. Apparently the natural heat of the waters was insufficient, for extensive remains of a hypocaust have been laid bare. Besides these the so-called Arch of Campanus, which seems to have formed part of a family mausoleum, is still standing. At Aix, as elsewhere, Roman ruins served

as convenient quarries from whence to take materials for new buildings, but when and how the Roman baths were destroyed, whether suddenly or gradually from neglect, is not known, and the earliest extant written record of the springs dates from the fourteenth century. Only one ancient basin or pool now remains, which was afterwards known as the Royal Bath.

Faith in the value of the waters and desire of cure must have been strong, for down to a period so late as the eighteenth century the amenities of Aix were but slight. Bathers were carried to and from the *douche* in litters or Sedan chairs, there was little privacy, and the surroundings of the *douches* were filthy. Small wonder then if some bathers had the water brought to their rooms. Moreover, in the sixteenth century there seems to have been nothing to do in the little town in the intervals between baths, although those who were active enough could explore the picturesque environs and take boat on Lake Bourget. But the roads were execrable, and "carriage exercise" could not have been pleasant. Nevertheless, aristocratic and royal personages of both sexes patronized the waters during the fourteenth and subsequent centuries.

Early in the seventeenth century Dr. Jean-Baptiste de Cabijs wrote *Les Merveilles des bains d'Aix en Savoye*. When you set out for Aix, he says, "you must leave all melancholy behind," which is easier said than done. On arrival, of course, in that age and country of clysters and purgatives, purgation is advised. His advice on diet is sensible, but the modern valetudinarian would be horrified to learn that he must get up at four in the morning (seemingly after going to bed at nine) and bathe between five and six o'clock, so as to leave the bath clear for the ladies. Above all the bather must not leave Aix before he has had a final purgation. As to lodging, it seems to have been a common custom for a number of visitors to share a room and often for two of them to share a bed.

By the middle of the eighteenth century things were better at Aix, but even then in the best inn there was only one room to serve as dining-room and sitting-room; even in that there were two beds in the corner, but as they were four-posters, with curtains, they afforded some degree of privacy. However, the majority of bathers and the most distinguished took lodgings in private houses, where their hosts were some of the most respectable residents of the town. A great step forward was taken in 1783, when the reigning Duke of Savoy authorized the erection of the first modest "Etablissement" at the sulphur spring; nevertheless, down to and after the end of the century Aix remained a small walled city of narrow lanes and thatched houses, subject to repeated conflagrations. Narrow as the streets were, they were rendered still more inconvenient by the habit of keeping small dunghills before the house doors; this practice seems to have been dear to many of the inhabitants and was the subject of often vain denunciation by the authorities. Nowadays the picturesque but stinking town has vanished and most of its site is covered by the great modern bathing establishment.

All this and more may be read with pleasure in M. Perouse's book, which tells not only of the place, but of its distinguished visitors, from the eccentric J. C. Roberts—eccentric because he actually stayed a whole year in 1789/90—to the Empress Marie-Louise and Queen Hortense and her sons, of whom one, as Napoleon III, was later to annex Savoy to France. The husbands of both these ladies were then deposed and the Queen was in course of being divorced, but M. de Flahaut and the Count Neipperg, who accompanied them, were doubtless able to console them. There is a chapter on Lamartine, who with his English wife frequented Aix, and notes on the visits of Alexandre Dumas and of Balzac, who there placed one of the scenes of his *La Peau de Chagrin*.

Thus for at least 400 years, no matter who were its rulers, Dukes of Savoy and Kings of Sardinia, France, or Spain, the waters have not lost their vogue, and the treatment given at the Etablissement benefits countless invalids, even if it has to be admitted that the water of the Bain d'Alun contains no alum and that the sulphur spring is almost if not quite innocent of brimstone.

<sup>1</sup> *La Vie d'autrefois à Aix-les-Bains*. Par Gabriel Perouse, Chambéry: Librairie Dardel. 1922. (5½ in. by 7½ in., pp. 348; 15 plates.)

# British Medical Journal.

SATURDAY, JUNE 30TH, 1923.

## HONOUR TO RONALD ROSS.

SIR RONALD ROSS's medical colleagues throughout the world will rejoice to learn that a movement is afoot to signalize the twenty-fifth anniversary of his successful transmission of malaria to the anopheline mosquito by some public recognition of the incalculable service he has rendered to the Empire and to millions living under its protection.

In a letter in the *Times* of June 22nd, signed by some of the leading men of affairs of this country, a noble tribute is paid to the world-wide importance of the knowledge acquired through Ross's patient and exacting labours and of the material benefits which have accrued therefrom to mankind. It is proposed to establish in London some permanent memorial to his achievement as a token of public gratitude while he is still with us. We believe that the appeal will meet with sympathetic and widespread support. It is one which cannot be overlooked by those whose financial interests are centred in the tropics. The suggestion is put forward that the occasion provides a fitting opportunity to establish a "Ronald Ross Clinic" for tropical diseases, in which laboratory research and clinical investigation should be combined as closely as possible. With the same ideal, clinical units for medicine, surgery, and gynaecology have recently been established at the leading London medical schools, and as His Majesty said recently, when laying the foundation stones of the new buildings at the University College Medical School, these have justified the high hopes with which they were founded in 1919.

We feel confident that the establishment of a similar unit or clinic in tropical diseases, with Sir Ronald Ross at its head, would fulfil a national purpose and give a powerful stimulus to the study of tropical medicine and parasitology, for which London has already become a centre. The clinic must have the fullest scope for the initiation and continuity of its researches, but if it is to serve more than an ephemeral purpose it must take its proper place with other institutes devoted to post-graduate study and research under the aegis of the University. It is stated that its primary object will be research, not teaching, but there must be provision for training others in research, since the permanent usefulness of the memorial is the avowed aim of the founders.

The relationship of the clinic to other bodies similarly engaged, as well as the best means of securing access to an adequate and constant supply of clinical material, will require the most careful consideration. In giving two million dollars for the building and equipment of a great School of Imperial Hygiene the Rockefeller Foundation was undoubtedly inspired by the desire to integrate the post-graduate work in preventive medicine in London, and this institute too must have its clinical laboratory for tropical diseases and be linked with the clinical wards of some accessible hospital.

Hitherto, apart from special military provision arising out of the war, the care of those suffering from tropical diseases has been undertaken in London by the corporation of the Seamen's Hospital Society. In its

hospitals at the Albert Dock and in Endsleigh Gardens over a hundred beds are provided for these maladies, and this total would appear to be adequate for present needs if fully endowed and utilized. The Seamen's Hospital Society has, in the past, notably helped the cause of education in London by opening its hospitals for post-graduate clinical instruction. Its interest in the promotion of research is shown by the way in which it has provided, in the premises partly occupied by the Hospital for Tropical Diseases at Endsleigh Gardens, accommodation for the London School of Tropical Medicine, the Tropical Diseases Library, the Tropical Diseases Bureau (Colonial Office), and the Research Institute for Agricultural Helminthology (Ministry of Agriculture). We believe that the greatest possible benefit to humanity would follow the further strengthening of this fine centre of scientific activities by the association of the proposed unit with it and eventually of both with the School of Hygiene. By this plan there would be no depletion of funds for unnecessary buildings, and, while the unit would remain separate from the London School of Tropical Medicine, much duplication could be avoided by team work between the unit and the research departments of the school.

In any case, the position which the London School of Tropical Medicine has won for itself in London, since its foundation twenty-four years ago by Sir Patrick Manson, and the support which it enjoys from the people of the metropolis, cannot be ignored. The statement in the *Times* letter that, like its sister in Liverpool, the school is engaged for the most part in training young doctors for practice in the tropics, shows that the significance of the unique organization of its staff and curriculum has not been fully appreciated. The curriculum is so arranged that while the clinical instruction is given by visiting lecturers, chosen for their practical experience in the tropics, the studies in the laboratory are in the charge of whole-time professors—not one of whom, however, is occupied in this teaching for more than three periods of twenty consecutive days in the year. During the intervening time the professors, with their staffs, are engaged wholly in research and are free, when need arises, to visit the tropics for their investigations. During the past three years eight of these whole-time workers have been sent abroad by the school, two are still in the field, and two more are preparing to leave.

The relation of the proposed memorial to the clinical material now available in London, to the projected School of Hygiene, and to the research activities of the London School of Tropical Medicine are matters, we feel sure, which will invite, not in vain, the immediate attention of Mr. Asquith and the distinguished men associated with him in the laudable endeavour to honour Sir Ronald Ross.

## WINDWARD ISLANDS MEDICAL SERVICE.

FROM time to time during the last two years we have had occasion to advise intending applicants for posts in the medical services of certain West Indian colonies to consider carefully the disadvantages and disabilities attendant upon the choice of that particular field of practice. We have done so in the belief that conditions so bad must surely find a remedy. It was reasonable to hope that when the inquiry urged centrally and locally by the British Medical Association had been completed the officers in those services would secure speedy and adequate redress of their grievances. The report of the Wind-

ward Islands Medical Committee, together with the recommendations of the Governor and the final ruling of the Secretary of State for the Colonies thereon, have now been communicated to the Dominions Committee of the Association, and it is clear that our confidence has been misplaced.

The recommendations of the Islands Committee failed to meet the case put forward by the British Medical Association in the first instance, for they allowed net commencing emoluments from all sources to fall short of £600 a year—the lowest sum recognized by the Association as adequate for colonial appointments. They also left untouched other local grievances. The settlement advocated by the Governor and sanctioned by the Secretary of State is worse still. Its distinguishing feature is that the medical officer in Grenada, with a consolidated salary on appointment of £400, supplemented by some £50, the net proceeds of private practice, is left to find out of his own pocket the difference between £70 forage allowance and the allowance of £120 to £180 estimated by the Islands Committee as meeting the cost of necessary expenditure on motor car or car and horse. The medical officer has to supply as well as run his car. In short, the Government of the Windward Isles, driven by economic pressure, has decided to perpetuate a state of affairs which, in our considered opinion, denies to members of its medical service conditions essential at once to the efficient exercise of their profession and to adequate provision for their dependants.

We are convinced that no practitioner fully conversant with existing conditions will apply for an appointment in the Windward Isles. This conviction alone would be sufficient justification for explaining more fully than is possible within the limits of the present article the position which has arisen, and we propose to deal with the matter in detail in future issues. In doing so we shall not forget the plight of those who, having served faithfully and with no small distinction in those islands, now see their last hope of relief vanish, and are left no alternative but to begin life afresh elsewhere, or to accept as final, conditions only tolerable whilst hope of immediate redress remained. To them we would say that if the tragedy of the Windward Islands medical services is a sorry chapter in the history of British medicine, it is one for which the profession itself has no responsibility.

#### BRITISH EMPIRE CANCER CAMPAIGN.

We are informed that the Royal Society and the Medical Research Council have agreed jointly to receive delegates from the British Empire Cancer Campaign to discuss the formation of a scientific committee for the distribution of money subscribed to the campaign for research purposes and the revision of the articles of association of the campaign which may be necessary to give effective powers to the committee. Representatives of the Imperial Cancer Research Fund will be present at this conference. The first meeting of the Grand Council of the British Empire Cancer Campaign was held at the headquarters of the British Red Cross Society, London, on June 25th. The Grand Council consists of seven representatives nominated by the Imperial Cancer Research Fund, seven by the Cancer Hospital, Brompton, seven by the Middlesex Hospital, three by St. Mark's Hospital, London, and several other members who have agreed to serve. The Earl of Athlone was elected chairman of the Council. A discussion took place on the constitution of the campaign, in which the representatives of the Imperial Cancer Research Fund, the

Middlesex Hospital Cancer Charity, and the Cancer Hospital pointed out the desirability, in the public interest no less than in the interests of research, of making the executive committee more representative. It was evident that these bodies viewed with some concern the articles of association of the limited liability company which the promoters had formed, and which, it was alleged, had not been disclosed to them in negotiations for their support. A small subcommittee of the Grand Council was elected to investigate these articles and to see what changes in them, if any, were desirable in order to secure the co-operation of all parties interested. It would thus seem that the Grand Council, which consists of elected representatives, means to make itself responsible for the policy to be adopted, and not merely to exist as a subsidiary body which the executive committee, provided in the articles of association as they now exist, might consult occasionally. As it has been declared that the present executive committee regards itself as provisional, and that its members are willing to give place to others who may be considered more suitable, and as the Royal Society and the Medical Research Council have agreed to discuss the position, it seems possible that an executive body representative of research may be formed. We feel sure that such a decision would meet hesitations we felt obliged to express when the campaign appeal was issued, and would receive general approval. A meeting will be held at the Mansion House on July 6th to inaugurate the campaign.

#### THE MANUFACTURE AND DISTRIBUTION OF INSULIN IN SCANDINAVIA.

THE Scandinavian countries, though politically independent, have a happy way of acting in unison in medical matters, and the manner in which the problem of insulin manufacture and treatment is being tackled by Professor August Krogh of Copenhagen affords a good illustration.<sup>1</sup> In November last Professor Krogh went to Toronto and arranged with the university authorities there for an adequate supply of insulin for the Scandinavian countries. The problem with which he was confronted was not quite simple. Remedies cannot be patented in Norway, Sweden, and Denmark, and it is thus open to any manufacturer to attempt to produce insulin and place it on the market. This procedure would, of course, be open to serious objections, and Professor Krogh has made arrangements with the Toronto authorities according to which no preparation can be sold as insulin in Scandinavia unless it has received Professor Krogh's approbation. He has approached Mr. Kongsted, the proprietor of Löven's Kemiske Fabrik, who has undertaken to manufacture insulin and to make no profit out of its sale in the Scandinavian countries. The laboratory in which insulin is to be made will be conducted as an independent institution, and the financial results will be published yearly. Only the direct costs of the manufacture, control, and distribution of insulin will be considered in fixing its price, and after the capital sum invested in the institution has been paid off—at, it is hoped, a comparatively early date—the proceeds of the sale of insulin will be devoted to further research and to the purchase of new plant. The charge provisionally fixed for every Toronto unit is 20 Danish öre, but this will be modified if and when circumstances warrant. Six clinical research workers in Norway, Sweden, and Denmark have accepted Professor Krogh's offer of a quantity of insulin, enough for one or more patients, and it is hoped that a supply may soon be available for Scandinavian hospitals; not till some time later will insulin be issued to general practitioners and their patients. This policy is adopted not only with a view to conserving the limited supply of insulin, but also on account of the dangers and difficulties

<sup>1</sup> *Ugeskrift for Læger*, May 21st, 1923.

associated with its administration. In this connexion Professor Krogh urges all who wish to administer insulin to their patients to familiarize themselves with the technique of blood sugar estimations, and the method he recommends as the most simple, rapid, and accurate is that described by Dr. H. C. Hagedorn and Dr. N. Jensen.<sup>2</sup> Professor Krogh has had to abandon, at least for the time, his project of preparing insulin from fish, and he has secured a supply of pancreases from the Danish swine abattoirs.

#### VACCINE TREATMENT OF TUBERCULOSIS BY A NEW METHOD.

WE gave last week a full account (pp. 1065 and 1059) of the researches conducted by Professor Dreyer at Oxford, which have resulted in the preparation of a new form of vaccine; they have naturally attracted a great deal of attention and we are informed that the Medical Research Council has received many inquiries. Professor Dreyer has so far given most attention to the production of the vaccine for tuberculosis in its various forms, but the principle applies also to some other infectious diseases. In reply to the inquiries mentioned the Medical Research Council has issued the following statement: "When it had been shown by experiment that small animals, highly susceptible to tuberculosis, when infected with tubercle bacilli were improved or lost the signs of active disease after the use of Professor Dreyer's new antigen or vaccine, arrangements were made for trials of this treatment under suitable control at three hospitals in London. The results which have been obtained hitherto have been favourable almost without exception. Upon the results, highly promising as they now seem to be, which have been obtained in cases of tuberculosis of the lungs or of other internal organs, no final opinion can be passed until a longer period has elapsed. In cases of tuberculous disease of the glands and of the skin it can be said already that the results of this treatment have surpassed any known to have been attained regularly by other methods. Encouraging results have also been gained in the treatment of infections like those in puerperal fever and other septic conditions. There is good ground therefore for hope that a very important advance in the curative treatment of tuberculosis and of some other diseases has been made. Until these laboratory and hospital results had been achieved, publication of Professor Dreyer's method was withheld. The Medical Research Council are now arranging, in consultation with Professor Dreyer, for extensive trials of the new treatment by physicians and surgeons at various centres in different parts of the country where suitable facilities can be provided. Much has still to be learned of the best modes of application of the treatment, and it is not ready yet for general use. For the series of trials now in view supplies of the new vaccine will be prepared for distribution at the Oxford School of Pathology, from which for some years standard diagnostic serums for typhoid, paratyphoid and dysenteric infections have been distributed after preparation on behalf of the Medical Research Council. As soon as the progress of the patients under treatment has been sufficiently watched and recorded, full publication will be made of the clinical results which have been obtained. If these justify the hopes which have been formed, and lead to a wide use of the new treatment, it is believed that, by arrangements which have already been made by the Medical Research Council, adequately large supplies of the necessary antigen will be ready at very small cost. Investigations are already in progress to ascertain what useful extensions can be made of the new method of antigen preparation and of its applications to the prevention or treatment of infective disease."

#### LAËNNEC.

THE Medical Classics Series edited by Dr. Charles Singer is designed to give extracts from the works of the men who have made great advances in the science and art of medicine. Each volume is to be accompanied by a short life and notes; the plan thus differs from the purely biographical plan of the Master of Medicine Series edited by the late Charles Louis Taylor, the gifted Assistant Editor of this JOURNAL. The first two volumes of the new series were devoted to Lord Lister and Sydenham, and are appropriately followed by one on Laënnec. It contains a translation of selected passages from the first edition of *De l'Auscultation médiate*,<sup>1</sup> which saw the light on August 15th, 1819. The life is short but of absorbing interest, and in its course Sir William Hale-White admirably brings out the extraordinary energy and ability of a man labouring under great difficulties, particularly the advances of the disease, chronic pulmonary tuberculosis, which he did so much to elucidate. Primarily a notable morbid anatomist, Laënnec, by a fortunate flash of his quick brain, struck out the idea of the stethoscope, and in little more than three years his epoch-making treatise appeared. That in so short a time the numerous râles, abnormal sounds, and cardiac murmurs audible in the chest should be described, classified, and correlated with morbid changes is a surprising triumph of industry directed by genius; added to this its lucid and accurate style ensures that it will always remain a classic. As Sir William Hale-White remarks, Laënnec was one of the founders of the clinical method of studying disease in relation to morbid anatomy, which, although other methods have since been elaborated, still remains the corner-stone of medicine. At first Laënnec did not consider it necessary to have a name for what he modestly spoke of as "so simple an instrument," but as others thought differently and used words sometimes barbarous and always unsuitable, such as sonometra, pectorilogue, pectoriloquie, thoracilogue, and cornet médical, he decided that, if it must be given a name, the most suitable would be stethoscope. Soon after the first edition of his book appeared the state of his health obliged him to leave Paris for Brittany, where he stayed for two years; the progress of his tuberculosis was thus stayed in some degree, and in 1821 he returned to Paris. During the next four and a half years he accomplished an almost incredible amount of work, but unfortunately was no exception to the rule that pioneers meet with opposition. In those days opposition was less mealy-mouthed than now; from the dogmatic and dominating Broussais abuse and ridicule were his portion, and his rapid success and wide reputation excited contemporary jealousy. In 1824, when 43 years of age, his marriage brought him great happiness and an optimistic view of his health. Two years later, when correcting the proofs of the second edition of his great book, he realized that he was dying, and soon after left Paris for the last time for Ploaré in Brittany, where the end came on August 13th, 1826.

#### BIOMETRICAL STUDIES IN TUBERCULOSIS.

It is sometimes difficult to understand how a patient with the grave changes found at necropsy has managed to live so long; how, in other words, damage to vital organs has been compensated so that an at any rate fairly successful new functional balance of interdependent parts or organs has been effected. Dr. Raymond Pearl, of the Statistical Department of the Johns Hopkins Hospital, is applying the methods of bio-statistics to the elucidation of these adaptive regulatory powers of the organism. In the first

<sup>1</sup> *Translation of Selected Passages from De l'Auscultation médiate (First Edition) by R. Théophile H. Laënnec. With a Biography by Sir William Hale-White, K.B.E., M.D. Medical Classics Series. Edited by Charles Singer, M.D., D.Litt., Oxon. London: John Bale, Sons and Danielsson, Ltd. 1923. (Crown 8vo, pp. x + 193; 10 illustrations. 12s. 6d. net.)*

of these Biometrical Studies in Pathology,<sup>1</sup> written with Miss A. L. Bacon—on the quantitative relations of certain viscera in tuberculosis—it is assumed that the relation between the weights of any two organs reflects in some degree and manner, in a statistical sense, the functional balance existing at the time between the particular organs considered, and also reflects in its duly proportional degree the functional balance of all parts of the body taken as a whole. The aim of these investigations is to discover and describe the type and variation of the weight relations of certain important organs of the body under various normal and morbid conditions; for example, an attempt will be made to find solutions to questions such as the following: Is the ratio of liver weight to heart weight, on the average, different, and if so by how much and with what degree of variation, in a group of persons found after death to show as the primary morbid lesion pulmonary tuberculosis, from what it is in a group showing endocarditis as the primary disease? The investigation into the quantitative relations of certain viscera in tuberculosis was based on the records of 3,848 necropsies at the Johns Hopkins Hospital, of which 1,341, or approximately 35 per cent., showed tuberculous lesions of some sort, 825 being active and 516 inactive. The cases were divided into groups of whites (male and female), coloured (male and female), and then further subdivisions were made according to the character of the tuberculous change—active, pulmonary alone, pulmonary and other, glandular alone, glandular and other, and generalized tuberculosis; inactive tuberculosis. The next step was to calculate for each case six organ-weight indices, such as liver to heart, and heart to spleen. The general result is that five of the six organ-weight indices gave very different values in the case of persons dying of tuberculosis only as compared with those dying with some tuberculosis but also with other grave lesions. The question is discussed whether persons with tuberculosis only have relatively small hearts and large spleens because they had fatal tuberculosis, or whether they had fatal tuberculosis in part at least because they congenitally had relatively small hearts and large spleens. Pearl's general statistical studies of tuberculosis indicate that it acts in many ways like an organic rather than as a simple infective disease, such as typhoid fever; and in this research the evidence is in favour of the view that fatal tuberculosis lowers the absolute weight of the heart and increases that of the spleen.

#### THE MEDAL OF THE WEST LONDON MEDICO-CHIRURGICAL SOCIETY.

The annual dinner of the West London Medico-Chirurgical Society was held at the Café Monico on June 19th, with the President, Dr. Alfred George Wells, in the chair. There was a large attendance of members and guests and a considerable toast list had been drawn up. The loyal toasts were followed by that of the Imperial Forces, proposed by Dr. J. Burnford and responded to by Surgeon Vice-Admiral Sir Robert Hill, Medical Director-General, R.N., Brevet Colonel J. W. West, R.A.M.C., and Air Commodore David Munro, Director R.A.F. Medical Service. The toast of prosperity to the West London Medico-Chirurgical Society was proposed by Sir Arbuthnot Lane, who in complimenting the Society on its fame and its vigour remarked on the need for combination between post-graduate institutions if London were to take its proper place as the great centre of medical graduate teaching. The President in his reply touched briefly on the year's work, and pointed to the satisfactory state of the Society's membership, now nearly 500. Mr. Dan Mason,

a vice-president of the West London Hospital, added a few words on behalf of the associated institution. The President then handed to the guest of the evening—Sir Clifford Allbutt—the Society's Triennial Gold Medal, amidst warm applause, everyone present standing throughout the presentation. The medallist, being called upon to respond, modestly disclaimed his title to this honour, greatly as he appreciated it. He supposed, however, that it might be that his professional brethren had come to look upon him, in the Bismarckian phrase, as an "honest broker" in the mart of medical ideas and discoveries, acting as a merchant between producer and consumer. The marvels of the present age of medicine, Sir Clifford said, impressed him deeply. New conceptions and achievements were leading to a greater power over disease; but what would happen to the medical student of the future, with so much to learn, he dared not imagine. Looking back on a very long professional life he could not but regret the passing away of the old style general practitioner, whose accomplishments and devices and instinctive skill used to fill him with wonder; in the flights of scientific medicine there was some risk of neglecting the craftsman-ship of such bygone practitioners. Lastly, Sir Clifford Allbutt said that to receive at the close of his career such compliments as the Moxon Medal of the Royal College of Physicians, the Gold Medal of Merit of the British Medical Association, and now the West London Medal, was to him peculiarly touching. The health of the Cavendish Lecturer, Dr. Henry Head, was proposed in very cordial and appreciative words by his friend, Sir Humphry Rolleston, President of the Royal College of Physicians, and Dr. Head replied in characteristically happy phrases. The toast of kindred societies and guests, proposed by Dr. Seymour Taylor, Consulting Physician to the West London Hospital, was responded to by Sir Bruce Bruce-Porter, President of the Hunterian Society, and Sir Crisp English, President of the Harveian Society. The evening's entertainment closed with the toast of the President's health, proposed by Sir William Hale-White, President of the Royal Society of Medicine, and a brief reply by Dr. Wells.

#### THE RESEARCH DEFENCE SOCIETY.

An uneventful year, the fifteenth in its history, was reported by the Research Defence Society at its annual meeting on June 20th. Viscount Knutsford presided and moved the adoption of the annual report, which showed that the Society had had a considerable accession to its membership; more than 450 new members had joined during the past few months. The lectures and debates had been fairly satisfactory in numbers and very satisfactory in results dealing with antivivisectionist misstatements. The Dublin Branch had decided that in view of the separate government of Southern Ireland, it ought to have no official connexion with the parent society, and accordingly it had been dissolved and a new association was being formed in the Free State capital. The parliamentary secretaryship of the Society had been vacated by Dr. Elliot, M.P., on his appointment as Under Secretary of Health for Scotland, and Sir Sydney Russell-Wells, M.P., had accepted the position in his stead. Sir David Ferrier presented the financial statement, which revealed an income of £806 and an expenditure of £948. He said, however, that this apparently none too prosperous state of affairs did not represent the actual position of the Society's finances at the moment, because, as the result of an appeal by Lord Knutsford, since the close of the Society's year there had been a considerable increase in subscriptions and donations. The remainder of the annual meeting was occupied by a lantern lecture by Dr. C. W. Saleeby, describing the work done in recent years on heliotherapy

<sup>1</sup> Raymond Pearl and Agnes Latimer Bacon: Biometrical Studies in Pathology. I, The Quantitative Relations of Certain Viscera in Tuberculosis. *The Johns Hopkins Hospital Reports*, vol. xxi, Fasciculus iii; pp. 157-230. 1.50 dollars.

in England, Denmark, Switzerland, and the United States. He mentioned that the credit for the discovery, or at least the anticipation, of the healing virtues of light in rickets belonged to an English medical man, Dr. Theobald Palm, who was still in practice at Aylesford in Kent. More than thirty years ago, when Dr. Palm was medical officer at a mission hospital in the Far East, he found that rickets appeared to be present when there was darkness and absent when there was sunlight, though he had no technical equipment with which to prosecute any researches. Afterwards came the experiments of Finsen of Copenhagen, in combating lupus by light treatment. In Switzerland evidence had been forthcoming that the action of sunlight, as yet largely unexplained, upon or through the skin might cure disease, notably tuberculosis. He spoke particularly of the wonderful results obtained by Dr. Rollier's method of treating tuberculosis at his solarium at Leysin in Switzerland, and Sir Henry Gauvain's work at Alton. Recently he had had the opportunity in New York of seeing some experimental work on animals, which went to show that the useful therapeutic agency in the sun's beam was the light and not the heat. Results improved with the exclusion of heat rays. The amount of phosphorus and lime in the blood of these experimental animals had been found to vary according to the light in the sky at the time of the year; it was highest in June, and gradually dropped, reaching its lowest point in March. Clothing had an important effect upon the exclusion of light from the body; mercerized white cotton would allow the light to act upon the skin almost as well as if the skin were naked, whereas the same material coloured black arrested the potent rays in their passage. He believed that in a few years' time exposure to an adequate amount of sunlight would be regarded as part of the régime of pregnancy.

#### MEDICAL FELLOWSHIPS IN THE UNITED STATES.

THE Rockefeller Foundation, New York, has entrusted the Medical Research Council with a fund to be used in providing fellowships in medicine in the United States. Fellowships will be awarded by the Council, in accordance with the desire of the Foundation, to graduates who have had some training in research work in the primary sciences of medicine or in clinical medicine or surgery and are likely to profit by a period of work at a university or other chosen centre in the United States before taking up positions for higher teaching or research in the United Kingdom. A fellowship will be of the value of not less than £315 a year for a single fellow, or £470 for a married fellow, payable monthly in advance. Travelling expenses and some other allowances will be made in addition. A fellowship will be tenable for one year, which will as a rule begin in September. Applications for fellowships tenable for the academic year 1923-24 should be made not later than July 20th next. Full particulars and forms of application are obtainable from the Secretary, Medical Research Council, 15, York Buildings, Adelphi, London, W.C.2. It is understood that similar medical fellowships provided by the Rockefeller Foundation will be awarded by the National Research Council at Washington to American graduates desiring to work for a time at selected centres of research work in this country. Both announcements are of great interest. It is of course a commonplace to say that science is international and knows no boundaries; but the practical application of the principle frequently encounters difficulties, to the detriment of progress. Some of these difficulties are removed when scientific workers know those of other countries and their methods of work. The United States now possesses many first-rate laboratories and research institutes, and it will be a great advantage to the British fellows to work in them.

#### THE NATIONAL PHYSICAL LABORATORY.

THE annual inspection of the National Physical Laboratory on June 26th was attended by a very large number of visitors, who were received in the Aerodynamics Building by Sir Charles Sherrington, President of the Royal Society and Chairman of the General Board of the Laboratory, Sir Arthur Schuster, F.R.S., and the Director, Sir Joseph E. Petavel, F.R.S. The first impression of the uninstructed visitor after he has observed the amenity of the place, which is at the gates of Bushy Park, is the bigness of the area already occupied but to be extended, and the second the multiplicity of the laboratories and testing rooms and the astonishing complexity of the researches and measurements conducted in them. Broadly speaking, the work of the laboratory falls into two classes. On the one hand, the staff is engaged in research into a great variety of scientific questions, and every year makes numerous contributions to the progress of many departments of science; on the other hand, it renders another kind of service to all these departments of science by its verification of the exactness of instruments of research. To take an example having a direct interest to medicine we may mention the testing of thermometers, including clinical thermometers, which is carried out systematically on a very large scale. The tests are made with great precision, and the method appears to leave no loophole for errors. In the Radiology Division work has been continued on the crystalline structure of metallic crystals by means of the x-ray spectrometer. The high voltage x-ray equipment has been employed on the examination of a number of samples of metal, and much thicker specimens have been radiographed than was previously possible. This work has necessitated the x-ray equipment being sufficiently protected, and to this end the box containing the x-ray tube is covered on all sides with sheet lead 6 mm. in thickness. The measurement of the protective value of materials used in x-ray installations has provided a considerable amount of work for the department during the course of the year, while in addition a number of hospitals have been inspected and reported upon along the lines of the recommendations of the X-Ray and Radium Protection Committee. In many cases the protection afforded to the operators was found to be defective, and in the reports on these inspections satisfactory means of remedying the various defects have been pointed out. The Metrology Department is concerned, among other matters, with the maintenance of standards used for the verification of sets of weights for scientific purposes, and a new weight made of stellite was shown; the material is found to be particularly stable, and, being extremely hard, is resistant to accidental damage. An instance of the astonishing minuteness to which the art of measurement is carried is afforded by two pieces of apparatus designed and made in this department; both are capable of measuring with accuracy to a millionth part of an inch. Some idea of what a millionth part of an inch is may be gained from the statement that in the thickness of a single cigarette paper there are as many millionths of an inch as there are cigarette papers in an inch. We cannot pretend to give any full account of all that the laboratory is doing, and will conclude by a brief reference to the Aerodynamics Department, which is now adequately housed. Among other appliances is a wind-tunnel in which a gale of over fifty miles an hour can be produced and the behaviour of model aeroplanes studied.

#### THE ORTHOPAEDIC HOSPITAL.

PRINCE HENRY, President of the Hospital, laid the foundation stone of the Nurses' Home which is to be built for the country branch of the Royal National Orthopaedic

Hospital at Brockley Hill on Saturday last. A brief dedicatory religious service was conducted by the Rev. Stewart F. L. Bernays, after which the Prince laid the stone, assisted by the architect, Mr. R. M. Pigott, A.R.I.B.A., and the contractor, Mr. Roland Holloway. Lord Denbigh, the chairman of the Committee of the Hospital, then thanked the Prince for attending and emphasized the necessity of finding out and treating cripples in the earliest possible stage, which the long waiting list of cases showed was not yet possible. Prince Henry in his reply reminded his hearers of the history of the Hospital, and quoted statistics to show the large number of cases which urgently needed treatment and the necessity of expansion to ensure that surgical tuberculosis should receive the most modern treatment of sunlight and fresh air while at the same time providing facilities for surgical operations in those cases in which they were necessary. The country branch, which already has nearly a hundred beds, including a large hut for open-air treatment, the gift of Queen Mary's Convalescent Auxiliary Hospitals, stands in twenty-seven acres of ground at Stanmore on the top of the Elstree ridge over 400 feet above the sea, commanding extensive views in almost every direction. It is therefore not surprising to find that the Romans, with their unerring judgement in the selection of sites, established here the station of Sullionæacæ, a stage on the great road to Chester and beyond. "Perierunt etiam ruinae!" and the surroundings are now so rural that it is difficult to believe that the tenth milestone from the Marble Arch is close at hand. Prince Henry also reminded his hearers that the work is expensive and that the upkeep of the country branch, where happy and unclothed children bask in the summer sunshine, costs the charity £8,000 a year, besides the expenditure in Great Portland Street, and that the Nurses' Home will cost over £8,000 in capital expenditure. He therefore asked for liberal contributions to the funds of the charity, since the needs of London were not nearly met by the existing cripples' hospitals and expansion to at least four hundred beds must be provided at Brockley Hill in the near future.

THE tenure of office as Lord Rector of Edinburgh University by Mr. D. Lloyd George ends in September, and the University Unionist Association has invited Mr. Baldwin to be its candidate at the forthcoming Rectorial election. The Liberals have nominated Sir John Simon, and a Labour group in the University has adopted Mr. Bertrand Russell as its candidate.

THE attention of members of the Association who propose motoring to Portsmouth to attend the Annual Meeting of the British Medical Association is called to the fact that garage facilities are very limited. Those members who require accommodation reserved for them must notify Dr. W. P. McEldowney, "Elmhurst," London Road, North End, Portsmouth, on or before July 6th.

DR. JAMES MOORES BALL, of St. Louis, U.S.A., has presented his collection of ophthalmic specimens to the Army Medical Museum, Washington. The museum was rich in specimens illustrative of other branches of surgery, but was poor in eye specimens. The collection includes a large number of original drawings of external ocular disease, photographs, pathological preparations of eye diseases, microscopical sections, eye instruments, rare ophthalmic literature, copies of well known ophthalmic atlases, and many portraits of bygone leaders in ophthalmic work. The drawings and pathological specimens have already been installed in the museum. Correspondents have been instituted in other cities and countries so that exchanges and additions may be secured; amongst these are Mr. Treacher Collins of London and Mr. Gray Clegg of Manchester.

## ROYAL COLLEGE OF SURGEONS IN IRELAND.

### HONORARY FELLOWSHIP.

At a meeting of the Royal College of Surgeons in Ireland on Monday, June 25th, Sir Harold Stiles, K.B.E., Regius Professor of Clinical Surgery in the University of Edinburgh, was admitted an Honorary Fellow. After the termination of the ceremony of enrolment the President, Sir William de Courcy Wheeler, addressed Sir Harold Stiles as follows:

Sir Harold Stiles,—It devolves on me now, in conformity with the unanimous wish of the Council of this College, to admit you an Honorary Fellow. We recognize that your original contributions to surgery have been signal and outstanding, and we follow with pride in the footsteps of the many great medical schools which have done you honour. The parchment which I will now ask His Excellency to hand you signifies that your name will be placed on the Roll of our Honorary Fellows, in company with many great scientists, including John Hunter, Lister, and Pasteur.

The presentation was then made by the Governor-General of the Irish Free State.

### CHARTER DAY DINNER.

In the evening the charter day dinner was held under the chairmanship of Sir William Wheeler. Among the guests were H.E. the Governor-General of the Irish Free State, the Lord Chief Justice of Ireland, the Recorder of Dublin, the Master of the Rolls, Mr. Justice Samuels, the Presidents of the Royal Institute of Architects, the Incorporated Law Society of Ireland, the Chamber of Commerce, of University College, Dublin, of the Royal Academy of Medicine, and of the Royal College of Physicians, the Archbishop of Dublin, the Provost of Trinity College, the Governor, Apothecaries' Hall, Dublin, the Chairman of the Institute of Journalists, the Registrar of the Royal College of Physicians, the Very Rev. Father T. Finlay, S.J., Sir T. Grattan Esmonde, Mr. G. J. Swift MacNeill, and the Master of the Rotunda Hospital (Dr. Gibbon Fitzgibbon).

Among the Fellows of the College present were the Vice-President (Mr. R. Charles B. Maunsell), Sir Lambert H. Ormsby, Sir C. Arthur K. Ball, Mr. A. Fullerton, Senator Gogarty, Dr. M. R. J. Hayes, Professor G. Jameson Johnston, Sir Thomas Myles, Professor Rowlette, Mr. J. B. Story, and Sir Robert H. Woods.

After dinner Sir WILLIAM WHEELER proposed the toast of the Governor-General and prosperity to Ireland. One of the reasons, he said, which had decided the College to revive, after an interval of some years, the charter day dinner was to have another opportunity of expressing the hope that His Excellency's tenure of office might be long and prosperous and marked by the establishment of peace and fraternity between all members of the community. The College was an institution which knew nothing of politics or sectarian strife; its impartiality had indeed been tested, for its building had within the last few years been occupied or besieged at different times by three separate military forces hostile to one another. Since the College was chartered by George III on March 9th, 1784, it had sought to promote surgical progress. The charter stated that the College was founded to improve the profession of surgery, and so to promote the welfare of the nation at large. The College and its Fellows gloried in the fact that Irishmen, north and south of the Boyne and overseas, had the welfare of the College at heart, but the salvation of a medical school was the fundamental truth that medicine and surgery, and for that matter, scholarship generally, were without nationality and knew no distinction of race or speech. Many of those present recognized in the Governor-General an old acquaintance, for as expert witnesses they had come under his hands, yet whatever happened to a witness Mr. Healy always brought his well known courtesy and kindness into play, and members of the medical profession left the courts with feelings unwounded and with pride unhurt.

Sir William Wheeler gave the toast of the Honorary Fellows of the College, coupled with the names of Dr. William Mayo and Sir Harold Stiles. Both, he said, through their writings, their disciples, and their followers, had become the daily friends of the entire community, and both were known personally to many of those present. Only the names of those who were in the very forefront of the profession were even suggested for the honorary fellowship, but when the time came to enrol Dr. William Mayo, in company with several other of his distinguished countrymen, there was not a dissentient voice. Like many pilgrims from other lands, the speaker had visited Rochester; some evidence of the position the Mayo Clinic had achieved was afforded by the fact that though the population of the town was about 8,000, in the previous year 60,000 patients, drawn from all over the globe, had sought advice and the help from Dr. Mayo and his 200 assistants. In that clinic, as in the surgical clinics of France, Germany, and Switzerland, the work of Sir Harold Stiles, as a scientific surgeon, was well known, and he was everywhere regarded also with feelings of affection. Sir William Wheeler then referred to the high tribute paid by Dr. Mayo and the late Professor Osler on more than one occasion to the general practitioner. They had referred to him as being a daily benediction in the community, living a life of self-denial and tender sympathy. The general practitioners in Ireland had lived up to the high reputation attributed to them; they had carried out their duties under conditions which would almost make those trained in the profession of arms shrink and retreat. It was no light matter to travel over roads strewn with mines; it was not a joy ride going through ambushes and of necessity by forbidden routes, to be mistaken for combatants and fired upon by friends and foes. Some fell wounded; some were killed; others escaped with their cars blown up, but there was never an instance of refusal to attend a patient when the summons was received. In conclusion Sir William Wheeler said that broadcasting was the order of the hour, but the fame of Mayo and Stiles had been broadcasted before the invention of Marconi of a mechanical plant. He asked his audience to tune their glasses and listen in for Rochester and Edinburgh.

Dr. Mayo, in reply, said that when it became known that Mr. Timothy Healy had accepted the position of Governor-General of the Irish Free State it was felt that the troubles between Great Britain and America were over. Speaking of men of Irish birth who had won distinction in America he mentioned the late Dr. John B. Murphy, and described him as the greatest surgeon of his day. The American College of Surgeons, which had been patterned upon the Royal Colleges of Surgeons of Ireland, England, and Scotland, was putting up in his memory a new building to cost about £100,000 in addition to the endowment.

Sir HAROLD STILES, who followed, said that he felt that the honorary fellowship conferred on him was a recognition, not so much of what he had been able to do in the science of surgery and in its practice and teaching, as a tribute to the College to which he belonged and the School of Surgery in which he had the honour to work. He was glad that the Governor-General had honoured the gathering with his presence, because it was an indication of his sympathy for learning and for the science of medicine.

The toast of the sister College and the guests was given by Sir THOMAS MYLES, and acknowledged by Dr. M. F. Cox, President of the Royal College of Physicians, the Provost of Trinity College, and the Lord Chief Justice. The last-named said that he was greatly struck by what Sir William Wheeler had said about general medical practitioners. During the last ten years Ireland had lived through difficult and dangerous times, and the one abiding admiration he had was for the general medical practitioner; in every county he had seen him responding with the greatest courage to the test he had to pass through, always performing his duty and never shirking it or even thinking of the danger.

The toast of the President, proposed by the Governor-General, was warmly honoured.

## CONFERENCE ON INDUSTRIAL HYGIENE.

UNDER the auspices of the League of Nations Union a Conference on the International Labour Organization and Industrial Hygiene was held at the Royal Sanitary Institute, London, on June 19th and 20th.

After a few introductory-remarks from the Chairman, Mr. W. L. Hichens, of Messrs. Cammell, Laird and Co., Mr. Grimshaw, of the International Labour Office, Geneva, gave a short and explicit statement of the constitution and aims of the office, and remarked that it was entirely a non-political body. Upon it were represented the various States which were members of the League, also representatives of employers and workers. Following him, the Right Hon. J. H. Thomas, M.P., general secretary of the National Union of Railwaymen, remarked that the war had not only created an abnormal condition of society, but also an abnormal state of the human mind. He dealt with safety and protection in industry, and showed in a well balanced and temperate speech how the introduction of "safety" measures had been followed by a considerable reduction in the number of accidents. There were still, however, far too many accidents among railwaymen. He thought the cases were few where it could be said that employers were not interested in the health and safety of the workmen. He pleaded for more frequent meetings of the masters and men to discuss problems concerning industry and health. Lieut.-Colonel J. A. A. Pickard, general secretary, British Industrial "Safety First" Association, alluded to frequent labour "turnover" as a cause of accident, and pressed the point that prevention was better than compensation. Experience showed that in factories only a small number of accidents was due to machinery, not more than 5 per cent., also that while the larger number was due to hand labour, many of these could not have been prevented. Alluding to minor accidents, he had found in an inquiry into 60 fatalities in coal miners that 10 of the deaths were caused by sepsis owing to minor injuries not receiving immediate and proper treatment shortly after their occurrence. Compared with these the serious cases in a London firm had fallen from 17.7 per cent. to 2.5 per cent. by immediate treatment. Mr. G. Stevenson Taylor, H.M. Senior Engineering Inspector, Home Office, read a paper on the safeguarding of machinery; he pleaded that engineers should receive instruction in regard to safety devices, and urged the desirability for united action among the nations. Mr. Bellhouse, who occupied the chair, lent the weight of his position in the Home Office to what had been said by the reader of the paper, and commented upon the fact that over two-thirds of the accidents occurring in factories were not the result of machinery.

### *Fatigue in Industry.*

After a few remarks from the Chairman, Mr. W. Graham, M.P., chairman, Industrial Fatigue Research Board, Mr. D. R. Wilson, secretary of this Board, in referring to the subject, preferred to use the words "physical unfitness or inefficiency" instead of "fatigue." Long hours were followed by smaller production. Quite apart from fatigue as a cause of accidents in factories, there was a "personal susceptibility" which could not be altogether ignored. He could not say how many countries were studying the question in the manner it was being done in the United States of America, in France, and Great Britain. An extremely interesting address was given by Dr. C. S. Myers, director of the National Institute of Industrial Psychology, in which he dealt with the muscular and nervous causes of fatigue. He reminded the audience that during muscular contraction it was not so much muscular substance itself which disappeared as the reserve of carbohydrate contained therein. The muscles of the body were always more or less in a state of contraction or "tone," and yet there was no sense of fatigue, nor were nerve fibres readily fatigued: it was the brain cells which came under the harmful influences of the waste products of the body. Fatigue was a large question and it was not really known what fatigue was. So far as industrial fatigue was concerned it could only be known by its results, for there was no real test for it. The objection to "Taylorism" was that it concerned itself too much with the wages of the men and their output, and that the men who adopted it had simply to follow their leaders. Professor

Cullis said that she would like to see more laboratory tests carried out in regard to women's work as compared with men's. She had given attention to the physiology of normal womanhood and of normal pregnancy; also to the subject of the elimination of carbon dioxide as a measure of muscular work. It made all the difference whether a woman's heart was in her work or not: if the work was agreeable to her the output was increased. Dr. Legge, of Columbia, U.S.A., expressed himself as doubtful as to the practicability of several of the tests suggested, since they could not be carried out in factories. Miss E. H. Howse, Postal Workers' Union, vividly exposed the hardships imposed upon girls employed in the telephone department of the Post Office. In twelve seconds calls had to be linked up. Some of the girls when at work were on their feet practically all the shift in front of a switchboard 3 feet high and 4 feet wide. By the end of four to eight years many of these girls were played out. In the United States of America girls gave up the work after three years, and in Australia no women were employed after the age of 28. Mrs. MacFadyen, South Africa, referred to a series of minor illnesses among the coloured men working in the gold mines in South Africa, where the malady was traced to overeating of the food and which disappeared on giving the men oranges. She alluded to child labour in the United States of America, where children of 5 and 6 years of age were working in the cotton mills for twelve hours a day while the children of the negro population were attending school. Sir Thomas Oliver paid a compliment to the reader of the paper, and enlarged upon some of the views expressed by various speakers. In regard to the excessive demands upon telephonists, he raised the point as to whether the application of science had in this instance at least not outstripped human physical capacity to cope with it. Dr. Bond, from the chair, thanked the readers of the papers and speakers, and remarked upon the interest which the discussion had aroused.

#### *Industrial Diseases and Injurious Processes.*

Dr. T. M. Legge, Home Office, paid a well deserved compliment to the certifying factory surgeons, and stated that he was opposed to the separation of industrial medicine from general medicine. It was extremely important to know more of the incidence of industrial diseases in the early stages. It was difficult to draw out a list of unhealthy trades. He did not think that the rarer toxæmias arising in industrial occupations were of little importance. He quoted the serious conditions of health which had occurred in submarines and which were traced to arseniuretted hydrogen gas; he also alluded to the nervous symptoms produced by manganese and which had been wrongfully attributed to carbon monoxide gas. He welcomed the work which the International Labour Office was doing, and paid a compliment to Dr. Carozzi, one of its scientific advisers.

Professor E. L. Collis spoke of miners' nystagmus and its supposed relationship to carbon monoxide, also of the large number of accidents which had occurred among agriculturists. It had been stated that the number of cases of miners' nystagmus had been increasing in this country, but on inquiry in Belgium and France the increase was more apparent than real. He drew attention to such maladies as miners' beat hand, knee, and elbow, a well known form of bursitis, as being unknown to the Central Office in Geneva. Dr. Collis subsequently dealt with the provision of baths at the pit head. Dr. T. M. Watts, M.P., who occupied the chair, mentioned that nothing had been done to put a stop to the dangerous practice and consequences of "shuttle kissing." Sir Thomas Oliver supported Dr. T. M. Legge as to the inadvisability of separating the two branches—general and industrial medicine. As regards a list of dangerous occupations, distinction had to be drawn between diseases caused by the trade itself—for example, plumbism, due to the action of lead upon the body—and diseases incidental to employment. It was a well known fact that tuberculosis and cancer were more prevalent in some occupations than in others. Sir Thomas Oliver pleaded that while information in regard to occupation and disease was being gathered at the Central Office, to be turned to good account afterwards, the working classes, especially those engaged in dangerous trades, should receive instruction as to the dangers to be averted in their particular calling.

The subject of women workers' health was introduced from the chair by Miss Margaret Bondfield, and elaborated at length by Miss Constance Smith, H.M. Deputy Chief Inspector of Factories, who maintained that women's labour still required protection as regards the limitation of hours, also no night work and no Sunday labour. It was also necessary that in dangerous trades women should be protected, since women were more susceptible to some poisons than men. There was the question to be considered of the influence of these upon motherhood. The introduction of national insurance had made it easier to control women working after their confinement. The lifting and shifting of heavy weights were also dealt with. Miss Gertrude Tuckwell, who followed, said that any laws which were introduced must, to be effective, meet the needs of the workers and have their sympathy. The session was brought to a close by Mr. E. L. Poulton, vice-chairman of the General Council of the Trades Union Congress, who stated that the International Labour Office was an outcome of the war, and that its function was to accumulate information which could form the basis of consideration at future congresses of the League.

The promoters of the Conference are to be congratulated upon having brought together men and women in this country who are interested in the medical and social problems arising out of industrial conditions, and which have been, and are still likely to be, discussed by industrial conferences of the League of Nations.

### *Medical Notes in Parliament.*

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

*Small-pox in Gloucester.*—Mr. Leach asked, on June 25th, what was the evidence that the epidemic which had occurred in the city of Gloucester was really an epidemic of small-pox, seeing that, although it was estimated that 2,000 cases of the disorder had occurred, there had been a complete absence of invalidity or injury during the attack, an absence of any invalidity subsequent to the attack, and that the mortality had been nil. The Minister of Health replied that the epidemic in Gloucester had been recognized to be small-pox by a large number of local medical men, by officers of the Ministry, and by Dr. Cameron of the Metropolitan Asylums Board, who was called in as an expert by the corporation. A number of cases of small-pox were recognized in other districts and traced to Gloucester. The statements as to the absence of injury or invalidity either during or subsequent to the attacks were not correct, as he was informed that although the type of the disease was mild and no deaths had yet occurred, many of the patients had been seriously ill. The action of the Ministry of Health had led to the localization and control of an outbreak which had already begun to spread to other parts of the country, and which, if unchecked, might have caused widespread disturbance of trade as well as danger to the public health. On June 26th Sir Arthur Holbrook asked the Minister of Health whether he would consider the repeal of Section I (1) of the Vaccination Act, 1907, exempting persons conscientiously believing that vaccination would be prejudicial to the health of the child. Lord Eustace Percy replied that the Government could not undertake to introduce legislation for the amendment of the Vaccination Acts during the present session.

*Infant Mortality.*—Mr. Chamberlain, at the instance of Mr. Lansbury, on June 21st, presented to the House a table showing infant mortality in London, Manchester, Birmingham, and Leeds in the years 1913, 1917, and 1922, and also the figures for each of the metropolitan boroughs. In London as a whole the deaths of children under 2 years of age in 1913 gave a rate of 136 per 1,000 births; in 1917 it was 143, and in 1922 it was 109. In Manchester the figures were respectively 169, 148, and 133. In Birmingham they were 164, 130, and 112. In Leeds they were 174, 183, and 131.

*London Housing By-laws (Public Health).*—On report on the Housing Bill, on June 20th, Dr. F. E. Fremantle proposed a new clause. The object is to make the London County Council the sole by-law making authority for London for the taking of precautions in respect of any infectious disease in working-class houses which are divided into separate tenements. The metropolitan boroughs will still have the powers and duties of enforcing the by-laws. Dr. Fremantle explained that the by-laws might be varied either in accordance with the wishes of different metropolitan boroughs for their respective areas or in respect of limitations as to rental, or in the case of the owner-occupier living in the house. But it was hoped that the County Council would vary the conditions as little as possible because it was for the general benefit to get a set of by-laws for London as uniform as possible. The clause was the subject of agreement between the County Council and the borough councils; and it was passed.

*General Disease.*—Sir W. Davison asked, on June 22th, whether any notification had been given on the lines of the report of Lord Trevelthain's Committee that chemists were entitled to sell disinfectants, or would legislation be necessary? Mr. Chamberlain

replied that no notification had been issued to chemists in consequence of the report. He was now inquiring into the question whether legislation would be required. Mr. Chamberlain's original answer to the question on this part of the report was given in the *BRITISH MEDICAL JOURNAL* of June 23rd (p. 1071).

**Hospitals and Legacy Duty.**—As promised while the Finance Bill was in Committee, Sir William Joynson-Hicks (Financial Secretary to the Treasury) received, on June 26th, a deputation to urge that legacies to hospitals should be exempted from legacy and succession duty by the present Finance Bill. Dr. Macnamara introduced the deputation, which included a number of members of both Houses of Parliament, and representatives of King Edward's Hospital Fund and the British Hospitals Association. It was stated that the concession might amount to between £40,000 and £70,000 a year for London, and possibly another £80,000 for the provinces. Such a form of indirect assistance would be particularly helpful, inasmuch as it should encourage testamentary gifts. Sir William Joynson-Hicks made a sympathetic reply, and promised to report to the Prime Minister what had been said.

**Ministry of Health: Medical Staff.**—Answering Mr. Becker, on June 20th, Mr. Chamberlain stated that fifty-four medical men were employed in the work of the regional staff of the Ministry of Health on a sessional basis. There would be no economy by placing any of them on the salaried staff. Three medical officers of the Ministry of Health were in receipt of retired pay; two of these were established civil servants, and the unestablished officer possessed special qualifications.

**Deaths from Silicosis.**—Lieut.-Colonel Lane-Fox (Secretary for Mines) informed Mr. Hurd, on June 20th, that it was not established with certainty that silicosis was the cause of death in the case of a miner at Newbury Colony in Somerset which had been investigated. But the departmental Health Advisory Committee, after examining the dust from the mine, was of opinion that there might be some danger from gritty particles. The owners, at the request of the inspector, had installed drills fitted with a spraying device, and these were now in use. The whole question was now under careful consideration.

**Miners' Cramp.**—Lieut.-Colonel Lane-Fox informed Mr. A. J. Bennett, on June 13th, that his attention had been called to the proposed remedy for miners' cramp. Professor Moss was working in close collaboration with the committee on the control of atmospheric conditions in deep and hot mines, which was one of the research committees now attached to the Safety in Mines Research Board of the Department.

**Registration of Nurses.**—Mr. Mitchell inquired, on June 20th, whether the Minister of Health was aware of the serious position in which the smaller hospitals had been placed in consequence of the Regulations of the General Nursing Council regarding the training of nurses, which had increased the difficulty of obtaining probationers. Mr. Chamberlain said he had not received representation in this sense. It was open to any hospital which was refused approval by the General Nursing Council to appeal to him, and no such appeal had been made. In reply to Dr. Chapple, Mr. Chamberlain said that 947 applicants had been rejected by the General Nursing Council as ineligible for registration under the rules hitherto enforced. He was advised that these rules were not inconsistent with the provisions of the Act of 1919. It rested with the Council to determine what steps should be taken to advise the nursing profession of the decision of the House, but in view of the publicity given to the subject in the papers he doubted whether many nurses were unaware of the effect of last year's vote. He agreed with Sir Henry Craik that the decision of the House did not have effect until an Order pursuant to it was issued. The best course for the 900 nurses who had already been rejected would be to put in fresh applications.

**Universities of Oxford and Cambridge Bill.**—This measure, which had been introduced in the House of Lords, was read a second time without division in the Commons on June 22nd. Mr. E. Wood (Minister of Education) explained that it was substantially in the same form in which it was presented last year by Mr. Fisher, and was consequential on the report of the Royal Commission over which Mr. Asquith presided. It was held that the establishment of a pension scheme would be outside the scope of the Commissioners' recommendations; the universities and colleges had power to make such a scheme, and the University of Cambridge had already formed one. During the time that the Royal Commission was sitting the Treasury gave assistance to the universities to the extent of some £30,000. Mr. Asquith and his colleagues recommended that an additional £70,000 a year should be given to each university, and that sums should be allowed to the women's colleges for a period of years and for extra-mural teaching. In addition a capital sum was suggested to put the finances of the universities in better condition. The times were somewhat changed since the Royal Commission reported and it was not likely that the Government could give the full measure of assistance recommended, but it would give such assistance to the universities as would be sufficient to meet the more pressing and immediate needs. Mr. Asquith, supporting the bill, touched on the inadequacies of the salaries of university teachers and administrators. Mr. William Graham, who was a Labour member of the Commission, deplored the practical starvation of important departments of research which had a most immediate bearing on economic and industrial problems. He thought a strong effort should be made to obtain £100,000 or more in each case at the earliest possible moment.

#### Answers in Brief.

The number of deaths attributed to pregnancy and child-bearing in 1922 was 2,971. In the same year the number of deaths associated with childbirth but attributed to other causes was 1,051.

## England and Wales.

### THE WELSH NATIONAL MEMORIAL ASSOCIATION.

The Welsh National Memorial Association is one of the best examples of the good that may be done by a wise benefaction well administered. The association owes its existence to Mr. David Davies, M.P., and its prosperity very largely to his continued interest and support. It has established country sanatoriums for pulmonary tuberculosis in several parts of Wales, and has for some time had a surgical tuberculosis hospital at Glan Ely, near Cardiff, where children suffering from joint and gland affections are received and treated. It has now established a large children's hospital at St. Bride's Castle, St. Bride's Bay, to which children from Glan Ely can be transferred, thus ensuring the continuity of treatment during the prolonged period necessary for the cure of joint disease. The new institution is known as the Kensington Hospital because the castle was until recently occupied by Lord Kensington. It has been converted into an orthopaedic hospital with 101 beds. It contains on the ground floor two wards of eight beds each, one ward of seven beds, and two wards of four beds each. A sun ward with fourteen beds has been erected on the south-east terrace. On this floor also are day and dining rooms, an operating theatre, and sterilizing room. On the first floor there are two wards of eight beds each, one of seven, one of five, three of six, two of three, and two of two beds each. The third floor opens on to a flat roof. A stable block has been converted into x-ray and plaster rooms, and a workshop and forge have been provided. There is also a post-mortem room, a mortuary chapel, and a disinfecting house. There are other buildings which can be converted into class-rooms, and it is hoped to utilize the greenhouses for training patients in horticulture. Steam cooking, electric lighting, and central heating apparatus have been installed.

The hospital was opened recently by Mrs. David Davies, to whom a vote of thanks was proposed by Sir John Lynn-Thomas, who said that since the opening of the first tuberculosis hospital thirteen years ago 30,000 patients had been treated in the different institutions, and Wales could now boast the finest organization in the world to deal with this scourge. Dr. Llewellyn Williams (medical member of the Welsh Board of Health), who seconded the motion, said that by opening so excellent an institution for the treatment of tuberculosis Mrs. Davies had inaugurated a new era in the fight against tuberculosis in Wales. He went on to say that as 20 per cent. of tuberculosis was believed to be caused by bovine disease every effort should be made to stop the supply of tuberculous milk. At a luncheon which followed, Mr. R. C. Elmslie, orthopaedic surgeon to St. Bartholomew's Hospital, proposed the toast of prosperity to the Memorial Association. He said that a survey of the number of crippled children in London made in 1907 showed that half were crippled by surgical tuberculosis; the proportion had now fallen to one-third. He hoped that parents in Wales would take full advantage of the splendid opportunity now afforded for the treatment of their children; the sooner they were admitted to the hospital the sooner would they recover and be able to return to their parents. Mr. David Davies, in reply, said that the association had now under its control or supervision 1,322 beds—1,014 for pulmonary tuberculosis and the remainder for surgical cases. There were, he said, 160 children still waiting admission, but as soon as the Kensington Hospital was completely equipped it would be possible to deal with all these cases.

### SMALL-POX IN GLOUCESTER.

Reference was made last week (p. 1071) to the seriousness of the situation at Gloucester, where there is an outbreak of small-pox. A special meeting of the Gloucester City Council was held on June 20th, to consider a report on the outbreak by Dr. W. H. Davison, assistant medical officer of health for Birmingham, who had been invited to undertake the administrative control of the outbreak of small-pox in Gloucester. According to the *Birmingham Post* of June 21st, Dr. Davison said that on June 12th,

when he undertook control, 148 cases of small-pox were known to exist in Gloucester, only 14 of which had been removed from their homes to the small-pox hospital. Up to June 18th 57 more cases had been discovered, making a total, to that date, of 205 cases. Dr. Davison said that great difficulty was being experienced in getting patients to agree to removal to hospital. There were certain influences at work endeavouring to foster this resistance and throw sand on the administrative machinery designed to protect the community. It had been necessary in six cases to apply for a magistrate's order for the removal of the affected person to hospital, and it could not be too widely known that the sanitary authorities had ample powers to compel persons suffering from small-pox to go to the isolation hospital provided. Captain J. Wood, chairman of the Public Health Committee, detailed the steps that had been taken to cope with the epidemic. Vaccination was no part of the policy of that committee, but he had been assured that there was no hope of dealing with this epidemic except by vaccination. Alderman Dr. Knight said that for some weeks there had been a strong feeling among doctors in the city that small-pox was there, and some were contemplating writing to the Ministry of Health on the matter. Alderman Caldwell said that he did not think it wise to talk too much about the epidemic. He felt sorry that the meeting had been called, and also that notices respecting small-pox in the city had been stuck all over the place. Mr. S. T. Stoddart said that any man who did anything to prevent the disease being checked was rendering a disservice to his fellows. Mr. J. Embling said that the bunkum of vaccination was being put up because of the financial gain that was behind it. The Mayor, Mr. J. O. Roberts, remarked that the local medical officer of health suggested that the expert who should be called in to decide between himself and the medical officer of the Ministry of Health, who diagnosed the disputed cases as small-pox, should be the medical officer of health for Leicester, but that eventually another medical officer was agreed upon. The reports and minutes of the Health Committee and of a subcommittee appointed for dealing with the outbreak were approved by the meeting, with one dissentient. At a meeting of the Health Committee at Gloucester on June 26th it was resolved to recommend to the City Council that the medical officer of health be relieved of all duties connected with the diagnosis of cases of small-pox and chicken-pox and hospital administration in connexion therewith; the medical officer has agreed to this course. The Committee decided to appeal to the Metropolitan Asylums Board for additional medical assistance.

According to the official *Weekly Return of Births, Deaths, etc.*, issued by the Registrar-General, a total of 79 cases of small-pox were notified in England and Wales during the week ended June 16th, 1923; they were made up as follows: Heanor (Derbyshire), 1; West Ham, 2; Stapleford (Notts), 5; Gloucester (county borough), 52; Gloucester (rural district), 3; Stroud (Gloucestershire), 1; Wheatenhurst (Gloucestershire), 2; Thornaby (Yorks), 1; Bentley (Yorks), 5; Doncaster (borough), 2; Doncaster (rural district), 4; and Risca (Monmouth), 1. Other cases of small-pox occurring since June 16th have been reported in the newspapers, including 23 cases at Warsop (Notts), 8 at Kirkby-in-Ashfield (Notts), 7 at Tylorstown (Glam), 10 in Middlesbrough, 3 in Birmingham, 1 at Broadheath (Worcestershire), and 2 at Millom (Cumberland).

#### INFANT WELFARE CONFERENCE.

A conference on infant welfare, under the auspices of the National Association for the Prevention of Infant Mortality and National Baby Week Council, will be held at Carnegie House, 117, Piccadilly, London, on Monday, Tuesday, and Wednesday, July 2nd, 3rd, and 4th. The representatives of the British Medical Association are Professor Louise Mellroy and Dr. Donald Paterson. On Monday the Minister of Health will deliver his presidential address, with Dr. G. F. Still in the chair; a debate will afterwards be held on the causal factors of infant mortality and their

prevention; in the afternoon a debate will take place on the value of maternity homes in a maternity and child welfare scheme, with Dr. Janet M. Campbell in the chair; and lectures will be given in the evening by Mr. R. C. Elmslie and Mr. C. E. Wallis. On Tuesday there will be a debate on the scope, staffing, and administration of maternity and child welfare centres, with Mr. H. O. Stutchbury, Assistant Secretary, Ministry of Health, in the chair; in the afternoon a debate will be held on the advisability of combining the functions of the health visitor with those of other officers of local authorities, with Dr. J. W. Robertson in the chair; in the evening there will be lectures by Mr. Bishop Harman and Mr. S. G. Moore. On Wednesday a debate will be held on the maternity convention passed by the Washington Convention in 1919, with Dr. Constance Ellis of Melbourne in the chair; in the afternoon there will be a debate on housing in relation to infant welfare, with the Hon. Sir Arthur Stanley in the chair, and in the evening there will be lectures by Dr. Evelyn Saywell and Miss Norah March. During the conference the annual meeting of the Maternity and Child Welfare Group of the Society of Medical Officers of Health will be held, and there will also be a meeting of the General Council of the Association of Infant Welfare and Maternity Centres; a number of visits to institutions have been arranged. Further particulars may be obtained from the honorary secretary, National League for Health, Maternity and Child Welfare, 117, Piccadilly, W.1.

#### PADDINGTON TUBERCULOSIS DISPENSARY.

At the annual meeting of the Paddington Tuberculosis Dispensary on June 25th the Mayor (Alderman H. B. Kenyon) read some figures which had been given him by Dr. Reginald Dudfield, M.O.H. Paddington, to illustrate the effect on the health of the borough of this, which was the first tuberculosis dispensary to be opened in England. Between 1914 and 1922 there had been in Paddington a fall of 49 per cent. in the number of cases of pulmonary tuberculosis notified, and of 27 per cent. in the number of cases of tuberculosis of other forms. The fall in the death rate from pulmonary tuberculosis during the same period had been 23 per cent., and in the death rate from other forms of the disease 26 per cent. Even more gratifying was the substantial fall (27 per cent. in the pulmonary cases) in the mortality of the cases notified since the dispensary was opened in 1909. Sir Robert Philip, upon whose Royal Victoria Dispensary, in Edinburgh, the Paddington work was modelled, congratulated the borough upon its honourable record. It had associated with the preventive and curative aspects of its work the investigation into and amelioration of the social and economic consequences of tuberculosis. Paddington was the first centre in Great Britain to introduce the principle of a Care Committee. It was at Paddington that it was first realized that, on account of the ubiquity of the disease, if tuberculosis was to be effectively dealt with it must be sought for. Sir Robert Philip bore strong testimony to the value of the combination of voluntary and official enterprise. He was confident that, thanks to a concentration of forces, pulmonary tuberculosis was on the run. He was sorry to read in an evening newspaper a statement attributed to a medical man that the consumption problem was probably never more serious than to-day, and that the death rate was higher than when the campaign against consumption was started. Such a statement was a libel on their efforts, and an illustration of ignorance and folly. He rebutted it by quoting the figures of the Registrar-General both for England and Wales and for Scotland. He recalled the fact that in 1910, to a great conference on the subject in the United States, presided over by Mr. Roosevelt, then President, he (Sir Robert Philip) was asked to send a cable stating what in his opinion would be the result of the adoption of the system then under consideration, involving the setting up of dispensaries, sanatoriums, open-air schools, and so forth. In his cable in reply he prophesied a 40 per cent. reduction in tuberculosis mortality within ten years. The New York statistics for the most recent year available showed that during practically that period of ten or eleven years there had been a fall in tuberculosis mortality in New York City of 51 per cent.

## ST. CHAD'S HOSPITAL, BIRMINGHAM.

St. Chad's Hospital, Birmingham, was opened in September, 1914, as a non-charitable, self-supporting institution intended to supply special medical and surgical treatment at a moderate inclusive cost. In its report for the year ending March 31st, 1923, the Committee of the hospital attributes the fall in the number of admissions to the general industrial depression, even the low inclusive fees being beyond the means of those who would otherwise have availed themselves of the hospital services. The fall is considerable, the number of in-patient admissions having dropped from 1,184 in 1920-21 to 752 during last year. The hospital staff now consists of 32 specialists, drawn from the consultants of the Birmingham hospitals. The hospital can accommodate 100 patients. It is run on business lines, with shareholders and a Board of Directors which controls the institution subject to the powers conferred upon the Medical Committee. The rules governing admission to the hospital are not quite clear. In the report of the Committee it is stated that "patients can obtain admission by applying to the House Governor, who is empowered to assess the amount of fees payable according to the nature of the treatment required and the financial circumstances of the patient." Again, "a patient admitted in this way will be placed under the care of a member of the staff who is a specialist for the disease from which he or she (*sic*) is suffering." And, "in the interest of the patient it is strongly recommended that a letter of introduction from his or her doctor should be presented at the time of application, or the name of the doctor given." On the other hand, in an article by Mr. William Billington, published in the *BRITISH MEDICAL JOURNAL* on February 21st, 1920, it is stated that no patient can be admitted except on the recommendation of a member of the medical staff; and that the amount of the inclusive fee (minimum charge 5 guineas a week) is arranged between the patient and the member of the staff concerned. Mr. Billington also said that the ordinary relationship between consultant and practitioner is maintained, the latter being invited where practicable to assist in the treatment. It appears that something like the group clinic method exists in the hospital, since each member of the staff has the right to call upon any other member for assistance without fee in treating what is called the "composition" patient.

According to the report the Committee has endeavoured to make St. Chad's fulfil as completely as possible the conditions laid down by the Advisory Committee to the Minister of Health, and it is stated that after a consultation between the Chairman of the Committee and Lord Dawson, it has been made possible for patients to make direct application to the hospital for admission and treatment. It seems likely that the Hospital Committee and the medical staff are not quite sure yet of the position of the hospital in the scheme of things; and that with the incentive of a falling admission list they are feeling their way in various directions. Whether a system of receiving direct applications from patients, who are then placed under the care of a specialist selected by some method not at present clear, will be satisfactory is a matter of experiment. But all experiments in the use of paying hospitals are interesting, and possibly valuable.

## LONDON AND COUNTIES MEDICAL PROTECTION SOCIETY.

The annual general meeting of the London and Counties Medical Protection Society was held for the first time at the society's new headquarters, Victory House, Leicester Square, on June 20th. Sir John Rose Bradford, who presided, referred regretfully to the loss which the society had sustained during the year in the death of three members of the Council—Colonel E. C. Bensley, Dr. D. B. Balding, and Dr. J. C. Pollock Muir—each of whom had served the society for more than thirty years. The society's membership had increased during the year, but unfortunately it still remained true that there were many members of the medical profession who did not belong to either of the defence societies. He could not help thinking that if they were acquainted with the risks they

ran in the course of their daily work, and with the valuable assistance which either of the two societies was capable of rendering, they would seize the earliest opportunity of becoming members. The finances of the society were in so satisfactory a state that the Council was able to waive the entrance fee in the case of the more junior members of the profession—those applying for membership within a year of registration—and there was now no difference in procedure as regards entrance fees or annual subscriptions between this society and the Medical Defence Union. The year had been marked by a closer association between these two bodies. A joint standing committee, including representatives of both, had been set up. The speaker drew attention to the number of instances in which practitioners had charges brought against them owing to their remissness in not examining the patients by modern methods, particularly x-ray examination in cases of fractures. Numbers of cases came before the society's council in which very obvious precautions had been neglected. Many practitioners, although they might, perhaps, recommend that a patient should have x-ray examination, did not protect themselves by means of a written record of the fact that the patient had declined to do what was recommended.

On the motion of Dr. C. M. Fegen, seconded by Mr. Sidney Spokes, Sir John Rose Bradford was re-elected to the presidency unanimously and with hearty acclamation. Dr. Fegen mentioned that Sir John had taken a principal part in bringing about the closer co-ordination and co-operation which now existed between the two defence societies. Dr. Fegen himself was re-elected treasurer, and all the retiring officers were re-elected.

The annual report, which was adopted, stated that the number of applications from members asking for advice and assistance was 645, as compared with 465 in the previous year. In the great majority of cases satisfactory results were obtained without litigation. The provision made by the society for indemnifying members against costs of the other side and damages in unsuccessful cases continued to give satisfactory results, and the Council had not yet had occasion to draw upon the sum of £20,000 provided for each year by an excess insurance policy with Lloyd's. After very careful consideration the Council had resolved, for the present at all events, not to elect as members any dentists who did not possess a registered degree or diploma.

## Scotland.

## THE CHAIR OF BACTERIOLOGY AT EDINBURGH.

THE court of the University of Edinburgh at its meeting on June 18th appointed Dr. Thomas Jones Mackie to be Robert Irvine professor of bacteriology in succession to the late Professor James Ritchie. Professor Mackie, who was born at Hamilton and educated at the academy there, is a Glasgow graduate, having taken the degrees of M.B. and Ch.B., with honours, in 1910, when he was awarded the Brunton Memorial Prize as the most distinguished graduate of his year. During the war he saw service at Gallipoli and afterwards had charge of a bacteriological laboratory at Alexandria. In 1917 he was released on his appointment to the Wernher-Beit chair of bacteriology in the University of Cape Town. Before the war he had been assistant in bacteriology with the director of the Bland-Sutton Institute of Pathology at the Middlesex Hospital, and has to his credit a large amount of valuable research work in bacteriology. In 1921 he received the M.D. degree, with honours, from Glasgow with a thesis entitled "Studies in Intestinal Bacteria."

## DEPARTMENT OF ZOOLOGY AT EDINBURGH.

At the same meeting of the University Court a letter was read by Principal Sir Alfred Ewing intimating from a donor, who desired to remain anonymous, a gift of £20,000 5 per cent. War Loan, to form the nucleus of a fund to provide a new department of zoology. It is hoped that other

support may be forthcoming in the near future to enable the department to be established. The laboratory accommodation for this department is at present quite inadequate, and both teaching and research are carried on under serious disadvantages. The department is well staffed, for in addition to the professorship of natural history which has existed since 1767, a chair in zoology was instituted in 1919, and there are four lecturers in zoology, a lecturer on genetics since 1911, and a lecturer on comparative anatomy since 1911.

Leave of absence has been granted to Professor Cossar Ewart, Regius Professor of Natural History, to enable him to accept the invitation of the Government of Australia to attend the Pan-Pacific Science Congress in Australia. His recent researches into the origin of the merino sheep and on the evolution of wool have been of great practical value, and he has been specially invited to contribute to the proceedings of the Congress.

#### SCOTTISH BOARD OF HEALTH.

The fourth annual report of the Scottish Board of Health has been issued and we hope to refer to it at more length in future issues. We will now only note the statement that throughout 1922 the policy of the Board was largely determined by two factors—the need for economy and the distress caused by the prolonged trade depression. The policy of economy prevented the Board from sanctioning developments that were not urgently necessary, and caused existing services to be restricted wherever this was possible without danger to the public health. Unfortunately the ban on developments has restricted several of the health services, notably the school health service and maternity and child welfare services, which were practically only in course of development when the need for economy arrested them.

#### SCOTTISH SOCIETY OF ANAESTHETISTS.

At the annual meeting of the Scottish Society of Anaesthetists, held in the Hall of the Faculty of Physicians and Surgeons on May 26th, a report by the executive on the present remuneration and status of specialists in anaesthetics in Scotland was considered and adopted. The report stated that the fees in Scotland are at present much below those paid in London and compare unfavourably even with those usual in the English provincial centres. Emphasis was laid especially on the following points:

1. At the request of surgeons, anaesthetists frequently reduce their fee to suit the pocket of the poorer private patients in exactly the same spirit as the surgeons themselves do. To this they have no objection, but unfortunately it seems to be a general experience among anaesthetists that what may be termed their standard fee for an administration of average gravity in a patient of ordinary means has come to be looked upon as a maximum to be exceeded upon very rare occasions. It is certain that a considerable number of patients are charged an anaesthetic fee which is too small in comparison with the other expenses associated with the operation.

2. The remuneration paid even to special anaesthetists of experience and acknowledged standing is little if any greater than that accorded to the surgeon's assistant, who is usually a man of junior standing and only at the beginning of his career.

3. In the teaching hospitals, also, the present status accorded to the specialist in anaesthetics shows too little recognition of his responsibility and of his special training and experience.

4. The developments of modern surgery are such as to require the services of the properly trained and fully responsible anaesthetist, and it is felt that neither in respect of status nor remuneration do the present conditions give recognition and encouragement to good and sustained work. For the making of a good anaesthetist, natural aptitude, proper study and prolonged hospital experience are all necessary, and unless those who devote themselves to the subject can look forward to reasonable prospects, the progress of the science and practice of anaesthesia must suffer.

The society recognizes that any attempt to lay down rigid rules and scales of remuneration is not in accordance with the spirit of the profession. The individual specialist in anaesthetics must charge for his services in accordance with his own standing. It is hoped, however, that ventilation of the matter in this way may be of value in bringing before the profession the unsatisfactory nature of the present position.

## Ireland.

#### IRISH MEDICAL COMMITTEE.

A MEETING of the Irish Medical Committee was held in the Royal College of Surgeons on June 20th. There were present: Dr. Joseph Power, Vice-Chairman, in the chair, Senator W. O'Sullivan, Drs. P. J. Hamilton, J. M. Kenny, G. Maguire, G. A. Hickey, R. J. Rowlette, M. R. Hayes, D. Forde, W. McCann, J. G. Holmes, J. S. Darling, D. Walsh, T. B. Costello, H. T. Warnock, P. J. Grogan, P. T. Magner, J. P. Shanley, A. D. Courtney, P. J. Quinlan, Dr. Hennessy, Medical Secretary, and Mr. C. H. Gick, Secretary. Apologies for absence were received from Drs. R. J. Johnstone, M.P., Chairman, W. S. Morrison, M.P., E. C. Thompson, P. J. O'Brien, W. J. O'Sullivan, J. C. King, P. McKenna, W. W. Murphy, J. Conihlan. Mr. R. J. Johnstone, Chairman, wrote stating that he wished to resign the chairmanship, but the Committee directed that he should be urged to reconsider his decision.

#### Advisory Committee to the Irish Insurance Commission.

A letter was received from the Irish Insurance Commission inviting the Irish Medical Committee to nominate three medical practitioners to act on an Advisory Committee to the Insurance Commission (Free State). Drs. Rowlette, W. O'Sullivan, and Hennessy were selected.

The Insurance Commission (Free State) forwarded a draft of the proposed report with regard to (1) Investigation of complaints against medical certifiers; (2) the appointment of a Complaints Committee to investigate, in the first instance, charges made against medical certifiers, etc. The report was considered in detail, and it was resolved:

"That the Irish Medical Committee is of opinion that the present arrangement whereby complaints against medical certifiers are submitted to Local Medical Committees should be continued, and that only such cases where the Local Committees failed; within a reasonable time, to take action, should be submitted to the proposed Complaints Committee.

"2. That there may be allowed to either party an appeal from the decision of the Local Medical Committee to the Complaints Committee.

"3. That the names of Dr. P. Grogan and Dr. P. Magner be forwarded to the Commission to represent the Irish Medical Committee on the Complaints Committee."

The revised form of medical certificate, and certain queries sent to the medical certifiers by approved societies, hitherto sent through the Insurance Commission, were considered. The Committee decided that it was inadvisable as well as a violation of the agreements of medical certifiers to forward certain queries through the approved societies, but that it would be prepared to consider favourably the adoption of such queries if embodied in the form of a certificate which would be used only at intervals agreed upon between the Insurance Commission and the Medical Committee.

#### Irish Medical Services.

A long discussion took place with regard to the position of the Irish Medical Services both as they affected the public and those members of the profession engaged in their administration. It was resolved:

"That an Executive Subcommittee, consisting of the Chairman, Vice-Chairman, Drs. Rowlette, O'Sullivan, Hamilton, Hayes, Shanley, Magner, J. M. Day, and the Secretaries, be appointed, and that it shall act as a deputation to wait on the Minister for Local Government and urge upon him (1) the necessity for the establishment of a Ministry of Health for Ireland and a National Medical Service on the lines recommended by the Irish Public Health Council; (2) pending legislation that the deputation urge on the Minister the grievances of medical officials in regard to salaries, holidays, pensions, etc."

The Medical Secretary was directed to continue his representations to the Ministry of Local Government in connexion with the refusal of that Department to sanction increases for medical officers passed by the local authorities in Mullingar, Kinsale, etc.

*Red Cross on Motor Cars.*

Arising out of communications in regard to the continuance of Red Cross and other distinctive marks on the motor cars of medical practitioners, it was resolved:

"That the Irish Medical Committee considers the use of the Red Cross on motor cars of medical practitioners, during the recent troubles, was justifiable, but it is now of opinion that all such distinctive marks should be dispensed with in districts where peace is restored."

*Medical Attendant to St. Patrick's College, Maynooth.*

The position of medical attendant in St. Patrick's College, Maynooth, and resolutions passed by the County Kildare medical practitioners, were considered. The Committee expressed its sympathy with Dr. Grogan and adopted the resolutions passed by the County Kildare doctors, which stated (1) that the increase asked for in the salary of Dr. Grogan as medical attendant to St. Patrick's College, Maynooth, should be granted without further delay; (2) that the County Kildare doctors considered it unprofessional, in the circumstances, for any doctor to accept Dr. Grogan's office, and that if any doctor did so they would not recognize him professionally.

*Medical Fees for Life Insurance.*

The following resolution was adopted:

"That the Irish Medical Committee is of opinion, for medical examination in life insurance cases, that if the profession, throughout Ireland, take proper steps to have itself locally organized it will secure the fees obtained and obtainable by the Limerick doctors. As the result of united action the doctors in the borough of Limerick are paid the following scale of fees for life insurance examinations:

Industrial assurance :					£	s.	d.
Under £100	...	...	...	...	10	6	
Ordinary :							
£100 to £500 (inclusive)	...	...	...	...	1	1	0
Above £500 and less than £1,000	...	...	...	...	1	11	6
£1,000 or any higher sum	...	...	...	...	2	2	0

*Remuneration for Holidays, Consultations, Administration of Anaesthetics, etc.*

The following resolutions were adopted:

"That the remuneration in dispensary districts for temporary work, in normal conditions, should be a minimum of £6 6s. per week, and for hospitals £5 5s. per week. For the administration of anaesthetics and assisting at operations, £2 2s. Where more than one anaesthetic is administered at one visit: First case, £2 2s.; subsequent cases at £1 1s. each.

"That the substitute nominated by the doctor going on leave should be appointed by the local authority—if the arrangements made for the discharge of the duties are satisfactory to the Local Government Department. Canvassing by doctors against the nominee of the doctor going on leave is to be very strongly condemned. Consultations under the Medical Charities Acts: Day, £2 2s. and mileage; night, £3 3s. and mileage. Midwifery, in the day, £3 3s. and mileage; at night, £4 4s. and mileage."

*Tax on Motor Cars.*

It was resolved:

"That motor cars engaged in work under the Medical Charities Acts should be exempt from taxation, and that the tax paid on motor cars of doctors engaged in other practice should be on pre-war basis of allowance."

*IRISH (FREE STATE) ARMY MEDICAL SERVICE.*

At the conclusion of the proceedings of the Irish Medical Committee the Chairman congratulated Dr. M. R. Hayes, F.R.C.S.I., late Director-General of the Free State Army Medical Service, on his success in organizing, under very great difficulties, a medical service which proved in every way equal to the difficulties it was called upon to meet during the recent troubles in Ireland. Dr. Hayes, in thanking the chairman and the meeting for their appreciation of his services, stated it was due from him to acknowledge the whole-hearted support he had received from the Irish medical profession, without which he believed his task would have been a great deal more difficult. General R. Mulcahy, Minister of Defence, at a recent meeting of the Dail also paid a very high tribute to the services of Dr. Hayes during the time he acted as Director-General of the Army Medical Service in the Free State.

## Correspondence.

*ETHER VERSUS CHLOROFORM.*

Sir,—There must be many surgeons who, like myself, were pleased with the strongly expressed opinion of Dr. McNamara in favour of ether which appeared in the JOURNAL of June 9th. In the issue of June 23rd (p. 1076) Dr. Samways argues for chloroform, but I venture to state that few anaesthetists and surgeons of ripe experience will agree with his views or the statements by which he attempts to support them.

Anyone who reads the daily papers with average regularity must be appalled by the frequency of the headline "Death under anaesthetic," and no one will dispute that the disaster has practically always occurred when chloroform (in whole or part) was the drug employed.

I have had the misfortune to see ten deaths under anaesthesia. Two were patients of my own; the anaesthetists were well known experts, and death occurred during induction and while I was preparing my instruments for operation. In one patient—an apparently healthy man—a few inhalations of chloroform were followed by sudden pallor, dilatation of pupils, failure of the pulse and respiration, and death. The post-mortem examination gave no satisfactory clue to the disaster.

There are few surgeons who cannot recall one or more similar tragedies.

Surely Dr. Samways is not accurate in his statement that "chloroform has the advantage of not irritating the bronchial tubes, of easily controlling movement, and of seldom causing after-sickness." If "open ether" be preceded by a hypodermic injection of 1/100 grain of atropine and pushed to the stage of complete relaxation the attributes he claims for chloroform will be equally well secured by ether. Above all, the patient will be under the influence of a drug which stimulates the cardiac and respiratory centres rather than depresses them. Even if we were to allow his contentions in favour of chloroform, our first interest must be the safety of our patient, and what comparison is there between a possible few temporary discomforts and the appalling tragedy of a "death on the table"? Very many patients have died, and others will yet die, under chloroform, even when the anaesthetic is given by an expert; such an event is extremely rare under ether anaesthesia. Why run the unnecessary and added risk by employing chloroform? Dr. Samways says that "ether as an anaesthetic requires a complicated apparatus." My reply is that, if administered by the "open" method, it only needs a few layers of closely folded gauze on which the drug is freely poured.

It seems to me that he both weakens his argument in favour of chloroform and strengthens it in favour of ether when he says that "From what I have seen of the administration of an anaesthetic abroad I am not astonished that ether should be popular. Ether lets off the anaesthetist..." I ask "Why?" My own explanation would be that the anaesthetists whom Dr. Samways met are wise men who, when confronted with two dangers, had no hesitation in choosing the less.

I apologize for the length of this letter, and only plead the wisdom and importance of the contentions raised by Dr. McNamara. If Dr. Samways will do me the honour of allowing me to arrange for him a demonstration of the open ether method I shall be delighted to avail myself of the opportunity.—I am, etc.,

HERBERT TILLEY.

London, W., June 22nd.

Sir,—Dr. Samways (June 23rd, p. 1076), referring to my letter, says that "Extremely common" is a loose phrase which, I believe, no statistics justify."

It is unnecessary to remind readers of London newspapers that hardly a week passes without the melancholy record of one or more of these tragedies. On the day on which I wrote my letter it was recorded that a London coroner, holding an inquest on one of these victims, said that he had already on that day held three similar inquests. Some time ago it was stated that one famous

London hospital had 42 chloroform fatalities in eight years. And this hospital was not alone in its misfortunes.

Dr. Samways says that "Ether as an anaesthetic requires a complicated apparatus." It does not. With "open" ether, which is the ideal, any simple apparatus like Rendle's inhaler, or even a tumbler with a towel and sponge, is sufficient. The Clover inhaler and all other closed apparatus forcing the patient to rebreathe his own poison are a mistake. Dr. Samways thinks if the truth were known that "If after-effects could be taken into account and tabulated," ether might present the darker picture. Where is this truth to be found? Not in the coroner's court, because the patients do not die; not in the experience of the anaesthetists who use the "open" ether method, for they are unhesitating in its praise. Many years ago, when I first wrote on this subject, I saw a statement by an American surgeon that at that time in all Philadelphia there was only one expert anaesthetist, and that although the ether was generally administered by non-experts there was almost no mortality under anaesthesia. Dr. Samways gives details of his method of giving chloroform, and implies that if others would do likewise things would be all right. He says that deaths under anaesthesia are very rarely the direct fault of the anaesthetic.

If this were true, then the fault must be with the anaesthetist. Every London hospital has one or several expert anaesthetists who devote most of their time to the practice of anaesthesia. Are we to assume that these gentlemen are all duffers?—I am, etc.,

London, W., June 22nd.

J. McNAMARA, M.D.

#### THE EDUCATION OF MYOPES.

SIR,—Anything by Dr. Harrison Butler is well worth reading, but if he agrees with me that the use of the eyes for near work has nothing to do with myopia why should he forbid his patients to use their eyes for near work? I always tell mine that they can read or use their eyes for near work as much as they like, glasses being given so that the book is not held too close.

The evidence as to the chief exciting cause of myopia is overwhelming. Myopia is caused by distension of the eye due to back pressure through the veins, such as is caused by lifting a heavy weight. Heredity may give anyone a weak sclerotic as it may give a man weak muscles, but in absence of the exciting cause he will probably remain normal sighted. As chairman of the Ophthalmic Board, Central London Medical Boards, National Service, I had exceptional opportunities of studying a very large number of cases of myopia, many of whom had not previously had their eyes examined. Myopia, especially the higher degrees, appears to be much commoner in the labouring than in the professional classes, although a large number of the former will not wear glasses.

Space will not permit me to go into details, but the reader will find them in my "Arris and Gale Lecture" (*Lancet*, March, 1921). On publication of the lecture I received letters agreeing with the conclusions from all parts of the world. Let the reader examine for himself any case of myopia, without leading questions, inquiring as to onset, progression, etc. A man, for instance, may have normal sight until he is 22 or 23 and be accustomed to go to the music hall and see clearly from the gallery, but on changing from a sedentary employment to one in which he has to do heavy lifting finds that his sight steadily deteriorates and that he is not able to see from the gallery, and then after a time gives up the theatre. He may even come to the conclusion that the work is affecting his eyes and go back to a sedentary employment where he has to use his eyes for near work, and that there is then no further increase in his myopia.—I am, etc.,

London, June 19th.

F. W. EDRIDGE-GREEN.

#### POLYTHELIA.

SIR,—I am much obliged to your correspondent, Dr. Graham Renshaw, for his remarks on my article "Polythelia." The fact that the situation of the accessory nipple in all his three cases coincides with the situation of the

nipple in my own case is interesting, but it is difficult to see what the significance, if any, can be. Supernumerary breasts are most commonly found upon the anterior thoracic wall near the mammillary line; less commonly are they situated in the axillae and on the anterior aspect of the abdomen; occasionally upon the shoulder; and on very rare occasions upon the thigh.

I am not aware of any other case of polythelia in the female subject, nor have I been able to find any reference to an authentic case in medical literature. In regard to the condition of "double nipple" in the male, one is aware that the abnormality is not sufficiently uncommon to merit it being described as a rarity, but I am not aware of any method by which it is possible to distinguish definitely between polythelia (supernumerary nipple) and polymastia (supernumerary breast) in the living male, except, perhaps, in the case of abnormally stout subjects. The mammary tissue of the average normal male may be scarcely palpable and in polymastia the supernumerary breast may be so minute as to be scarcely distinguishable. Is it not therefore more likely that Dr. Renshaw's cases are really cases of polymastia?

I have always, without dogma, held the view that such conditions as polythelia and polymastia are to be regarded as atavistic reversions. Many observers, however, do not accept this view. Whitridge Williams (Baltimore) has observed that in not a few instances an apparent hereditary influence can be traced. Others prefer to accept the theory of Ahlfeld concerning the distribution of the mammary tissue.—I am, etc.,

Bradford, June 16th.

R. DOUGLAS HOWAT.

#### BLOOD SUGAR ESTIMATIONS BY GENERAL PRACTITIONERS.

SIR,—The recent discovery of insulin has led to a large amount of correspondence in your columns on blood sugar, and has increased the interest taken in diabetes by general practitioners. The prominent advertisements in the *JOURNAL* of Professor Maclean's excellent book on the treatment of diabetes by modern methods, and those of a firm of chemists supplying the necessary solutions for these estimations, will probably result in a number of medical men attempting what I believe to be impracticable, and to a large extent unnecessary.

My experience of over twenty years in a large practice, in which all urines are examined as a routine, is that the number of glycosurias is very small—perhaps six to ten cases per annum. Of these, nearly all fall into one of two classes: (1) temporary glycosuria due to a septic focus, often situated in the teeth or tonsils, (2) elderly persons with a deficient storage capacity for sugar. The former are highly amenable to treatment, and the latter pass comfortable lives on a slightly restricted diet, and eventually die of something else. For these blood sugar estimations are unnecessary.

There remains a very small number—not one in twelve months—of true and severe diabetes; cases where it is impossible to get sugar-free urine on a diet sufficient to keep them alive. Even with these very little can be learnt from frequent blood sugar estimations; one investigation is sufficient to exclude renal glycosuria, and this can be done better at a laboratory.

However, if a general practitioner wishes to do it himself, is it practicable to do so by Maclean's method? This so-called simple method requires fifteen special pieces of apparatus and six special solutions. It requires a room, or at least a bench, set apart for its use. It takes one hour to carry the test through, and experimental errors due to want of practice in the use of capillary tubes make it essential to perform more than one estimation in order to obtain a reliable result.

My opinion, after having tried the method, is that we should carry on at present on the old lines, testing our treatment by quantitative urine estimations with Fehling's solution, and curing a large proportion of our patients. If we wish to experiment with insulin one complete blood sugar estimation should be made at a laboratory, and overdosing guarded against by keeping a mere trace of sugar present in the urine during its administration.

I believe this is the only practicable method, and the

attempt to do more will involve the busy practitioner in a large and unnecessary expenditure of time and trouble, and should be left to scientific workers.—I am, etc.,

Poplar, June 18th.

W. H. F. OXLEY.

#### THE PEPTONE TREATMENT OF ASTHMA: A DISCLAIMER.

SIR,—In a recent monograph, entitled *Asthma*, by Mr. Frank Coke, certain statements are attributed to me to which I must emphatically take exception. It is affirmed that I prescribe "5 per cent. each of Armour's and Witte's peptones" intravenously. I have never done so, nor should I think of recommending such a dangerous concoction. The peptone prescriptions I have given will be mainly found in the *BRITISH MEDICAL JOURNAL* (1921, vol. i, p. 698), where it is stated *inter alia* that when the Armour peptone is not used alone (as I generally recommend) a 5 per cent. solution may be tried of a mixture containing one part of Witte's peptone to three parts of "peptone siccum" (Armour), the latter greatly differing in composition from the ordinary Armour No. 2 peptone in that it contains extremely little proteose. It will be seen how wide is the difference between this and the preparation attributed to me above. The other statement to which I take exception is that, as an explanation of the *modus operandi* of peptone, I have suggested "that the peptone, being a common derivative of all proteins, may desensitize the patient to them all." I should be sorry to think that I ever offered a suggestion so crude. My view, uniformly expressed, is that the peptone interacts with the fluids and tissues of the body in the production of a poison which desensitizes to a poison produced from the interaction of the fluids and tissues with the antigen-antibody complex.

It is a recognized rule in medical authorship to give chapter and verse in verification of statements attributed to others; yet no reference to any paper of mine on the peptone treatment of asthma is given in this volume, and I would certainly have expected that, in the case of a delicate method of treatment, care would have been taken in the matter of quotation. This is the more inexplicable in view of my responsibility for the method, a consideration which is entirely ignored.—I am, etc.,

London, W., June 19th.

A. G. AULD.

#### FREEDOM OF NEGRO RACES FROM CANCER.

SIR,—The May number of *American Medicine* contains an article entitled "The Sewage System of the Human Body," by Sir William Arbuthnot Lane. On page 268 Colonel McCarrison is quoted as never having seen a case of asthenic dyspepsia, of gastric or duodenal ulcer, of appendicitis, of mucous colitis or of cancer, during the nine years he practised in the Himalayas. On the same page Dr. Hoffman is quoted as having asserted that during a seven months' trip to South America he did not come across a single case of cancer amongst the native Indians or mixed bloods.

With the above statements my personal experience in South Africa fully agrees. For six and a half years I was District Surgeon in the Orange Free State. The district in which I practised had a native population of 14,000, the large majority of the Basuto race. During the whole of that period I never saw a single case of gastric or duodenal ulcer, colitis, appendicitis, or cancer in any form, in a native, although these diseases were frequently seen amongst the white or European population.

Whilst, however, acting as locumtenent for a colleague in the Western Province of South Africa, I saw two cases of carcinoma of the breast in native women. They both belonged to the coloured race peculiar to that part, a race which has lived under civilized conditions for the last 300 years at least. These facts are well known to all medical men in South Africa who have practised amongst the native races. In view of the present stimulus given to research in the causation of cancer, I think the article and facts quoted above ought to receive serious consideration.—I am, etc.,

London, N.W., June 16th.

F. P. FOUCHÉ.

#### Obituary.

W. D'ESTE EMERY, M.D., M.R.C.P.,

Formerly Director of Laboratories and Lecturer on Pathology and Bacteriology at King's College Hospital.

We regret to record the death on June 19th, at Red Cross Hospital, Brighton, of Dr. Walter d'Este Emery, at the age of 53. Dr. Emery was educated at Queen's College, Birmingham, and St. Bartholomew's Hospital, and graduated B.Sc.Lond. (with first-class honours in physiology) in 1892, M.B.Lond. (gold medal in medicine and obstetric medicine) in 1896, and M.D. (qualified for gold medal) in 1897; he had taken the L.R.C.P.Lond. and M.R.C.S.Eng. in 1894, and obtained the M.R.C.P.Lond. in 1918. After having been house-physician and obstetric house-surgeon at Queen's Hospital, Birmingham, he was appointed assistant surgeon to the Birmingham Skin and Urinary Hospital, and lecturer on pathology and bacteriology in the University of Birmingham. He was next appointed pathologist to the Paddington Green Children's Hospital, and afterwards became director of the laboratories and lecturer on pathology and bacteriology at King's College Hospital, and lecturer on general pathology at the London School of Medicine for Women. He was a former Hunterian professor to the Royal College of Surgeons. He was a Fellow of the Royal Society of Medicine and of the Pathological Society of Great Britain and Ireland, and a member of the British Medical Association; at the Annual Meeting of the Association in Birmingham, in 1911, he was vice-president of the Section of Pathology. Among his published works are *Clinical Bacteriology and Haematology*, a practical handbook which has passed through six editions, *Tumours, Their Nature and Causation*, and *Bacteriological Diagnosis for Practitioners*. He was also the author of many contributions to periodical medical literature, and was at one time editor of the *Journal of Vaccine Therapy*. Owing to ill health he had recently retired, and was living at Shirehampton, near Bristol.

Sir GEORGE LENTHAL CHEATLE writes: All who knew Dr. d'Este Emery were deeply concerned to learn that the state of his health necessitated his retirement from the teaching staff of King's College Hospital. They are now more deeply grieved to hear of his early death. In the natural course of busy lives, most of us know only of his public career; those who knew him always recognized that they were in contact with a modest man who possessed an original and philosophical mind combined with great intellectual ability. He seldom spoke on matters to which he had not devoted conscientious study, and, in consequence, anything that he said was interesting and worthy of the attention it attracted. Dr. Emery's brilliant career as a student, and the variety in the branches of work in which he had studied and shone specially fitted him for original work. Some of the early researches which I heard him describe before the Medical Research Club were the result of pioneer work. The conclusions at which he arrived were always based upon accurate, ingenious, and controlled experiments, and were received by that critical body as coming from one in authority. Philosophical and profound, he was also a clear and concise teacher, and the advice which he gave to me and to others was always of value, not only in elucidating the point at issue, but also in aiding the further investigations to which his opinions led. Latterly, his labours at King's College Hospital were almost more than one man could accomplish; he had to teach pathology and bacteriology, and to superintend the many and varied calls that clinical claims made upon his department. In many ways this was a great pity; his knowledge, originality, and desire for research work could not be granted the scope that they required. They were almost entirely limited to simplifying, and to rendering more accurate, the usual technique employed in the investigation of clinical material. The ingenuity and resource of his methods were examples of the loss he was to the work of exposing to light facts hidden in dark places. The students and patients of King's

College Hospital have lost an invaluable servant, science has lost a master, and his friends have lost an accomplished, an inspiring, and a lovable companion.

### WALTER PETTER, M.B., C.M.EDIN.,

Honorary Physician to the Darlington General Hospital.

DR. WALTER PETTER, who died on May 24th, was born at Barnstaple in 1857, and received his medical education at the University of Edinburgh, graduated M.B. and C.M. in 1883. He was an expert in medicine, and was house-physician at the Royal Infirmary to Sir Douglas McLagan. Shortly afterwards he became assistant to the late Dr. Munro of Barnard Castle, where his skill, straightforwardness, and genuine kindness won him many friends. In 1887 Dr. Petter settled in Darlington, where he soon obtained the success he deserved, making many friends among his fellow practitioners and the general public. He was medical officer to the post office and the training college and medical assessor to the county court judge. In 1914 he was appointed assistant honorary physician to the Darlington General Hospital, and in 1919 he became full physician.

During the war he worked very hard; in addition to his private practice he acted as civilian medical officer to the Durham Light Infantry and physician to the V.A.D. Military Hospital. For four years in succession he was unanimously elected chairman of the Darlington Division of the North of England Branch of the British Medical Association, and was regularly in the chair at every meeting discharging the onerous duties with supreme tact and fairness; but his intimate friends who watched him are convinced that the extra duties imposed by the war shortened his life considerably, especially as he had never enjoyed what might be called robust health. After the war he did a large amount of work on pension boards. Those who served with him on the hospital staff regret much the loss of a colleague so loyal to the hospital and its medical and nursing staffs; he was beloved by his patients and by all who knew him.

The funeral, which took place at the Darlington West Cemetery, was attended by most of his fellow practitioners and by a very large number of the general public; the hospital committee and nurses were well represented. He leaves a widow (who did most valuable war work as commandant of the V.D. Hospital, Woodside, Darlington), one daughter, and one son to mourn his loss.

### WILLIAM FLEMING,

Secretary of the Royal College of Physicians of London.

A WELL KNOWN and widely respected figure in the medical world has passed away in the person of Mr. William Fleming, the Secretary of the Royal College of Physicians, who died suddenly on June 21st. Mr. Fleming had passed fifty years in the service of the College, and it would be difficult to point to a finer example of complete and unswerving devotion to duty. For him the College came before all other considerations, and although advancing age and ill health made their insistent demands for rest, he remained at his post and died, as we think he would have preferred to die, in harness to the last. From the days of Sir Thomas Watson to the present time he had seen Presidents and College officers come and go. He had watched the changes taking place during his long association with the College, and it was pleasant to find him in reminiscent mood, when he sketched with delightful touch the characters and peculiar personal traits of distinguished Fellows of the College who have long since passed from our ken. His knowledge of the traditions and history of the College was profound, and from his long experience he could always provide the reason for some ceremony or the origin of some practice. His courtesy in discharging the duties of his office made him respected by all with whom he came into contact, and his loss will be deeply felt. For him we can truly subscribe the epitaph he would have valued—"Well done, thou good and faithful servant."

## The Services.

### INDIAN MEDICAL SERVICE.

THE annual dinner in London of the Indian Medical Service was held on June 20th, when ninety-seven officers and two guests were present.

After dinner Major-General Sir W. R. EDWARDS, K.C.B., K.C.I.E., who was in the chair, spoke at some length about the present and future of the Service. He indicated that many Indian politicians held that the Indian Medical Service could be conducted efficiently by medical men of Indian birth possessing British qualifications, and that a sufficient number of such men would be available. With regard to the present he said: "I am informed by the India Office that regulations have now been made by the Secretary of State in Council under Rule 12 of the Devolution Rules reserving for officers of the Indian Medical Service a total of 305 civil posts and thus providing civil employment for 388 Indian Medical Service officers, including leave and study reserve. Of these posts 65 are under the Government of India and 240 under Local Governments. Of the latter the posts of Surgeon-General, Inspector-General of Civil Hospitals and Director of 1st Class Provincial Bacteriological and Pasteur Institutes will be filled by the nomination of the Government of India. I understand that the regulations are declared to be provisional and without prejudice to the final orders to be passed by the Secretary of State in Council when he has received and considered the report of the Royal Commission which is being appointed under the chairmanship of Lord Lee of Fareham to inquire into the Public Services, including officers of the Indian Medical Service in civil employment. The text of the regulations will be published in the *Gazette of India*, and copies will be obtainable shortly from the India Office." Sir William Edwards expressed the view that this did not go far enough and that appointments of professors, of alienists, as clinical examiners, and to jails and to public health offices should be made by the Government of India from an all-India service. It might very well happen that a provincial service would not on occasion be able to provide a suitable person when there was a vacancy in one of these services.

The officers present were as follows:

Major-Generals: Sir W. R. Edwards, K.C.B., K.C.I.E., C.M.G. (Chairman); Sir R. H. Charles, G.C.V.O., K.C.S.I., B. H. Deare, C.I.E., Sir G. G. Giffard, K.C.I.E., C.S.I., T. Grainger, C.B., G. F. A. Harris, C.S.I., H. Hendley, C.S.I., J. B. Smith, C.B., C.I.E.

Colonels: Sir H. E. Banatvala, C.S.I., P. F. Chapman, C.I.E., J. K. Close, J. Crimmin, V.C., C.B., C.I.E., J. Garvie, T. A. Granger, C.M.G., C. R. M. Green, A. J. Macdonald, C.B., C.M.G., J. J. Pratt, W. A. Quayle, H. A. Smith, C.I.E., T. Stodart, C.I.E., R. G. Turner, C.M.G., D.S.O., C. N. C. Wimberley, C.M.G.

Lieutenant-Colonels: A. Aleck, C.I.E., W. G. P. Alpin, O.B.E., J. Anderson, C.I.E., F. L. Blenkinsop, J. T. Calvert, C.I.E., W. V. Coppinger, D.S.O., D. G. Crawford, J. M. Crawford, O.B.E., C. D. Dawes, C. Donovan, C. Duer, C. A. Gill, J. D. Graham, C.I.E., J. A. Hamilton, C.M.G., C. T. Hudson, C.M.G., E. V. Hugo, C.M.G., J. G. Hulbert, C. H. James, C.I.E., S. P. James, J. G. Jordan, H. Kirkpatrick, J. C. G. Kunhardt, Clayton Lane, W. B. Lane, C.I.E., C.B.E., R. A. Lloyd, D.S.O., J. Masson, F. O. N. Mell, C.I.E., C. W. F. Melville, A. Miller, R. K. Mitter, T. R. Mulrony, F. O'Keefe, C.I.E., C.V.O., E. J. O'Meara, O.B.E., S. E. Prall, R. H. Price, N. Rainer, Sir J. R. Roberts, C.I.E., Sir L. Rogers, C.I.E., E. R. Rost, O.B.E., R. D. Saigol, W. S. J. Shaw, G. M. C. Smith, C.M.G., H. Smith, C.I.E., R. F. Standage, C.I.E., R. Steen, A. Street, C. Thomson, W. H. Thornhill, J. N. Walker, J. H. Tull Walsh, H. J. Walton, D. P. Warlicker, J. W. Watson, C.I.E., H. G. L. Wortabst, A. C. Younan.

Majors: H. C. Brown, C.I.E., A. Cameron, O.B.E., R. C. Clifford, D.S.O., M. C. T. A. Hughes, N. H. Ilume, R. B. Lloyd, C. R. Lynn, D.S.O., P. S. Mills, A. C. Munro, K. S. Thakur, A. A. Tresidder, R. T. Wells, M. F. White, O.B.E.

Captains: J. W. F. Albuquerque, P. Basu, G. Corvill, M. M. Khan, C. Melver, G. R. McRobert, D. R. Thomas.

The guests were representatives of the *British Medical Journal* and the *Lancet*.

## Medico-Legal.

### TUBERCULOUS INFECTION IN A HOUSE.

A RECENT judgement of Mr. Justice McCardie has an interesting medico-legal aspect. The lessor of a furnished house was mulcted in damages for the breach of an implied warranty that it was reasonably fit for habitation, the breach consisting of the fact that a person suffering from pulmonary tuberculosis had been living in the house up to six weeks before the lessee entered.

It appeared that the plaintiff, Mr. B. M. Collins, entered the house on October 26th, 1922, but on the following day he discovered that the husband of the defendant, Mrs. E. Hopkins, while suffering from pulmonary tuberculosis, had lived in the house until September 11th, 1922, when he went to Switzerland for treatment. The plaintiff at once repudiated the agreement of tenancy and quitted the house on the ground that it was infected with tubercle bacilli and therefore was not reasonably fit for habitation.

As Mr. Justice McCardie pointed out, no warranty of fitness is implied in the letting of an unfurnished house, though there is a statutory exception in respect of working-class dwellings. As to the nature and extent of this warranty in law, he cited two cases where the tenant had been held to be justified in repudiating the tenancy of a furnished house—in the first case because the house was infected by insects, and in the second case because the tenant had heard before his tenancy commenced on March 28th that a child suffering from measles had been living in the house from March 10th to March 19th. It will be observed that some nine days elapsed between the departure of the infected person from the house and the arrival of the new tenant in the measles case, whereas some six weeks elapsed between the departure of Mrs. Hopkins's husband from the house and the arrival of Mr. Collins, the new tenant in the case before Mr. Justice McCardie. In the measles case Mr. Justice Field held that the tenant was entitled to repudiate because (1) the best disinfecting processes had not been used, and (2) the house was not free from infection on March 28th. Mr. Justice McCardie spoke of the implied warranty as one "which tends to the public good and the preservation of public health," and one to be extended rather than restricted. Construing the phrase "fit for habitation," he said that in the case of unclean furniture, or defective drains, or a nuisance by vermin, there was not, as a rule, much difficulty. The eye or the nostrils could detect the fault and measure its extent. But in the case of a house lately occupied by a person suffering from an infectious disease the eye and other senses were of no avail. Yet a peril was none the less grave because it was hidden. Mere apprehension or dislike of a house because a person had died there of small-pox or scarlet fever was not sufficient. "Was there an actual and appreciable risk to the tenant, his family, or household, by entering and occupying the house in which the infectious disease had occurred?" The answer to this question depended upon (1) the nature of the disease; (2) the degree and persistence of its infectivity; (3) the date when the sufferer lived in the house; (4) the steps taken to prevent the risk of infection.

Speaking of the dangers of the tubercle bacilli, Mr. Justice McCardie said:

"I doubt whether the terrible prevalence of consumption in this country is fully realized. One person in seven dies from it. In recent years science has made rapid progress. Yet up to the day of the trial before me the medical profession had failed to find a serum that would prevent the assaults of infection or a drug that would kill the germs of the disease. Now what is the cause of this terrible measure of suffering and death from consumption? The answer is infection. It is clear that pulmonary tuberculosis in the adult (which causes nearly 80 per cent. of the deaths from all forms of tuberculosis) is the result of infection through direct or indirect contact with human beings already suffering from the disease. All infection is caused by tubercle bacilli. The sputum or other ejection from the mouth of the sufferer may fix on and adhere to the walls or the floors or carpets or rugs, curtains, cushions, bedding, coverings, or any kind of article. I feel no hesitation in coming to the conclusion that a large number of persons are infected by other means than personal association with those who suffer from the disease. If the sputum be allowed to dry, then the bacillus may preserve its virulence and capacity for six months. It can, however, be destroyed in a few days or even hours by open exposure to the direct rays of the sun, and several antiseptics are fatal to it. I should add that I am satisfied that if the bacilli are only exposed to the light and air of an ordinary room (that is, apart from direct sunlight) their life and danger may last for five or six months."

As we have seen, the last date on which the sufferer occupied the house was about six weeks before the date fixed for the entry of the plaintiff, and, as the learned judge accepted the evidence of one of the plaintiff's witnesses that the house was "one of the dustiest and dirtiest he had ever seen," thus negating the contention that it had been cleansed, and, added to this, was satisfied that "if the bacilli are only exposed to the light and air of an ordinary room their life and danger may last for five or six months," his conclusion follows: "that there was a substantial risk that the house and its contents were so infected with tubercle bacilli on October 26th, 1922, as to constitute an actual danger to the plaintiff and his household," and "to render it unsafe for occupation."

Mr. Justice McCardie commented upon the omission of the medical attendant, through an oversight, to notify the case to the medical officer of health. Also it was, said the learned judge, a matter of regret that after the husband's departure for Switzerland no doctor visited the house or gave any directions or advice as to the needs and methods of disinfection.

The duty of medical practitioners to notify tuberculosis is laid down in the Public Health (Tuberculosis) Regulations, 1912, Article V, whilst the duties devolving upon the medical officer of health upon the receipt of such notification are laid down in Article XII—that is, that he "shall make such inquiries and take such steps as are necessary or desirable for investigating the source of infection, for preventing the spread

of infection, and for removing conditions favourable to infection"

It may be presumed that if the medical attendant in this case had notified the disease, then the machinery set up by these Public Health (Tuberculosis) Regulations would have been put in motion, and the house and its contents cleansed and disinfected before the plaintiff entered into occupation.

#### PROSECUTION UNDER THE MEDICAL ACT.

A MAN named William Lumsden was charged before the Bradford stipendiary magistrate on June 15th, on seven summonses, with falsely pretending to be a bachelor of medicine. Defendant pleaded guilty. According to the *Yorkshire Post* of June 16th, Mr. Ross Pashley, who prosecuted on behalf of the Director of Public Prosecutions, said that the defendant had been a medical student at Edinburgh, but did not pass his final examination. From 1913 to 1915, representing himself to be a registered medical practitioner, he acted as locumtenent to a medical practitioner in Bradford. He then went to sea as a surgeon. In 1916 he applied to the General Medical Council for a certified copy of the entry in the *Register* of William Lumsden (a registered medical practitioner who had no connexion with defendant). As the General Medical Council had at that time no specimens of signatures of practitioners registered in Scotland, a copy of the entry was sent to the defendant. From 1920 to 1923 he again acted as locumtenent in Bradford, and had signed seven death certificates, putting his qualification as M.B. When interviewed by a detective he produced the certified copy of the entry which he had obtained from the General Medical Council. Mr. Pashley pointed out that the case was serious, because of the danger to the community. The stipendiary magistrate said that it was of the first importance that death certificates should be given by properly qualified and registered persons. He imposed fines and special costs amounting to a total of £106 15s.

Dr. William Lumsden, M.C., M.B., C.M. Aberdeen, D.P.H. St. Andrews, of Darlington, is the only William Lumsden whose name appears on the *Medical Register*. Dr. Lumsden qualified at Aberdeen University in 1897, and served with distinction in the war, in France, and at Salonica, being awarded the Military Cross. He is anxious that his friends should know that he has no association with the person charged at Bradford, who in fact seems to have attempted to personate him.

### Universities and Colleges.

#### UNIVERSITY OF OXFORD.

At a congregation held on June 21st the degree of Bachelor of Medicine (B.M.) was conferred on C. R. Lane.

#### UNIVERSITY OF CAMBRIDGE.

At a congregation held on June 19th the following medical degrees were conferred:

M.D.—A. A. Prichard, W. T. Beswick.  
M.B.—F. E. Higgins.  
M.B., B.Ch.—J. G. Drew, W. F. T. Adams.

The following candidates have been approved at the examination indicated:

THIRD M.B., B.Ch.—Part I (*Surgery, Midwifery, and Gynaecology*): J. C. Ainsworth, Davis, P. E. Bardsley, B. Broadbent, J. T. Burrell, N. E. Chadwick, W. E. F. Davidson, G. S. W. Evans, M. W. H. Evans, L. S. Fry, T. S. Goodwin, C. J. P. Grosvenor, H. E. Harris, G. T. Henderson, E. G. Holmes, J. W. W. Jeps, A. H. Johns, L. P. Lockhart, C. A. Lupton, R. J. Lythgoe, G. C. Millie, A. C. Mowle, E. B. Murrell, L. R. W. Price, R. J. V. Pulvertaft, J. Russell, C. E. G. Smith, R. W. Smith, J. D. M. Stewart, J. H. G. Thompson, E. R. Weaver, Adams, M. H. Webb-Peploe, R. Whittis, L. E. H. Whitby, R. N. P. Wilson. Women: G. M. Brown, M. F. Kennedy. Part II (*Medicine, Pathology, and Pharmacology*): B. Broadbent, E. B. Brooke, G. H. Cniger, B. H. Cole, G. K. Cooper, E. J. Crisp, W. E. F. Davidson, W. Edwards, L. E. Frazer, L. B. Hartley, L. Lavan, A. G. Story, C. Sturton, E. Tagoe, C. G. Taylor, G. D. Thomson, A. S. H. Walford, L. E. H. Whitby, R. N. P. Wilson. Women: M. E. Kennedy.

#### UNIVERSITY OF LONDON.

At a meeting of the Senate held on June 20th Mr. H. J. Waring, M.S., F.R.C.S., was re-elected Vice-Chancellor for the year 1923-24.

Professor Frederick Wood Jones, D.Sc., M.B., B.S., was appointed as from September 1st next to the University Chair of Anatomy tenable at St. Bartholomew's Hospital Medical College. He has been Demonstrator in Anatomy at the London Hospital, Senior Demonstrator and Lecturer in Anatomy at Manchester, and Senior Demonstrator in Anatomy at St. Thomas's Hospital, and head of the Department of Anatomy at the London School of Medicine for Women. Since 1919 he has been Professor of Anatomy in the University of Adelaide.

Mr. R. J. S. McDowall, M.B., Ch.B., D.Sc., was appointed as from August 1st next to the University Chair of Physiology tenable at King's College. During the war he served in the R.A.M.C. with the Egyptian Expeditionary Force. He has been Lecturer in Physiology at Edinburgh, and since 1921 he has been Lecturer in Experimental Physiology and Experimental Pharmacology at Leeds.

Mr. Gilbert Stead, M.A., was appointed as from August 1st next to the University Readership in Physics tenable at Guy's Hospital Medical School.

#### UNIVERSITY OF DURHAM.

THE following candidates have been approved at the examination indicated:

THIRD M.B., B.S.—*Materia Medica, Pharmacology and Physiology; Public Health; Medical Bacteriology*: C. C. Schofield, C. W. Arnot, D. R. F. Bertram, F. H. Blackburn, A. Brodie, J. Brown, A. Charlton, Nora E. Coleman, N. Davidson, J. W. Dickinson, D. Ewart, J. T. Garson, A. Gray, J. T. Holliday, A. H. Holmes, S. Hughes, Marjory G. T. Jacko, M. H. Jones, B. Kaplansky, H. Levy, F. Lishman, D. W. McLaren, R. A. Pallister, Ethel G. Potts, A. Purvis, S. C. Stouler, W. Toward, W. S. Walton, R. Wear, J. Y. Woodhouse.

\* Second class honours.

#### UNIVERSITY OF MANCHESTER.

THE Council, on June 20th, appointed Mr. H. S. Raper, C.B.E., D.Sc., M.B., Ch.B., as Brackenbury Professor of Physiology and director of the physiological laboratories as from September next. Dr. Raper is at present professor of physiology and biochemistry in the University of Leeds. During the war he was engaged in research work on protection against poison-gas, and from 1918 was head of the Anti-Gas Department, with control of the factories in which respirators were made.

The Council have accepted with regret the resignation of Dr. A. M. Mitchell, lecturer in vaccination.

The following appointments have been made: Clinical Lecturer in Ophthalmology, Mr. T. M. Bride; Assistant Lecturer in Anatomy, Dr. David Stewart; Demonstrators in Anatomy, Dr. G. V. Ashcroft, and Miss Eugenia R. A. Cooper, M.B., Ch.B.

Dr. W. H. Wood has been appointed Tutor and Secretary to the Faculty of Medicine.

#### UNIVERSITY OF LEEDS.

DR. JOHN KAY JAMIESON, Dean of the Faculty of Medicine and Professor of Anatomy, University of Leeds, has been appointed Pro-Vice-Chancellor of the University for two years, in succession to Professor Smithells.

#### UNIVERSITY OF BRISTOL.

THE following candidates have been approved at the examinations indicated:

FINAL M.B., Ch.B.—*Part I, including Forensic Medicine and Toxicology*: E. R. Clutterbuck, E. B. Eadie, J. A. James, F. G. Jenkins, F. Langford, G. S. Mundy, A. S. Prowse. *Part I only*: R. H. Dammitt, K. F. Platt. *In Forensic Medicine and Toxicology only*: Helen M. Dixon. *Part II*: \*F. H. Bodman, \*Constance L. Griffiths, Dorothy Staley, Idris Williams.

\* With second-class honours.

#### UNIVERSITY OF GLASGOW.

AT the summer graduation ceremony which took place on June 21st a number of distinguished graduands were presented for honorary degrees in various departments. Amongst those who received the degree of LL.D. (*honoris causa*) from the Principal, Sir Donald MacAlister, were the following members of the medical profession: Sir Walter Morley Fletcher, K.B.E., D.Sc., M.D., F.R.C.P., F.R.S., Secretary of the Medical Research Council; Graham Lusk, Ph.D., D.Sc., F.R.S.E., Professor of Physiology in Cornell College, New York; Andrew Maitland Ramsay, M.D., F.R.F.P.S.G., ophthalmic surgeon, Glasgow, and formerly lecturer in diseases of the eye in the university.

The following degrees were also conferred:

M.D.—\*Grace H. Anderson, †J. B. D. Galbraith, †B. S. Nicholson, †Lydia I. H. Torrance, C. Averill, A. D. Blakely, L. L. Fyfe, A. Macphail, J. M. Melvin, G. W. Ronaldson.

\* With honours. † With high commendation. ‡ With commendation.

#### UNIVERSITY OF DUBLIN.

##### TRINITY COLLEGE.

AT the later summer commencements in Trinity Term, held on June 23rd, the following degrees were conferred:

M.D. (*honoris causa*)—W. J. Mayo, E. Hastings Tweedy.

M.D.—H. H. James, G. Fitz M. Keatinge.

M.B., B.Ch., B.A.O.

Mr. A. A. Darlington, R. A.

M. A. Downing,

Mr. S. D. Gab

Grobler, H. L. Hanna, L. Herman, R. J. Hill, W. T. Hogan, W. E.

Hutchinson, R. T. Jackson, M. Jaffe, H. Kohlberg, J. Kruser,

LICENTIATE IN MEDICINE, SURGERY, AND OBSTETRICS.—W. L. Duncan.

#### ROYAL COLLEGE OF SURGEONS OF ENGLAND.

AT the recent primary examination in anatomy and physiology for the Fellowship 134 candidates presented themselves, of whom 42 were approved and 92 were rejected. The following are the names of the successful candidates:

W. S. Adams, R. M. Ainsworth, G. Armitage, R. M. Bates, C. E. Beare, C. M. Brodie, C. J. O. Brown, C. M. Carruthers, J. Carver, E. T. Cato, Violet H. Comber, C. H. Corbett, J. Dreman, Georgiana M. Duthie, N. L. B. V. Eckhoff, J. T. Fathi, R. A. Fitzsimons, S. J. P. Gray, R. John, P. J. Jory, C. A. King, P. Metcalfe, B. S. Nat, J. B. Oldham, G. H. Pfeiffer, R. Pilot, L. S. Pot, Seddon, H. R. Sgar, Beatrice G. Smith, H. B. Stallard, F. H. A. Walker, C. A. Wells, and E. F. Wilson.

## Medical News.

THE Albert Medal of the Royal Society of Arts has been awarded in duplicate to Major-General Sir David Bruce, K.C.B., D.Sc., LL.D., F.R.C.P., F.R.S., and to Colonel Sir Ronald Ross, K.C.B., K.C.M.G., D.Sc., LL.D., M.D., F.R.C.S., F.R.S., in recognition of the eminent services they have rendered to the economic development of the world by their achievements in biological research and the study of tropical diseases.

STATISTICS of the sanitary conditions among the Jews in Russia and an account of the activities of the O.Z.E. (Society for Preserving the Health of the Jews) were given by Dr. M. Schwartzman at a recent meeting of Jewish doctors at Jews' College. The civil war and the social revolution resulted in complete economic ruin, in which the Jews were the principal sufferers. The rate of mortality was computed at 80 per 1,000, and in some places it reached 150-200 per 1,000. The rate of births sharply declined. Dr. Schwartzman's address had for its object the stimulation of interest in the O.Z.E. organization. Started before the war with the object of stemming the effects of economic and political persecution on the physique of the Jewish masses, it had established before the revolution a network of institutions, hospitals, sanatoriums, open-air colonies, and the like, and had developed physical culture and sanitary education. Between 1914 and 1918 the O.Z.E. was at work in 218 localities, had 105 hospitals and 190 sanitary establishments, and was taking care of 90,000 children. The budget of the O.Z.E. in these three years exceeded £500,000. A resolution was passed to establish in London an organization in support of the O.Z.E. Mr. A. H. Levy, F.R.C.S., was elected chairman of the committee which will be in charge of the work of the organization. Dr. Redcliffe N. Salaman, who presided at the meeting, read a number of messages containing expression of support and sympathy. Among these were letters from Lord Robert Cecil, Mr. Ramsay MacDonald, Sir Sydney Russell-Wells, Sir Frederick Mott, Dr. Charles Myers, and Professor Zeligman.

THE annual meeting of the Dutch Pediatric Society was held at Groningen on June 9th and 10th, when the following papers were read: Etiology and clinical aspects of rickets, by J. Haverschmidt; pathogenesis of rickets, by J. Gorter; lipodystrophia progressiva and osteopsathyrosis, by E. S. Frank; the result of the Albee-Halsted operation, by G. J. Hoet; treatment of pertussis by vaccine, by J. H. van der Starp; and two cases of leukaemia, by B. E. J. H. Becking.

ACCORDING to the annual report for 1922 of the Manchester Babies' Hospital, 253 children were in the hospital during the year. The greatest number of admissions was in the fourth month, and over 50 per cent. of admissions of all cases under one year were in the third, fourth, and fifth month. Of the 206 cases discharged during the year, 142 were discharged improved in health, 6 were discharged on transfer to other hospitals, 14 for other reasons, and there were 44 deaths. Nursing mothers were established in the hospital for the first time during the year, and it was found that they yielded from 27 to 31 oz. of milk a day in addition to their own children's feeds. During the previous four and a half years only 22.2 per cent. of premature infants had survived; since the employment of nursing mothers 64.7 per cent. of the premature infants fed lived.

A STUDY tour—the seventeenth *Voyage d'Études Médicales*—will take place under the direction of Professor Paul Carnot and Dr. Rathery, of Paris, from September 9th to 22nd. In fourteen days visits will be made to the Jura spas (La Mouillère, Salins-du-Jura, Divonne), the Swiss universities of Geneva and Lausanne, the Savoy spas (Evian and Thonon, Chamonix, Saint-Gervais, Annecy, Aix-les-Bains, Le Revard, Challes, Allevard, Moutiers-Salins, Brides, Pralognan), and the Dauphiné spas (Uriage, Grenoble, and Saint Pierre de Chartreuse, La Motte-les-Bains, La Grave and Le Lautaret). The party will break up on September 22nd at Lyons, after visiting the school of medicine there. This study tour is

exclusively reserved for medical practitioners and medical students; they can, however, up to 15 per cent. of the total, be accompanied by their wives or one of their daughters. The cost of the journey, from the meeting place, Besançon, to the breaking-up place, Lyons, is 790 francs, including all expenses. A 50 per cent. reduction will be granted on the French railways from the frontier station to Besançon, and a similar reduction from Lyons back to the frontier station. Further information may be obtained from Madame Juppé-Blaise, representative of the French spas, at the French Touring Office, 56, Haymarket, S.W.1.

The annual meeting of the Medico-Psychological Association of Great Britain and Ireland will be held under the presidency of Dr. E. Goodall at the house of the Medical Society of London, 11, Chandos Street, Cavendish Square, W.1, on July 9th, 10th, 11th, 12th, and 13th.

The Council of the Royal Institute of Public Health has accepted invitations from the mayor and the University of Bordeaux to hold its annual meeting there at Whitsuntide next year. The president will be Viscount Burnham, and the local honorary secretaries, Professor René Cruchet, professor of medicine in the University of Bordeaux, and M. G. Faure, treasurer of the Chamber of Commerce. The meetings will take place in the University. Special arrangements are being made for travelling and hotel accommodation.

DR. S. J. CLEGG, on leaving the post of deputy medical officer of health for Newcastle to take up the duties of medical officer of health for Durban, South Africa, has been presented by his colleagues in the Newcastle Health Department with a pair of binoculars. Dr. Clegg has also received a silver inkstand from the members of the 50th (Northumberland) Sanitary Section, of which he was commanding officer in France.

#### ERRATUM.

READERS of the JOURNAL are asked to substitute the following for the last seven lines of the paragraph beginning "The remainder of this absorbing report" in the issue of June 9th (p. 988, col. 2):

the whole more efficacious than the mercury vapour lamp or cod-liver oil, especially as regards improvement in general health; but there was an impression that the addition of cod-liver oil to open-air treatment accelerated cure (p. 84). It is important to note that excellent conditions of hospital hygiene in winter, with a diet of high calorie value (Diet I), did not effect a cure of rickets.

## Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, Aitiology, Westrand, London; telephone, 2630, Gerrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate, Westrand, London; telephone, 2630, Gerrard.
3. MEDICAL SECRETARY, Mediscra, Westrand, London; telephone, 2630, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus, Dublin*; telephone, 4737, Dublin), and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: *Associate, Edinburgh*; telephone, 4361, Central).

#### QUERIES AND ANSWERS.

"T. P. G." asks for advice in the treatment of a married woman (2-paral), aged 45, who is troubled with a constant sensation of "fluttering" down the course of the left sciatic nerve from the thigh to the calf. There is no pain. It is worse at night, especially if she is tired. Blisters have been tried without benefit.

#### INCOME TAX.

"I. N." who holds a resident appointment at a sanatorium, inquires (a) whether the cost of removal from one sanatorium to another is an admissible expense, and (b) what allowance can be

claimed for the use of his car for the purpose of attending committee meetings.

\* \* (a) Nothing is legally due if the removal arises from a change in the appointment held. The expense could be claimed if the removal were from one sanatorium to another of the same authority by that authority's direction. (b) No allowance is due for the initial cost of the car—which represents capital outlay—but assuming that attendance at the committee meetings is a part of his duties, "I. N." can deduct the amount of the expense necessary—that is, if he were to go by car, train, tram, etc.—as included in the total cost of running the (private) car.

#### LETTERS, NOTES, ETC.

##### MEDICINE AND MEDICINES.

DR. JAMES GARDNER (Burnley) writes: From your review of it Dr. Harry Roberts's book, *A National Health Policy*, must be interesting and worth reading, and I shall get it and read it during my holiday. Your reviewer gives one quotation—"Nine out of every ten bottles of medicine prescribed are entirely useless to the persons taking them, and are known to be useless by the doctors who prescribe them." How does Dr. Roberts know this to be true? He cannot be so intimate with other doctors' practices to know the results of their prescriptions, and if the statement be true of the practice carried on by him and his partners he should say so and not make the sweeping assertion quoted in your review. The matter does not end here, because drugs are noxious articles and cannot pass harmlessly through the body; if they are not useful they are not merely useless but harmful, and a corollary to Dr. Roberts's statement must be that nine out of every ten bottles of medicine are harmful—minus the mere placebos. This is serious from two points: (1) Public finance; (2) our system of therapeutics.

(1) There are 14,000,000 insured persons, and the drug bill is between 1s. 6d. and 2s. per insured person. At 2s. the bill is £1,400,000, and nine-tenths of this amount is £1,260,000, spent on useless and harmful drugs. Or if the figure is 1s. 6d., the amount spent uselessly and harmfully is £945,000. Comment is superfluous.

(2) Dr. Roberts's statement is an indictment of our system of therapeutics. If nine-tenths of our prescriptions are useless, whose is the fault? Our teachers', or ours individually? Some years ago the Royal Colleges in London cut pharmacology out of their examination. Has it been reinstated, or do the Colleges still disbelieve in it? The subject is still taught in universities, but for what purpose should students spend time over a subject if nine-tenths of it be useless, not to say harmful? We talk of the honour and dignity of the profession, and yet we go on prescribing and outwardly professing our faith in the healing virtue of drugs we know to be harmful; to my mind, there is neither honour nor dignity in us if the assertion be true.

Is our system of therapeutics at fault, or have we any system at all? It certainly behoves us to reconsider our position, both on account of the financial aspect and "for the honour and dignity of the profession."

\* \* The curriculum of the Conjoint Board in England has for many years past included a course of pharmacology and therapeutics; therapeutics was specified as one of the final examination subjects, but pharmacology was included under the head of medicine and therapeutics. In 1919 pharmacology was grouped with materia medica as Part II of the second professional examination of the Board, leaving therapeutics only to be included under medicine in the final examination. It would appear, therefore, that pharmacology has never ceased to be a part of the curriculum but has been a subject of examination with materia medica since 1919.

#### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 32, 33, 36, 37, and 38 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 34 and 35.

A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 285.

#### SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Six lines and under	...	...	0 9 0
Each additional line	...	...	0 1 6
Whole single column (three columns to page)	...	...	7 10 0
Half single column	...	...	3 15 0
Half page	...	...	10 0 0
Whole page	...	...	20 0 0

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, W.C.2, not later than the first post on Tuesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive *poste restante* letters addressed either in initials or numbers.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## MEDICINE.

### 1. Treatment of Scarlet Fever by Injection of Convalescents' Serum.

R. DEBRÉ and J. PARAF (*Paris méd.*, November 4th, 1922, p. 418), who record a case of severe scarlet fever in a girl aged 5 years successfully treated by this method, state that Weisbecker in 1897 was the first to employ injections of convalescents' serum in the treatment of scarlet fever. His example was followed by Huber and Blumenthal, von Leyden, Rumpel, and Scholz, all of whom gave only small quantities of serum and often only a single injection. The results varied and no definite conclusion could be drawn. The treatment was therefore abandoned until 1912, when Jungmann and Reiss employed the method again in a modified form. Relatively large doses (50 to 60 c.cm.) were given, usually intravenously, and repeated three or four times. The results were very favourable, and were confirmed by other observers, such as R. Koch, Reiss and Herz, A. Zingher, Schulz, Griesbach, Kling and Widfeld, Weaver, and Mironesco and Sager. The authors' conclusions are as follows: The serum of convalescents is indicated in the treatment of scarlet fever. It should be employed at the onset of the disease, as it does not appear to have any effect on the secondary complications. The serum should be injected intramuscularly and subcutaneously as well in doses of 40 to 50 c.cm., and the injections should be repeated the following days in the same or slightly smaller doses (30 to 40 c.cm.). Intravenous injections, which may give rise to shock, should not be employed except with great care and in cases where the prognosis appears hopeless otherwise. Three facts stand out against the treatment being of a specific character. In the first place Zingher employed injections of the citrated blood of normal individuals with success in malignant scarlet fever, although it is true the favourable action appeared to be less marked than with convalescent serum. Secondly, convalescents' serum does not produce the Schultz-Charlton extinction sign more readily than does the serum of normal individuals. Lastly, the injection of convalescents' serum does not have any definite action on the eruption of patients treated by this method.

### 2. Infective Myocarditis and Cardiac Failure.

R. LAUTIER (*Arch. des Mal. du Cœur des Vaisseaux et du Sang*, October, 1922, p. 686) observes that if the symptomatology of cardiac failure is well known, its etiology in many cases is still obscure. He divides cardiac failure into two classes—(1) active and (2) passive. Cases in the former class result from physical or mental overwork or from some circulatory obstruction within or outside the heart which the myocardium cannot overcome—for example, valvular lesions, certain arrhythmias, and raised blood pressure. In the latter class, cardiac failure results from myocardial degeneration, fatty, fibrous, or toxic. Clinically, both forms may be present in the same patient. The author quotes three typical cases, and emphasizes the fact that treatment may at first produce improvement, but this is only transient, slight dyspnoea persists, and sometimes a few râles at the bases of the lungs, the improvement disappears and further treatment is useless. Lautier states that in this particular type the patient appears to be in good health; the onset is rather sudden, though the patient may be aware of some previous cardiac lesion. There is more or less severe anaemia, due to reduction of the number of red corpuscles and of the haemoglobin content. Leucocytosis may be slight or may rise to a count of 25,000, chiefly polymorphs. There is slight fever with morning remissions; the temperature curve is irregular and uninfluenced by antipyretics. The heart's action is tumultuous and irregular, there may be tachycardia, arrhythmia with extra-systoles, or total arrhythmia. These three symptoms in combination indicate an infection, which may be confined to the myocardium, or in cases of acute rheumatism may invade the endocardium or pericardium. When these alone are invaded few subjective symptoms occur, and they produce only insignificant disturbance of the circulatory equilibrium. Conversely, when the myocardium only, or with endocardial and pericardial complications, is attacked great circulatory disturbance follows immediately, owing to reduction of the functional power of the myocardium. This sudden invasion of the myocardium is very common, and rarely extends to the endocardium or pericardium. The author has performed autopsies in many of these cases. Some show signs of old healed endocarditis, but he has not found any evidence of

active endocardial lesions. Others had perfectly healthy endocardium and valves intact. The author discusses rheumatic infections, and emphasizes the fact that he has seen a large number of these infective cases with no rheumatic history, in which the myocardium alone was involved. In rheumatic cases he has had remarkable results from vaccine therapy, either alone or combined with salicylate treatment. In "infective passive cardiac failure" he has had no permanent good results from this treatment. He thinks that hexamethylenetetramine, given intravenously in daily doses of 25 to 50 cg., has definite action on the infection, but it is often necessary to continue it for months. Cardiac tonics are also indicated, but the physician must be guided by clinical symptoms. The author prefers powdered digitalis leaves to digitalin. In syphilitic cases specific treatment requires great caution on account of the dangers of arsenobenzol, and even of mercuric cyanide in these cardiac cases. Quinine and quinidine are very dangerous and lead quickly to a fatal termination. The author observes that careful dietetic treatment should be combined with the treatment recommended above, and that success will depend largely upon the commencement of such treatment at an early stage of the disease, before the patient's strength is exhausted.

### 3. Urinary Infection.

A. S. ROE (*Med. Journ. of Australia*, October 14th, 1922, p. 433) considers that absorption of bacteria into the blood, obstruction to the urinary outflow, and disturbances in metabolism producing a highly irritating urine, are the three factors concerned in the production of urinary infection. While these may operate either singly or in conjunction, the last appears to be the most important from the point of view of preventive medicine. In the majority of cases the urine is definitely acid, while fatigue is a prominent factor in determining an attack, and the disturbance in metabolism, by producing a highly irritating generally acid blood, impairs kidney efficiency and lowers resistance. The elimination of bacteria which have been absorbed into the blood from such foci as the bowel, teeth, tonsils, pelvis, etc., also takes place through the already damaged kidneys, producing still further damage, with a resulting renal infection. Similar infection also follows from the presence of bacteria alone if there is obstruction to the urinary outflow from stricture, stone, prostatic disease, etc., though in obstinate cases foci of infection must be sought for as well. The physiological conditions tending to cause disturbances in metabolism are those associated with deficiencies in diet, disorders of internal secretions connected with pregnancy, puberty, and the climacteric, and physical or mental disturbances resulting from fatigue.

### 4. Conservative Treatment of Pneumonia.

E. E. CORNWALL (*New York Med. Journ. and Med. Record*, November 15th, 1922, p. 563) describes the treatment of pneumonia on conservative lines as adopted by him during the past ten years. The main features are: (1) The provision of fresh air with protection from exposure to cold when the temperature falls, and with no definite treatment for fever beyond tepid sponging if excessively high; (2) a fluid lacto-vegetarian diet on the general lines of two pints of milk to one of barley water daily, 9 oz. of orange or grape fruit juice, 2 oz. of lactose, 1½ drachms of sodium bicarbonate, and half a drachm of calcium chloride in addition to the salts in the food, and over 90 oz. of water; (3) avoidance of cathartics and enemata during the acute stage; (4) heart stimulation only when needed, but when so needed in the later stages given freely; and (5) conservatism in the relief of distressing and dangerous symptoms—opiates, expectorants, and sedatives being employed only in exceptional cases. In a series covering five and a half years in which such treatment was adopted, and including cases moribund when admitted, statistics show a mortality of 18.8 per cent., as compared with 30.6 per cent. in a previous series of less conservative treatment, especially as regards the diet and the avoidance of catharsis; of 70 cases during 1921 the mortality rate was 13.2 per cent., and the average duration of the fever 8.1 days. The diet should be changed to suit conditions, being reduced to barley water, salts, lactose, and fruit juice, or to water and salts alone should tympanites and diarrhoea or critical conditions arise; the fluid intake is restricted in the face of great cardiac weakness. Tympanites was observed less frequently than when routine catharsis is practised, and the bowels may remain unmoved for several days without untoward results and with apparent safeguarding

against dangers which threaten from the alimentary canal. Of cardiac stimulants, strophanthus, strychnine, and caffeine are the best, but in by no means every case are they required, and in children but seldom.

#### 5. Atophan Poisoning.

K. SCHROEDER (*Ugeskrift for Læger*, September 7th, 1922, p. 1141) has found atophan of great value not only in uric acid diseases, but also in sciatica, lumbago, and neuralgia, and even when salicyl preparations have failed the action of atophan has often been prompt. But he regards it as a dangerous drug which ought not to be sold without a prescription. He records seventeen cases of atophan poisoning, the most prominent symptoms being an urticarial eruption with or without oedema, albuminuria, fever, headache, general malaise, and gastro-intestinal disturbances. In two cases there were also cardiac symptoms. The gastro-intestinal symptoms, as well as the renal symptoms, may be mitigated by giving the drug with sodium bicarbonate and with plenty of water, and the rash and other symptoms are best treated with a calcium salt. The patient should always be under close medical observation in order that the drug can be instantly discontinued at the first sign of poisoning. The author has seen symptoms of poisoning even when he began cautiously with 0.5 gram three times a day, increasing the daily dosage by 0.5 gram every day till a dosage of 0.5 gram six times a day was given.

#### 6. Treatment of Syphilis with Bismuth.

H. MÜLLER (*Ugeskrift for Læger*, November 9th, 1922, p. 1547) has received from Professor Levaditi a supply of potassium and sodium tartro-bismuthate (trépol), and has administered it to twenty-five cases of syphilis in Mainz. Every adult was given 2 grams by intragluteal injection, care being taken to introduce none of the drug into a blood vessel. The injections were repeated every fourth or fifth day, each case being given approximately ten injections. The response of the symptoms was more prompt to trépol than to injections of calomel, and was as satisfactory as to silver-salvarsan; but while this drug banishes the spirochaetes from the primary lesion in twenty-four hours, trépol took about three days to do so. The clinical results were as satisfactory in tertiary as in primary and secondary syphilis, and albuminuria was never observed. It was, however, almost impossible to avoid a narrow bismuth line in the gums, resembling the lead line. This bismuth line could be disregarded provided the teeth were in a healthy state; otherwise it was apt to be the precursor of stomatitis. The Wassermann reaction did not become negative as soon as after silver-salvarsan or a combination of mercury with salvarsan. The author's verdict is favourable, and he urges the clinical trial of this drug on a large scale.

#### 7. Differential Diagnosis of Lobar Pneumonia and Appendicitis in Children.

A SERIES of 145 cases of lobar pneumonia in children, aged from 2 to 15, have been studied by F. D. ADAMS and B. J. BERGER (*Journ. Amer. Med. Assoc.*, November 25th, 1922, p. 1809) to determine the most common sources of error in diagnosis, and the signs and symptoms in early pneumonia which are of the greatest value in reaching a correct diagnosis. For purposes of comparison a series of 63 cases of proved appendicitis have been reviewed. Of the cases of lobar pneumonia, 17.5 per cent. had at one time or another been wrongly diagnosed as acute appendicitis or surgical condition of the abdomen, and 4.8 per cent. as cerebro-spinal meningitis. The authors stress the fact that a history of cough or pain in the chest points toward a diagnosis of pneumonia, but absence of respiratory symptoms does not rule out this disease. A history of vomiting, abdominal pain, and diarrhoea is of no value, as these occur as frequently in pneumonia as in abdominal conditions. The pneumonia patients always seem more ill and present a characteristic general picture not seen in the abdominal cases. If recognized, this is a very important differential point. Pneumonia patients show much more of a systemic reaction, as seen by pulse and temperature chart, than do the abdominal cases. Careful examination of the lungs will frequently reveal a small area suggesting early solidification; but if it is located in the upper half of the chest; or in patients who do not otherwise present the picture of pneumonia, it must be interpreted with caution. Abdominal tenderness and spasm are relatively frequent in pneumonia, but are of a type unlikely to be found in acute abdominal conditions. A high leucocyte count favours the diagnosis of pneumonia, except when peritonitis or appendix abscess is suspected, in which case it is of no value in differentiating the condition from pneumonia. In the presence of symptoms or signs of meningial irritation, lobar pneumonia should be ruled out before lumbar puncture is done.

## SURGERY.

#### 8. Oesophageal Achalasia.

D. M. GREIG (*Edinburgh Med. Journ.*, November, 1922, p. 217), in dealing with cardiospasm, considers that three factors are of importance—namely, the anatomical, the physiological, and the pathological. Recent work shows that the oesophagus is a potential sphincter, but possesses no anatomical sphincter at its lower end. The oesophageal opening in the diaphragm is not modified by the movement of the diaphragm, and retains an unvarying diameter; beyond being the aperture through which the oesophagus passes it has little relations to it. The oesophagus receives its nerve supply from the vagi and the mediastinal sympathetic, but it must be realized that, in common with the lungs, it has a parasympathetic supply from the bulbar area. These anatomical facts must be borne in mind before the physiological question can be approached. The oesophagus contains both striated and non-striated muscle, yet there is no evidence that the former can be contracted voluntarily. The oesophagus has tonus, and is always in a state of tonic contraction ready for the reflex act of swallowing. It is doubtful if the oesophagus ever contains air; the tonus of the muscle is sufficient to maintain the tube gently closed. In all varieties of oesophageal obstruction the essential feature is dysphagia; in congenital deficiency the anatomic structure is at fault, in all others it is the function that is deranged. The crucial factor in spasmodic obstruction must be the innervation of the muscles. In achalasia there is a condition of hypertonus or difficulty in relaxation of the muscle; this may be due to some local cause, as undue stimulation from the oesophageal lumen. The oesophagus is a sphincter, and relaxation takes place in advance of the bolus as part of the correlated action through the oesophageal nerves. When a want of balance is set up a localized achalasia results, and it is not the muscles that are primarily at fault but the nerves. Analogous conditions are found in the intestinal tract and in congenital idiopathic dilatation of the colon. Here there is limitation to one portion of the bowel, as the affection may be limited in the oesophagus.

#### 9. Spontaneous Cure of Cancer.

RONCALI (*Annali Ital. di Chirurg.*, August 30th, 1922, p. 484) concludes his careful study of cases of so-called cure of cancer, either without or with only limited partial surgical treatment, and he states that those cases which are cured spontaneously cannot, in the light of rigorous criticism, be accepted as true cancer. Of the cases which seem cured after partial operation, it is necessary to distinguish those which go on to complete and definite cure (such as simple infiltration of the chorionic villi) from those which only reach a temporary and not a lasting cure. As an exceedingly rare exception some epithelial cancers have been known to get well (and usually where no surgical intervention has taken place), but such cases are very rare and even at the best perhaps doubtful. Even if it is granted that such cure may take place, it is only likely to occur in the chronic forms and not in the acute types with embryonal cells—for example, chorion-epithelioma. Spontaneous cure is still more unlikely in the case of metastatic growths. A bibliography of about 100 references is given at the end of the paper.

#### 10. Correction of Squint by Muscle Recession.

P. C. JAMESON (*Arch. of Ophthalmol.*, September, 1922, p. 421) records experience of 56 operations for the correction of (with two exceptions) internal concomitant squint by recession without advancement, with deep scleral suturing short of perforation. The muscle is freely exposed through a conjunctival incision following the curve of the semilunar fold with its centre corresponding to the caruncle, and, after being completely separated from the globe, and its capsular continuity severed above and below by incisions carried back beyond the equator, it is transplanted and fixed by a method of safe scleral suturing to the exact position required. In the technique of introducing the sutures it is important that the bend of the needle after counter-puncture and of the suture after it has been drawn should be distinctly seen in their entire continuity through the translucent sclera, the motion employed being similar to that used in picking up the fibres of a thick linen handkerchief bent over the finger without pricking the finger. Three sutures are used, the first being introduced from without the conjunctival lip nearest the caruncle perforating the outer surface of the muscle just below the centre. In order further to ensure its hold the needle is passed through the muscle from the under side above its first perforation and brought out on the upper side, the thread being looped round the thread of the first perforation. The sutures are continued through the sclera and brought out through the lip of the

conjunctiva nearest the cornea. The two remaining sutures are carried in a parallel course about 3 mm. above and below the centre one, and when they are all tied the muscle is firmly held in its new position and the conjunctival opening closed. By leaving the sutures sufficiently long to be held loosely by an adhesive strip to the bridge of the nose, their removal in a week is facilitated by abducting the eye by making traction on them and so bringing the knots into view. Any ultimate retraction of the caruncle is negligible. By this method convergence is safeguarded, and its corrective capabilities are extensive and uniform, so that a single recession of 5 mm. will correct a deviation of 25 degrees in a large percentage of cases.

#### 11. Prophylactic Injection of Glucose in Major Operations.

B. TENCKHOFF (*Zentralbl. f. Chir.*, October 7th, 1922, p. 1472) remarks that every surgeon has lost patients after severe operations in spite of perfect technique and normal healing of the wound, owing to damage to the internal organs, especially the heart, lungs, liver, and kidneys. More frequent still are the cases which survive but with permanent damage to these organs. Operative shock and the long duration of the anaesthesia are rightly incriminated, and it is not always the apparently most hopeless or weakest cases which succumb. It is not surprising to find a fatal issue in patients who at the time of the operation presented signs of heart failure or an imperfect circulation, but many of the cases have occurred in patients who have shown no signs or symptoms of cardiac disease. It is in such patients especially that Tenckhoff has found that the prophylactic intravenous injection of 10 c.cm. of a 10 per cent. solution of glucose on the evening before a major operation is of value. The only unpleasant results were a feeling of chilliness and shivering and occasionally a rigor. The good results of the injection were shown by the pulse not becoming rapid, weak, or small after the operation, as so frequently occurs, but remaining slow, strong, and of good tension—an indication that the injection has acted not only on the heart but also on the peripheral part of the circulation. This good effect lasts two to three days and tides the patient over the most dangerous period. The injection also appears to diminish or entirely prevent the unpleasant symptoms of the excitement stage of anaesthesia, as well as the after-effects, such as vomiting and nausea. Tenckhoff remarks that if these observations are confirmed a high percentage solution of glucose will form part of the armamentarium of the surgeon. The rationale of the treatment is not yet fully explained. Büdingen, who was the first to introduce glucose therapy, has shown that a number of subjective and objective cardiac disturbances are due to a low sugar content of the heart muscle or to inability of the heart to make use of its normal sugar content.

#### 12. Treatment of Inoperable Cancer of the Rectum.

G. F. GAARENSTROOM (*Nederl. Tijdschr. v. Geneesk.*, November 11th, 1922, p. 2165) records two cases of inoperable cancer of the rectum—in a woman aged 53 and a man aged 29—in whom as the result of combined treatment by radium and x rays all the signs of the tumour disappeared and the general condition improved to such an extent that they were able to carry on their occupation. At the time of publication of the note this condition had lasted six and five years respectively, so that the patients might be regarded as cured. The successful result was due to three factors. In the first place, the creation of an artificial anus had removed all sources of irritation from the rectum. Secondly, very powerful irradiations were employed in both cases. Thirdly, the courage of the patients in undergoing such vigorous treatment and submitting to the necessarily unpleasant reactional phenomena was to be taken into account. Often patients give up the treatment at an early stage, or are compelled to do so owing to various complications, such as fever, thrombosis, intestinal obstruction, or asthenia.

#### 13. Intestinal Obstruction due to Ascarides.

W. GERLACH (*Deut. Zeit. f. Chir.*, August, 1922, p. 396), who records an illustrative case, remarks that infestation by ascarides in the great majority of cases is a harmless disease, either because the number of worms is small, or because the intestinal mucosa possesses a high degree of immunity to the toxins of the ascarides. Under special conditions, however, the results of infestation may be dangerous and even fatal. Sometimes the presence of ascarides may complicate a pre-existing intestinal disease, such as typhoid fever or tuberculosis, and cause perforation of the intestinal ulcer, while in other cases the bad results may be due entirely to the ascarides, either from their toxic or mechanical effects. The surgical diseases due to ascarides have been classified by Schlossmann as follows: (1) Presence of the parasites in the abdominal cavity; (2) intestinal obstruction of a spastic or

mechanical nature; (3) peritonitis; (4) appendicitis. Gerlach's case occurred in a girl, aged 9, admitted to hospital with acute peritonitis. Death took place a few days after laparotomy. The autopsy showed diffuse fibrinous peritonitis, following spastic intestinal obstruction caused by ascarides in the lower part of the small intestine. Histological examination showed extensive necrosis of the intestinal mucosa, in which there had been an agglomeration of ascarides.

## OBSTETRICS AND GYNAECOLOGY.

#### 14. Vesical Calculus in the Female.

ACCORDING TO TÉDENAT and M. CATHALA (*La Gynéc.*, September, 1922, p. 514), the *intubular form* of the urethrovaginal opening and the shortness and susceptibility of dilatation shown by the urethra account for the readiness of elimination of urinary concretions in the female, and the greater rarity, in comparison with the male, of vesical calculus; with regard to gravel, however, the degree of distinction between the sexes is less. Gravelly collections not infrequently give rise to referred pain in the back, ankles, or heels; the urine shows abundant deposits, and treatment by dieting, purgation, and exhibition of alkalis or sodium benzoate is followed by rapid improvement. Backache, ascribed to chronic adnexal disease or uterine retroposition, is not infrequently due to a urinary lithiasis which has been overlooked. Vesical calculus is usually single, as in 29 of the 32 cases forming the basis of this paper. The symptoms consist in (1) frequency of micturition; (2) pain, which may radiate from the hypogastrum to the urethra, clitoris, sacrum, or thighs; (3) haematuria, which, however, is infrequent, not usually profuse, and sometimes absent. All these symptoms are notably worse after walking or other exercise, and after jolting. Diagnosis may sometimes be made after vaginal examination, usually after exploration of the bladder by sound or lithotrite; sometimes, however, radiographic examination is required. Treatment is operative in nearly all cases, and varies according to the consistence and size of the calculus, the state of the bladder, and the virginity or married state of the patient. In any case operation must be preceded by a period of absolute repose during which any coincident cystitis is carefully treated by administration of urotropine, salol, turpentine, or eucalyptus, by daily lavage with 1 per cent. silver nitrate and instillations of 2 per cent. protargol or 5 per cent. argyrol, or, if necessary, by continuous vesical drainage by catheter. Extraction of the calculus per urethram after dilatation by Hegar's or other instruments is suitable for stones of which the diameter does not exceed 3 cm. Lithotripsy—according to the authors the operation of choice—is suitable for stones which are not too hard nor too large (the diameter not exceeding 5 cm.), and for cases in which the bladder is not infected or is susceptible of disinfection. Cystotomy from the vagina, which is very rarely followed by fistula, is called for in cases of large or hard oxalate stones, and according to some authors is preferable to urethral extraction for calculi measuring 2 to 3 cm.; it should be done if there is persistent medium grade cystitis without pericystitis. Suprapubic cystotomy finds its indications in cases of stone formed around a foreign body, in cases of extremely infected bladder, and in some virgin subjects.

#### 15. Cancer of the Cervix.

J. W. ROSS (*Canadian Med. Assoc. Journ.*, November, 1922, p. 772) summarizes the results of various methods of treatment of cancer of the cervix from a study of 475 cases (1913-19) at the Mayo Clinic, at least three years having elapsed since the patients were first seen. Vaginal and intra-cervical radium applications were used in inoperable cases in most instances, and a modified Wertheim in the operable cases was employed, or a more conservative procedure in which a cuff of vagina well beyond the growth was removed with as much of the parametrial tissue as was necessary. The interval between cauterization and hysterectomy giving most favourable results was one month, and, following radium treatment, hysterectomy should be performed after from two to four weeks. Sixty of the 475 patients (12.6 per cent.) have lived more than three years. Thirty three modes of treatment, mainly variations in technique, were used, grouped under four main headings—namely, surgery, radium, Percy cautery, and simple cautery. Fistulae resulted in 46 cases (9.7 per cent.), the largest number following the Percy cautery, which was probably partly due to the fact that the abdomen was not always opened to control the uterus and estimate the heat. In very early cases surgery alone gives good results, but these are slightly better when it is used in combination with radium. In operable but not early cases surgery alone, or combined with radium, gives the best results, radium alone or Percy cautery alone being of

equal value but less efficient. In cases inoperable because of extension to the vagina surgery gives the best results, radium being disappointing, but in other inoperable cases radium alone, or in combination with cautery or surgery, is the only effective treatment, while in advanced cases radium is superior to all other methods but is not curative.

#### 16. Rupture of the Symphysis Pubis during Labour.

R. HORNUNG (*Zentralbl. f. Gynäk.*, November 25th, 1922, p. 1898) has found in the literature 110 recorded cases of obstetric rupture of the pubic symphysis, of which about one-sixth occurred during spontaneous delivery, the remainder being for the most part associated with high application of forceps in contracted pelvis. Walcher's position appears to have played a contributory part in certain cases. Not infrequently partial ruptures have been produced during labour and have become complete at a later period as a result of muscular strain; and partial ruptures occurring during delivery of the head may not become complete until the passage of the shoulders. In the recorded cases the mortality was 75 per cent., but most of them were reported in the pre-antiseptic era. In a case radiographically illustrated by the author the rupture dated from high forceps extraction without narcosis in a patient with contracted pelvis; the puerperium was long and febrile, but there was no injury of bladder, urethra, or ureter. One and a half fingerbreadths separated the divided bones, but six months after delivery the patient could walk without difficulty. BENTHIN (*Monats. f. Geburts. und Gyn.*, lviii, 1922) records a case of puerperal abscess formation in the symphysis which he ascribes to a spontaneous rupture during labour.

#### 17. Cerebro-spinal Haemorrhage in the Newborn.

ANGELIS (*La Pediatria*, November 15th, 1922, p. 1054) reports the case of a child born asphyxiated after a tedious labour (non-instrumental). Next day it was noticed to be very pale, with cyanosis of the face, hands, and feet. It lay supine and sluggish and responded very little to any stimulus; there was no muscular tone and no tendon reflexes, the corneal and pharyngeal reflex was normal, the pupils small and reacting slowly. Lumbar puncture was done on the second day, and 5 c.cm. of bloody fluid withdrawn; except for marked delay in coagulation time the blood was normal; the Wassermann reaction was negative. The general paralytic condition increased and the child died on the sixth day. *Post mortem* about 15 c.cm. of black fluid blood ran out when the skull was opened. Haemorrhagic patches were noted on the right occipital lobe and the cerebellum was immersed in a large collection of grumous blood. There was no blood in the ventricles. In the whole length of the spinal canal there were extradural exudations of blood in big clots. The author draws attention to the poor coagulability of the blood as a possible adjuvant cause of haemorrhage. The child had no convulsions.

### PATHOLOGY.

#### 18. Haemolytic Streptococci in Scarlet Fever.

W. P. BLISS (*Journ. Exper. Med.*, November, 1922, p. 574) found that haemolytic streptococci can be obtained from 100 per cent. of patients suffering from scarlet fever if the throat be swabbed during the first week of illness. After the first week of the disease the number of haemolytic streptococci diminishes rapidly, although great numbers may still be present as late as the twelfth day, and the average length of time that these organisms are present in the throat varies from ten to twenty days. No morphological or cultural characteristics peculiar to the haemolytic streptococcus from scarlet fever can be demonstrated. Scarlatinal streptococci are not agglutinated by immune serums prepared from haemolytic streptococci isolated from other pathological sources, but ten immune serums were prepared from different strains of scarlet fever streptococci, and each of the serums agglutinated more than 80 per cent. of the strains isolated from scarlatinal throats. The homologous strain of the haemolytic streptococcus may be agglutinated weakly by the serum of patients convalescent from scarlet fever. Some degree of protection against virulent scarlet fever streptococci is provided by scarlatinal antistreptococcal serum, but such serum has no protective power against haemolytic streptococci from other diseases. It is interesting to note that in a small epidemic of scarlet fever a healthy carrier of haemolytic streptococcus was discovered, and the organism carried was identical in its serological reactions with strains of haemolytic streptococci isolated from active cases of scarlet fever. The scarlatinal type of haemolytic streptococcus was only once found in the study of a number of cases of scarlet fever.

#### 19. The Etiology and Epidemiology of Epidemic Encephalitis.

C. KLING (*Hygiea*, November 15th, 1922, p. 894) investigated on the spot an outbreak of epidemic encephalitis in the north of Sweden, where, early in 1921, the epidemic assumed alarming proportions. In the four villages in which every person was examined it was found that, by the inclusion of slight and abortive cases, the morbidity ranged from 7.1 to 45 per cent. In certain families several members were simultaneously affected, and the abortive cases were characterized by the same prodromal symptoms (fever, catarrhal symptoms, headache, tenderness of the scalp, and "rheumatic" pains) as the fully developed and typical cases. The abortive cases were in the majority, and were doubtless chiefly responsible for the rapid spread of the infection. No evidence of infection by indirect means—that is, by milk, water, or insects—could be demonstrated. The spread of the epidemic was remarkably rapid; in the course of two months it had spread over an area of 87 square Swedish miles, populated by about 9,000 persons. In three cases in which the incubation period could be determined with accuracy, it was invariably one of ten days. About 100 cases, including 12 which terminated fatally, were subjected to a bacteriological examination. All the 30 inoculations of the virus into monkeys proved negative, but rabbits proved susceptible, although the disease was not acute as in man, but was of a chronic, slowly progressive character. The characteristic changes in the brain did not, as a rule, appear till three to five months after intracerebral infection or injection of the virus into the anterior chamber of the eye. When the virus was contaminated with cocci a mixed disease was provoked, and the rabbits died in four to eight days with signs of acute inflammation of the brain. It was evident, however, that they harboured the specific virus, for by filtration and other devices it was possible to isolate the virus from these cases of mixed infection and to induce uncomplicated encephalitis in other rabbits. The author has succeeded in passing the virus from one rabbit to another through eight generations in the course of eighteen months, during which the toxicity of the virus was gradually raised.

#### 20. The Question of a Gastric Hormone.

R. K. S. LIM (*Quart. Journ. Exper. Physiol.*, September 30th, 1922, p. 79) investigated the distribution of "gastrin" in the stomach and duodenum in order to locate the cells responsible for its production, and to ascertain whether it is secreted internally, by demonstrating its presence in the blood. Experiments were conducted upon anaesthetized cats, and the effects of organ extracts, histamine, and adrenaline studied. The organ extracts were extracted with boiling water or acid from the three regions of the stomach and the intestinal mucosa, their potency being in the descending order of pyloric, cardiac, duodenal, fundic, jejunal, and ileal, thus confirming the observations of Edkins regarding pyloric extracts and their effect upon gastric secretion. Extracts from the cardiac and duodenal areas are less active, fundus extracts inert, and jejunal and ileal extracts ineffective. The pyloric principle, or gastrin, is closely allied to histamine, which causes gastric secretion when injected intravenously. Possibly the order of potency might vary with the methods of extraction, which would account for differences in results obtained by other observers. Adrenaline does not inhibit the secretion so provoked, but may delay its outflow from the stomach, and in some individuals it may excite secretion. Since the distribution of gastrin in the stomach and duodenum corresponds with that of the mucoid glands, it is suggested that it is extracted from these cells. Neither direct nor indirect transfusion of citrated blood of fed animals taken at various intervals after a meal has any effect upon gastric secretion, and, since there is no gastric exciting substance in the blood after meals, it is concluded that the excitant found in pyloric and other extracts is not secreted into the blood stream, and that the mechanism of secretagogue action is not due to internal secretion.

#### 21. The Test of Digestive Haemoclasis in Pulmonary Tuberculosis.

M. PIÉRY and M. PAPADOPOULOS (*Bull. Soc. de Théor.*, October 11th, 1922, p. 213) state that Vidal's test of digestive haemoclasis not only possesses a diagnostic value in revealing a functional insufficiency of the liver, but also may be employed in therapeutics for testing the value of various methods of treatment of hepatic insufficiency. The authors treated 16 cases of pulmonary tuberculosis in which the test of digestive haemoclasis was positive by various kinds of Vichy water for four weeks, with the result that 12, or 75 per cent., showed a return to normal digestive leucocytosis in place of leucopenia. The test therefore appears to be a ready and accurate guide in the feeding and chemotherapy of pulmonary tuberculosis.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## MEDICINE.

### 22. Auricular Flutter.

J. H. KEATING and J. HAJEK (*Amer. Journ. Med. Sci.*, November, 1922, p. 656) report eight cases of auricular flutter, a condition characterized by regular co-ordinated action of the auricle so rapid in rate that the ventricle is rarely able to respond to each auricular impulse, thus giving rise to a partial or complete heart-block, the impulses no longer arising from the sino-auricular node, but from some other portion of the auricle. While dyspnoea, palpitation, and precordial distress are the chief symptoms, these depend upon the amount of cardiac insufficiency, and are modified by the presence or absence of complications. Physical signs may be absent when the amount of cardiac insufficiency is slight, and clinically the diagnosis is difficult because of the paucity of definite symptoms and signs. Sphygmograph tracings of the large veins and radial pulse may in some cases enable a diagnosis to be made, but the condition can only be detected definitely by the use of the electrocardiograph. Clinical experience and experimental work show that paroxysmal tachycardia, flutter, and fibrillation are stages of the same pathologic condition causing cardiac insufficiency, tachycardia being the first stage, flutter the second, and fibrillation the third. In the eight cases reported the auricle showed a remarkable stability while fluttering—atropine, rest, exercise, or emotion, though affecting the ventricle, having no effect upon the auricular rate. The treatment advised by the authors consists of rest in bed to increase the cardiac reserve, and the administration of large doses of digitalis in tablet form or intravenously, with a view to causing the auricle to fibrillate, the drug being discontinued when this is attained. In those cases in which digitalis produces no effect other than slowing the ventricle, the condition may persist for years if the patient leads a sedentary and uneventful life. The value of quinidine sulphate is as yet undetermined, the cases in which it has been used being too few to allow of any definite conclusions being drawn.

### 23. Intermittent Quinine Treatment in Malaria.

K. GLAESSNER (*Wien. Arch. f. innere Medizin*, Bd. v, Heft 1, October 15th, 1922, p. 43) records his experience of the intermittent quinine treatment in malaria. He gives reasons for considering the intermittent treatment specially indicated; he had demonstrated its value by intravenous injections of quinine. In the meantime Ochsner had advocated an intermittent treatment with quinine given by mouth, which he based on similar theoretical grounds. Glaessner has carried out this latter treatment in 77 cases of malaria with good results. On the evening of the day of the attack of malaria—the day of high fever—the patient is given 30 grams of castor oil. Then on the next day, and the day following, he is given 0.15 gram of quinine sulphate in a cup of tea every two hours (during day and night). During these two days no meat is given, and the diet consists of milk, soups, vegetables, milk, and farinaceous foods. After these two days of quinine treatment, no quinine is given for eight days, and the mode of life is normal in this period. On the ninth and tenth days the treatment is repeated. If another attack occurs, or if the malarial parasites are still detected in the blood, and the spleen has not diminished, then a third course of treatment is carried out after another eight days; occasionally a fourth course is given. In 56 of his 77 cases only one course of the treatment was required (that is, four days of treatment, with the eight days' interval between the first two and the last two days). In 21 of the cases two or three courses of the treatment were required. The author estimates that successful results were obtained in 80 per cent. of his cases; he is unable to state the permanent results, except in a small number of cases, but he considers this method of treatment worthy of further trial.

### 24. Dietetic Treatment of Gastric Ulcer.

A. NIELSEN (*Hospitalstidende*, October 25th, 1922, p. 67) has come to the conclusion that, in estimating the value of the medical treatment of gastric ulcer, it is essential to distinguish between immediate and ultimate results. As a rule, in a well conducted hospital, 95 to 98 per cent. of the patients given medical treatment are discharged symptom-free or improved. To ascertain the late effects of such treatment the author investigated the subsequent fate of 239 patients two and a half to nineteen years after discharge. The clinical diagnosis was in every case founded

on reliable data. About 200 were found not to have been permanently cured, and a remarkable difference was observed when the cases were classified according to the duration of the symptoms before the institution of medical treatment. Among the patients whose symptoms had lasted less than six months the proportion of permanent cures was 60 per cent., and of improvement 16.7 per cent. In cases in which the symptoms had lasted one to three years the proportion of complete cures was only 36.9 per cent. This percentage was reduced to 20 among the patients whose symptoms had lasted three to five years, and to 5.3 among the patients whose symptoms had lasted more than ten years. The fact that only 5.3 per cent. recovered among the patients whose symptoms had lasted more than ten years indicated the comparative futility of medicinal and dietetic treatment. Included among these cases was a certain number of cases of duodenal ulcer.

### 25. Ponto-cerebellar Tumours with Few Symptoms.

A. GORDON (*Arch. Intern. Med.*, November 15th, 1922, p. 607) points out that often the diagnosis of brain tumours developing at the ponto-cerebellar angle is made without great difficulty. If the tumour originates in the cerebellum, cerebellar symptoms will occur first. If the tumour originates in the eighth nerve, vestibular or auditory symptoms will occur first. Besides the eighth, also the seventh, sixth, and fifth nerves are very often affected. But in some cases the symptoms are slight and indefinite, and the author records seven such cases. In these seven cases even the ocular fundi were normal in five, and in the other two only retinal haemorrhages and venous engorgement were found. A sign detected, however, in all of these cases was the error in pointing with the hand on the side of the disease (the result of a disturbance in the regulation and in the co-ordination of voluntary movements, which are controlled, directly or indirectly, by the cerebellum). The author regards the pointing error as a sign of great localizing value. He also considers persistent pain in the area of distribution of one or two branches of the trigeminal nerve as highly suggestive of the disease. This pain is not of the typical neuralgic character, but is described as a burning, boring, pulling pain. H. W. Stevens has pointed out that in several instances x-ray examination has revealed erosion of the mesial part of the petrous bone in tumours of the cerebello-pontine angle.

### 26. Transmission of Sheep-pox to Man.

A. BEVILACQUA (*Il Policlinico*, Sez. Prat., November 27th, 1922, p. 1563) states that in the southern provinces of Italy, on the Adriatic coast, there is an epidemic of sheep-pox, caused by periodic emigration of infected animals from the plains to the mountains and vice versa. The epidemic is of slight intensity, and the mortality does not exceed 15 to 16 per cent. Owing to the avarice of the owners, and the lack of supervision, most of the infected animals are sent to the slaughter-house, where their flesh is sold at a moderate price to the public. Bevilacqua has recently seen two cases of slaughterers who had been infected by the animals which they had killed. In the first patient, who had never been vaccinated, nor had a previous attack, there was considerable constitutional disturbance in addition to two pustules, one on the right hand and the other on the right forearm. In the second patient, who had been vaccinated twice, and had had a similar attack three years previously, the disease was confined to an eruption of vesicles on the forearms and hands, and there was no constitutional disturbance. Bevilacqua recommends that all who have to handle infected animals should use a fresh solution of a 5 per cent. solution of potassium permanganate for washing their hands after touching the animals.

### 27. Pyrogenic Treatment of Bronchial Asthma.

SCHOTTMÜLLER (*Deut. med. Woch.*, November 3rd, 1922, p. 1474) had been driven almost to despair in trying to combat very severe attacks of asthma in a woman, aged 45, when she developed influenza with high fever. With the defervescence of this illness the asthma, which had been violent for several weeks, disappeared completely. Three months later the asthma returned and the patient was again admitted to hospital in great distress. After the most common remedies had been tried in vain for eight days, an attempt was made to exploit her experience with influenza. She was given an intravenous injection of a vaccine prepared from germs cultivated from a case of sepsis. The author does not state what these germs were nor the dose of the injection. It was followed in about an hour by a rigor and a temperature of

nearly 106°F. The leucocytes rose to 18,000, and there was an extensive eruption of herpes labialis. The asthmatic symptoms disappeared completely, and when the patient was again seen, two months later, she was still free from even slight attacks. The author has followed the same procedure in eight other cases of asthma, and only in one case did it fail to disappear. This system of treatment has no claim to permanent results, and its action probably depends on the presence in the body of a non-specific protein. But though the relief it gives may last only a few weeks or months, its effects are often remarkable even in cases which have resisted treatment with adrenaline.

#### 28. Relief of Pain in Herpes Zoster by Paraffin.

A COLLEAGUE who had suffered from a very severe attack of thoracic herpes zoster suggested the use of an occlusive dressing of paraffin to HOWARD FOX (*Journ. Amer. Med. Assoc.*, December 9th, 1922, p. 1979), and he has followed the procedure in twenty selected cases. The method was reserved solely for those patients who were suffering from pain severe enough seriously to interfere with sleep. Experience soon revealed the fact that the best results were obtained by a daily application of the paraffin, and it was seldom necessary to continue the treatment for more than a week. In even the severest cases the applications of the paraffin gave almost immediate relief, and were followed by more or less freedom from pain for twenty-four hours and by a complete night's rest. The most convincing proof of the efficacy of this treatment was shown by patients who had obtained complete relief from pain, but who for some reason or other had not returned for several days, during which time the pain had recurred; by further treatment the pain was again promptly relieved. The technique of treatment consisted simply in spraying the melted paraffin with an atomizer on the cutaneous lesions and covering those areas with a generous layer of absorbent cotton, held in place by bandages. In a few cases the paraffin was applied by cotton swabs—an equally efficient, although slower and less convenient, method. When fresh applications were made the previous layer of paraffin was gently removed.

#### 29. Conjugal Tuberculosis.

A. E. DE BESCHE and J. O. JØRGENSEN (*Norsk Mag. for I*, December, 1922, p. 1000) have investigated the order which conjugal tuberculosis exists in Christiania. In 742 marriages, in each of which one partner was notified as suffering from pulmonary tuberculosis, there were 39, or 5.25 per cent., in which both partners suffered from pulmonary tuberculosis. In 33 of these 39 cases one of the partners developed pulmonary tuberculosis after marriage. Of these 33, 16 had grown up in tuberculous surroundings, and 5 had had enlarged glands, apical catarrh, or pleurisy before marriage; about one no information could be obtained. Thus there remained only 11 cases in which the infection could reasonably be regarded as conjugal. The authors conclude that, though slight tuberculous infection in childhood probably confers considerable immunity, there is some risk connected with life in wedlock with the subject of open pulmonary tuberculosis.

#### 30. The Relation of Rickets to Fat-soluble A Vitamin.

C. E. BLOCH (*Ugeskrift for Læger*, November 2nd, 1922, p. 1486) has made certain observations in the Children's Department of the Rigshospital in Copenhagen, and has deduced therefrom that rickets is not due to deficiency of vitamin A. He assumes that xerophthalmia is due to a lack of vitamin A. If this assumption is correct, then the association or non-association of xerophthalmia with rickets should throw light on the latter's relation to vitamin A. Between 1912 and 1921 the author observed 77 cases of xerophthalmia between the ages of 2 months and 10 years. Only two showed signs of scurvy, and it was therefore evident that the supply of vitamin C had been adequate in most cases. Most of the patients were admitted to hospital during the winter and spring—that is, in the rickety season. All had been artificially fed. Yet among 65 children in the rickety age—that is, 3 months to 3 years—there were only 12 with signs of rickets. Considering the season of the year, the artificial diet of the patients, and the poverty of the homes from which they came, this number of rickety patients is surprisingly low. The author is therefore very sceptical with regard to the teaching that the ordinary form of rickets is a deficiency disease, and he refers to the investigations of Jundell and others as showing that an apparently vitamin-rich milk does not prevent or cure rickets. Nor does butter containing much vitamin A cure rickets. The rarity of rickets in the autumn may, he suggests, be largely due to the rate of growth being comparatively slow at this season.

## SURGERY.

#### 31. Post-anaesthetic Gastric Paralysis.

H. L. COOPMAN (*Nederl. Tijdschr. v. Geneesk.*, November 18th, 1922, p. 2280) states that in a relatively small number of operations under a general anaesthetic a peculiar condition develops, in which the patients die with symptoms of intestinal obstruction and shock, unless a correct diagnosis is made and appropriate treatment employed. In about 700 laparotomies Coopman has seen two examples of this condition. The course is usually as follows: on the third or fourth day after a relatively simple operation, such as ovariectomy, antefixation of the uterus, or appendicectomy, as well as after cholecystitis, Bassini's operation, etc., the patient begins to vomit, although the effect of the ether has long worn off. The vomit contains bile but no faecal matter. An acute dilatation of the stomach and intestines takes place, the abdomen becomes distended like a balloon, the pulse becomes rapid and small, and there is no passage of flatus. If the patient is now placed in the ventral or lateral decubitus flatus is passed, the distension subsides, and rapid recovery takes place. Washing out the stomach should be tried if the change of position fails to cause relief. A second operation is rarely necessary, but if no improvement occurs after the above treatment . . . should be performed. Of 148 cases collected . . . or about 50 per cent., succumbed. The condition is due, as was shown by Glénard in 1885, to compression of the duodeno-jejunal junction by the relaxed mesentery.

#### 32. Radiographic Diagnosis of Bone Tumours.

B. H. NICHOLS (*Surg., Gyn., and Obstet.*, September, 1922, p. 301) draws attention to the x-ray diagnosis of bone tumours. Bone tumours are classified according to the following plan: (1) Their origin, whether medullary or cortical; (2) whether characterized by bone production or destruction; (3) the condition of the cortex, whether expanded or destroyed; (4) whether the growth is invasive or non-invasive. The author gives the following characteristics of the more important bone tumours: Round and spindle celled sarcomata are medullary in origin, contain no new bone, and are destructive; this type breaks through the cortex and invades the soft tissues; they usually arise in the ends of the long bones, but do not cross a joint, as the cartilage seems to be a barrier to growth. In periosteal sarcoma new bone is laid down perpendicular to the shaft. These tumours appear after 30 years of age and are invasive in character. In syphilis the new bone is laid down parallel to the shaft. In exostosis a definite outline is seen with no semblance of invasion. Bone carcinoma is always metastatic and is medullary in origin; most often it is seen at the middle of the bone where the nutrient artery enters. There is no bone production, only destruction, and it never involves a joint. This variety is almost never found below the elbows or knees, and occurs in later life. It is the most common type of bone tumour in females after 40 years of age. Myelomata are multiple and medullary in origin; they show expansion and later destruction of the cortex; Bence-Jones bodies are present in the urine. Giant-cell sarcoma is benign, and of medullary origin; it shows destruction and no new bone; it grows at the end of the bone and occurs after middle age. These tumours do not metastasize and are single lesions, but have a multilocular appearance. Bone cysts are multilocular and occur in a single bone; they extend up and down the medulla and expand the cortex. Osteomata are lawless growths of cortical origin; they grow from the shaft in any direction and do not invade. In myositis ossificans new bone is deposited parallel to the shaft; it is due to trauma where periosteum is torn off and produces new bone. Tuberculosis is usually of joint origin; if not, it is an osteomyelitis. Destruction without production is the characteristic appearance. The cartilage is attacked, and both sides of the joint are involved.

#### 33. After-results of Cranioplasty.

TERMIER (*Le Scalpel*, October 14th, 1922, p. 977), in considering the after-results of cranioplasty, approaches the subject from two sides: first, from the point of view of the improvement or recovery of the nervous symptoms due to the injury of the skull or brain; secondly, with regard to the restoration of the bony wall of the skull. In 31 of his own cases he finds that the distant results, as far as the first question is concerned, are only moderate; 2 of these cases have died, one from Jacksonian epilepsy; the other, a case of hemiplegia, died later from coma. About 10 cases show no improvement, whilst 12 others state that they are a little better, but the improvement has been slow. The most marked feature has been the disappearance of the headache in many of these cases. He does not consider the operation of cranioplasty capable of curing all the nervous and other

symptoms, whether the cerebral scar tissue be excised or not; they depend rather on some deeper lesion which we are at present powerless to deal with. However, the cases of neuralgia and headache may be improved or cured, and the operation itself is almost devoid of risk and certainly does not aggravate the condition of the patient. With regard to the reconstruction of the cranial vault it is certain that the operation gives almost perfect results; the patients all feel a sense of security, and are able to leave off the means of protecting the brain they previously adopted. The use of cartilaginous grafts taken from the ribs has not proved satisfactory. On two occasions the author has taken a graft from the anterior surface of the patella, and considers this preferable to rib grafts. He now follows the technique of Delagenière and uses osteo-periosteal grafts, with excellent results in all cases. These grafts are easily removed from the tibia and give rise to no subsequent ill effects, as sometimes arises after those taken from the chest wall.

#### 24. Prolapse of the Rectum in Children.

L. G. ALEXANDER (*Annals of Surgery*, October, 1922, p. 496) finds the treatment of this disorder by injections of alcohol very satisfactory. Prolapse of the rectum in children can often be cured by careful diet, removing the cause, strapping the buttocks, and the administration of cod-liver oil. Some cases do not yield to these conservative measures and demand more radical treatment. The most frequent exciting cause appears to be abnormal intra-abdominal pressure, with muscular weakness as the predisposing factor. The treatment by injection is performed under general anaesthesia. The finger is placed in the rectum to gauge the position of the needle, and 1.5 c.cm. of absolute alcohol is injected on each side of the rectum at about a depth of 7 cm. The needle is inserted about a quarter of an inch from the anal margin and passed along the side of the bowel just outside the mucosa for about two inches, where the alcohol is injected on both sides; the punctures are sealed with collodion and the buttocks strapped. The child is kept in bed ten days and the bowels kept constipated. Findlay, who described this treatment, believes two factors to be responsible for the cure by this method. There is a certain amount of irritation at the seat of injection, with formation of fibrous tissue which fixes the bowel to the pelvic cavity. The sphincter usually regains its tone within ten days following the alcohol injection. The author has used this method in eleven consecutive cases and has obtained a cure in each instance without any post-operative complications.

#### 35. Meningitis of Otic Origin.

C. F. YERGER, Chicago (*Journ. Amer. Med. Assoc.*, December 2nd, 1922, p. 1924), presents a statistical study of 63 cases of meningitis of otic origin; only two of the patients recovered—a mortality of 97 per cent. Given a case of meningitis, in a person with a history of chancre, with clinical evidences of syphilis or with a positive Wassermann reaction, in the presence of an otitic infection, Yerger says that it becomes a very difficult matter to decide correctly the etiology of the meningitis in some of the cases, before the therapeutic test has been tried. An otitic meningitis can develop in a syphilitic patient who is harbouring an otitic infection with the same ease as in one who is not syphilitic; the same may be said of syphilitic meningitis—that is to say, it may develop in a syphilitic person harbouring an otitic infection. One case of meningitis cited, though complicated by an otitis media, responded promptly to large doses of potassium iodide. In this case the history and the Wassermann test gave the clue, and a speedy recovery under antisyphilitic treatment proved the case to be one of undoubted syphilitic meningitis.

#### 36. Relief of Pain on Defaecation in Anal Fissure.

E. SYLVEST (*Ugeskrift for Læger*, November 30th, 1922, p. 1671) points out that in cases of fissure of the anus the pain of defaecation gives rise to a vicious circle. The patient defers defaecation for several days because he fears the pain, and the result is an accumulation of hard and bulky faeces which, when they are ultimately evacuated, give rise to excruciating pain. If the pain of defaecation could be mitigated or banished the vicious circle would be broken. The device recommended by the author is that the patient should press very firmly with one finger between the tip of the coccyx and the anus during defaecation. He has almost invariably found this simple device perfectly effective, and he suggests that the explanation of its efficacy is to be found in the work of Head and others on reflex impulses. As Head has shown, diseases of the lower part of the rectum are associated with a zone of hyperalgesia behind the anus, extending up to the lower part of the sacrum. The maximum point of hyperalgesia is in the middle line, at the level of the lowest part of the sacrum. Pressure on this point also has

been found by the author to relieve the pain of defaecation due to fissure of the anus. His device is analogous to that of P. T. Hald, who found that the dysphagia associated with inflammation of the tonsils and surrounding structures could be greatly relieved by exerting firm pressure on the tragus, and through it on the posterior wall of the auditory meatus, on both sides of the head.

## OBSTETRICS AND GYNAECOLOGY.

#### 37. The Retroverted Gravid Uterus.

J. MOREAU (*Le Scalpel*, November 25th, 1922, p. 1137) states that the great majority of cases of incarceration of the retroverted gravid uterus occur in organs which were in the retroverted position prior to conception. Pregnancy in such a uterus is frequently followed by abortion about the ninth week, and uterine retroposition accounts for many cases of repeated abortion in non-syphilitic subjects. A different type of abortion may take place between the twelfth and twentieth weeks, as a sequel to incarceration which is produced about the end of the third month, when the uterus occupies practically the whole of the pelvis. Prognosis is worse in the later than in the earlier type of abortion, for complications such as severe cystitis or uraemia may be already present. In the majority of cases the malposition becomes spontaneously corrected. The author believes, however, that such an event is impossible if the retroflexion is so great as to bring the uterine attachment of the round ligament at a lower level than its other end; at operation he has found that in these circumstances traction on the round ligament tends to emphasize the displacement. Clinically it is nearly always the urinary complications which lead to detection of retroversion of the pregnant uterus; Moreau points out that catheterization is difficult and sometimes dangerous, and that after the bladder has been emptied its enlargement and thickening may lead to diagnostic difficulty by confusion with myoma, adnexal tumour, or extrauterine gestation. Treatment before incarceration is comparatively simple and consists in bimanual correction followed by application of a pessary. When incarceration has led to urinary retention, repeated catheterization may be followed by spontaneous correction; bimanual replacement may require general anaesthesia. In certain cases it is necessary to open the abdomen, and even then correction may present very great difficulties—in one case symphysiotomy was necessary. In cases of gangrenous cystitis the bladder must be drained suprapubically, uterine manipulations being deferred.

#### 38. Tuberculosis in Ovarian Cysts.

ACCORDING TO C. LEFEBVRE (*La Gynéc.*, September, 1922, p. 534) the occurrence of tuberculosis in an ovarian cyst, first reported by Spencer Wells in 1864, is comparatively rare, 45 cases only—of varying degrees of authenticity—having been recorded. Unilocular or multilocular and pseudo mucous or dermoid cysts may be affected. In simple cases the various intra-abdominal structures, the cyst included, are not adherent; the tuberculous lesion of the cyst may be internal (leading to formation of a cold abscess) or external, the interior of the cyst being scattered with numerous minute subperitoneal tubercles. Complex cases are characterized by adherence of the cyst with the neighbouring viscera; in some instances the Fallopian tube communicates with the cavity of the cyst. Diagnosis presents very great difficulty, especially from tuberculous pyosalpinx, tuberculous peritonitis with encysted abscess, or non-tuberculous suppuration of an ovarian cyst; in advanced cases with extensive degeneration of the cyst wall even histological examination may not determine with certainty the origin of the condition. The contents of many tuberculous ovarian cysts remain non-purulent for very extensive periods, but the sediment after centrifugalization is characterized by marked preponderance of lymphocytes; the tubercle bacillus is rarely if ever detected. In a case recorded by the author excellent results followed drainage and marsupialization of a large cyst showing tuberculous changes, in spite of the presence at the time of operation of extensive peritoneal tuberculosis.

#### 39. Treatment of Placenta Praevia.

SCHWEITZER (*Zentralbl. f. Gynäkol.*, November 15th, 1922, p. 1869) records fifteen years' experience at the Leipzig clinic in the treatment of 333 cases of placenta praevia, of which 227 were partial. In 22 cases of slight haemorrhage partial placenta praevia and vertex presentation treatment consisted in simple rupture of the membranes, and was without maternal mortality. About 40 per cent. of cases with incompletely dilated cervix were treated by intra-amniotic introduction of a dilating bag, and about the same proportion of similar cases by version. The former treatment, attended as

it was with comparatively copious loss of blood, was reserved in the interest of the foetus for cases in which the maternal condition was good and the foetus living. Version, chosen for cases in which the maternal condition was poor and it was desirable to minimize haemorrhage, gave a maternal mortality of 6.6 per cent., as compared with 3.8 per cent. after metrorrhysis; the mortality from haemorrhage is given as smaller after the former treatment, which showed, however, a much greater foetal mortality. The total mortality of the cases treated on these, the older, lines was 5.6 per cent. (3 per cent. ascribed to haemorrhage, 2 per cent. to sepsis); at the initiation of hospital treatment, however, the majority of patients were in poor condition. Of those untreated outside the hospital, none died; of those examined, 2 per cent.; of those in whom tamponage had been performed, 6 per cent.; and of those who had received obstetrical manipulations, no fewer than 11 per cent.—all these treatments having been given extra-institutionally. For the diminution of maternal and foetal mortality two points are considered by Schweitzer to be of paramount importance: (1) that every patient suffering from haemorrhage in the last month of pregnancy should be admitted to hospital without previous vaginal examination, and especially without the insertion of a tampon, which is usually unnecessary and often ineffectively applied; (2) that for diminution of foetal mortality the most hopeful treatment is intraperitoneal cervical Caesarean section, which, however, demands admission of the patient to hospital at an early and uninfected stage.

#### 40. Pre-cancerous Conditions of the Cervix.

R. R. HUGGINS (*Amer. Journ. Obstet. and Gynec.*, November, 1922, p. 552) thinks that cancer of the cervix probably starts in an erosion, which has become re-covered by vaginal epithelium, the columnar cells of the erosion being buried beneath. These cells still secrete and cysts form, which may be found on the surface or may extend deeply into the cervix. These cysts often become inflamed, which can be demonstrated clinically by the tenderness of the cervix, and the author thinks that this chronic inflammation acts as an irritant and incites cancer to develop. He quotes several cases where examination of the cervix microscopically had shown such chronic pathological changes, and which later had developed cancer. He therefore urges that every woman of 40 who has borne children should be examined, and if disease of the cervix is found this should be treated either palliatively or more often by removal of the diseased tissue. By such means cancer will be prevented. The author puts forward the following points concerning cervical cancer: (1) Cancer begins as a benign growth; (2) there is a pre-cancerous stage, in which removal is a sure means of relief; (3) it is absolutely local to begin with; (4) as a rule tissues are more susceptible to its development at the age when atrophy and degeneration take the place of the building-up process; (5) it is prone to develop into an acid medium such as is produced by the vagina.

### PATHOLOGY.

#### 41. Influenza.

A FRESH outbreak of influenza in the early months of 1922 gave P. K. OLITSKY and F. L. GATES another opportunity to continue the study of the filter-passing organism they have previously recorded as being present in the naso-pharyngeal secretions from influenza patients. It may be recalled that during the epidemic wave of 1918-19 these authors demonstrated that a filter-passing virus was present in the naso-pharyngeal secretion during the first few hours of an attack of influenza, and that the intratracheal injection of these filtered secretions produced typical influenza-like lesions in the blood and lungs of rabbits. These findings have since been confirmed by many other workers, who succeeded in mastering the difficult technique involved—in this country notably by Mervyn Gordon (as reported to the Microbiological Section of the meeting of the British Medical Association at Glasgow in 1922). The main developments of recent months may be summarized as follows: The intratracheal injection of this filter-passing virus, to which Olitsky and Gates have given the name *Bacterium pneumosintes*, favours the invasion and infection of the lung with other bacteria, such as the pneumococcus, streptococcus, and *B. Pfeifferi*; it leads to the development, in experimentally infected animals, of a specific immunity against reinfection with similar material. The organism can be cultivated under strictly anaerobic conditions in a medium composed of sterile human ascitic fluid and a fragment of fresh rabbit kidney, producing a faint haze in the region of the kidney fragment, and stained films from this show countless Gram-

negative, minute bodies of regular morphology, measuring 0.15 to 0.3  $\mu$  in the long axis. Rabbits intravenously injected with such cultures produce antibodies which can be recognized by precipitation, agglutination, complement fixation, and phagocytic tests. Finally, surface colonies of these minute organisms have been obtained on blood agar plates incubated under anaerobic conditions. In the present series of experiments (*Journ. Exper. Med.*, November, 1922, p. 501) carried out during the outbreak of influenza in January and February, 1922, Olitsky and Gates succeeded in six cases of human influenza out of nine in transmitting the disease to rabbits by the intratracheal injection of filtered naso-pharyngeal secretions from early cases of influenza. Negative transmission experiments were obtained with three persons not suffering from influenza used as controls. Cultures of strictly anaerobic, filter-passing, Gram-negative organisms were obtained with material derived from four of the six influenza patients from whom an active agent had been transmitted to rabbits, from a seventh influenza patient whose naso-pharyngeal washings were not injected into animals, and from four of ten other persons not suffering from influenza. Thus *Bacterium pneumosintes* is not the only anaerobic, filter-passing, Gram-negative organism to be found in the human respiratory tract, but these other filter passers, which Olitsky and Gates isolated, were found not to be pathogenic to rabbits and could be distinguished by cultural and morphological tests. The authors do not commit themselves to any definite opinion about these other filter passers. "What the importance of these micro-organisms may be or whether they have any pathogenic significance we are not prepared to suggest." On the other hand, the four new strains of *Bacterium pneumosintes* which were isolated in pure culture were identified on morphological, cultural, and serological grounds with the strains previously isolated in 1918-19 and in 1920. All the significant characteristics of the old strains were noted in the four new strains isolated in this epidemic, including their effect upon the resistance of the lungs of rabbits to secondary invasion with other bacteria.

#### 42. Cholesterinaemia in Arteritis Obliterans.

J. HEITZ (*C. R. Soc. de Biologie*, November 4th, 1922, p. 1024) records some investigations which he has made on the amount of cholesterol—or more strictly of lipoids giving Liebermann's reaction—contained in the blood of patients affected with arteritis obliterans. Of the 22 individuals studied 20 were males and 2 females. All were suffering from intermittent claudication; in the majority of the cases only one leg was severely attacked, but in a few both the lower limbs manifested this symptom. There were no diabetics amongst them, and syphilis appears to have been excluded. The normal titre of cholesterol in the blood may be taken as about 0.16 per cent.; the average titre in these patients was 0.282 per cent.; in only one of them was it below 0.2 per cent. Without there being any definite relation existing between the degree of hypercholesterinaemia and the extent or duration of the arterial lesions, it was noticed that the highest figures were encountered in those patients suffering from bilateral disease of the femoral vessels which had existed for several years. What is the cause of this increase in blood cholesterol? It is difficult to believe that it is merely fortuitous. Rather it is more logical to regard the hypercholesterinaemia and the arterial disease as proceeding from a common cause; in this case the latter may be accentuated by the former. A further investigation, dealing with diabetic patients, showed that hypercholesterinaemia was the rule, but that it was more marked in those cases showing arteritis obliterans than in those whose vessels were unaffected. In connexion with these results it will be remembered that arterio-sclerosis has been produced experimentally in rabbits by feeding them on large quantities of lipoidal substances.

#### 43. The Cerebro-spinal Fluid in Herpes Zoster.

R. TARGOWLA (*Paris méd.*, November 25th, 1922, p. 480) states that during the course of, or in convalescence from, herpes zoster a meningeal reaction is frequently found, characterized by hypertension of the cerebro-spinal fluid, with or without increase of albumin and the number of cells in the fluid. He has recently observed five cases at the Villejuif Asylum, consisting of three cases of general paralysis, one of dementia praecox, and one of mental enfeeblement due to a circumscribed lesion of the brain, in which herpes zoster developed and lumbar puncture was performed. The cerebro-spinal fluid in these cases did not appear to be affected by the occurrence of herpes zoster. The reaction of colloidal benzoin in particular was not changed, and the albumin and lymphocytosis in the fluid did not undergo any appreciable alteration. In two cases of general paralysis, however, the tension of the fluid was raised.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## MEDICINE.

### 43. Difficulties in the Diagnosis of Thoracic Aortic Aneurysm.

CASSART and SECOUSSE (*Journ. de Méd. de Bordeaux*, November 25th, 1922, p. 731) describe a remarkable case. A workman aged 59 was under daily observation by several physicians for more than six months, but, in spite of the use of many different diagnostic methods, the diagnosis remained doubtful until the necropsy. The patient was admitted to hospital in July, 1921; he complained of cough, sputum, left-sided thoracic and epigastric pains. In 1920 he had had pneumonia on the left side, and in February, 1921, bronchitis, which did not clear up. His physician suspected tuberculosis, and advised admission to a sanatorium. He was admitted in June, 1921, and discharged after a month's observation as non-tuberculous. His father and one sister were diabetics. The patient was married; there were no children. At 21 he had a chancre; the Wassermann reaction was positive on admission. Three years previously he had a slight cerebral haemorrhage and right hemiplegia, which cleared up entirely. On admission he was very ill, anaemic, face very drawn, constant cough, difficult expectoration, dyspnoeic. The left lung was generally dull, especially in the upper three-quarters in front and at back. There were vocal fremitus and vocal resonance, a harsh murmur, and the heart sounds were plainly transmitted. There were no signs of effusion. The symptoms indicated an extensive mediastinal compression. The right eye was normal; the left eye was retracted, and the pupil contracted, indicating compression of the left sympathetic. The voice was hoarse and weak; the laryngoscope showed paralysis of the left vocal cord. The cough was paroxysmal, with anginal attacks suggesting pneumogastric compression. A skiagram showed compression of the trachea. The patient stated that he could not swallow bread, and deglutition of solids became more and more difficult. Liquids excited the paroxysmal cough. Oesophagoscopy showed a compression without parietal change at 34 cm. from the incisors. The left radial pulse had almost completely disappeared, but there was no oedema nor sensory disturbances. The blood pressure was practically equal on both sides. The heart did not appear to be enlarged, but was displaced slightly to the right. There was no albuminuria. A series of skiagrams confirmed the diagnosis of a large intrathoracic tumour on the left side, pushing the viscera to the right and approaching the middle line. No pulsation nor expansion was observed in the tumour. A normal blood count (eosinophiles, 1 per cent.) negative a diagnosis of hydatid cyst, lymphosarcoma, or abscess. An exploratory puncture met with deep resistance similar to that of the chest wall, and at 8 cm. depth yielded a drop of blood which showed no abnormal cells. A diagnosis of sarcoma was rejected, as this would have bled freely on puncture. Under energetic antisyphilitic treatment the patient appeared to improve, but hypostatic congestion supervened, and he died on February 16th, 1922—that is, seven and a half months after admission. At the autopsy an enormous aneurysm, 15 cm. by 18 cm., occupied the whole of the left chest except the extreme base; it was densely adherent to the chest wall and had eroded the bodies of the third, fourth, and fifth dorsal vertebrae on the left side. The heart was not enlarged and its walls were firm. The authors give further details and observe that the thick resistant clot explains the absence of pulsation, the aneurysm, *per se*, was cured and behaved as a solid tumour, dangerous from its size, and rendering the diagnosis difficult.

### 45. Quinidine in Auricular Fibrillation.

T. S. HART (*Arch. Intern. Med.*, November 15th, 1922, p. 592) records the results of quinidine treatment in 15 cases of persistent and in 2 of paroxysmal auricular fibrillation. Quinidine sulphate was employed, administered in capsules, each containing 0.2 gram. For the first twenty-four hours two doses of 0.2 gram were given; then afterwards 0.4 gram was given three times a day after food. Of the 15 patients with persistent auricular fibrillation, 5 recovered a normal rhythm after the administration of quinidine. In all of these the fibrillation recurred in course of time, but in 4 of them quinidine was given again, and in each instance the normal rhythm followed. One of these patients still maintains a normal rhythm after five months; in another of the cases a third period of quinidine treatment was followed by a normal rhythm. If quinidine was effective the good results were

obtained within sixty hours. In the cases in which the good results were obtained the total amount of quinidine given was never more than 3 grams. In 2 cases of paroxysmal fibrillation quinidine was successful, and in one of them no paroxysms have occurred for nine months. Cases exhibiting electrocardiograms with coarse auricular waves appear to be more readily affected by quinidine. There is some experimental and clinical evidence that the action of quinidine and of digitalis are antagonistic.

### 46. The Meyer-Betz-Haas Treatment of Pyelitis.

G. DANIEL (*Deut. med. Woch.*, December 8th, 1922, p. 1624) has since 1917 treated 38 cases (14 ambulant and 24 in hospital) of pyelitis on the following lines. On the first day the fluid intake is cut down and on the second to the fourth day it is limited to 300 grams. Urotropine and sodium salicylate, 1 gram of each, are given three times a day, and a 20 per cent. solution of phosphoric acid (40 in 1,000) is distributed over three days. Twice a day the patient is given a hot-air bath for twenty to thirty minutes to promote sweating. On the fifth to the seventh day the drugs are discontinued, ordinary diet is given, and the system flushed by an "intensive drink cure" consisting of 2 to 3 litres of tea, a tablespoonful of *uva ursi* folia and another of herb. herniaria being added to each litre. The urine is examined every day with reference to its specific gravity and reaction, and on the last day of the cure a microscopic and bacteriological examination is made. The rationale of this treatment is the following: The growth of *B. coli* is inhibited in acid urine. Formaldehyde is obtained from urotropine only in an acid medium, and the more concentrated the urine the less vigorous is the growth of *B. coli*. The sudorific treatment is therefore given to make the urine more concentrated. The less urine there is secreted the less frequent will micturition be and the longer will be the time during which the germs will be under the action of the acid and antiseptic urine. The water cure at the end of the treatment is intended to flush the system and thus prevent the ill effects of the reduced intake of water. The results obtained by the author were very satisfactory, and it was only occasionally necessary to repeat the treatment. It invariably brought down the temperature and only in a few cases was it necessary to repeat the treatment once or twice to bring the temperature to normal. Other effects were the cessation of pain in the back and frequency of micturition.

### 47. The Significance of the Thyroid "Red Line."

M. G. MARAÑON of Madrid (*Bull. et Mém. Soc. Méd. des Hôpitaux de Paris*, December 7th, 1922, p. 1635) states that he described in 1919 a vasomotor reaction which he and others have observed very frequently in hyperthyroidism. For a long period it has been known that on gently tapping the skin on the front of the neck and upper part of the chest in patients whose vasomotor system is somewhat irritable a transient diffuse red colour of the irritated skin appears. In certain cases, however, this reaction is closely confined to the region of the thyroid gland; in some cases the generalized original flush becomes restricted in a short time to the thyroid region, in others from the first it is confined to that area. In either case the erythema persists for several minutes, and either disappears gradually or in irregular patches. Vasomotor instability has been noted as one of the cardinal symptoms of Basedow's disease—sudden flushing or true factitious urticaria—but its localization in the thyroid region has not been previously described. The author has found it in 85 per cent. of cases of hyperthyroidism; in others, in which the erythema was less well defined, these often : The author has termed them "vegetative neurosis," as he considers it is a factor in their etiology. The various tests proposed—the adrenaline test, thyroid extract, or leucocyte count—have not thrown light upon these doubtful cases; if, clinically, a case is obscure the reactions remain obscure also. The intensity of the symptoms has no relation to that of the hyperthyroidism—it has no prognostic value. For instance, it fails or is very slight in severe cases of senile hyperthyroidism and, conversely, is very well marked in the transient and slight hyperthyroidism associated with sexual crises. The author discusses fully the etiology of this phenomenon, which is admittedly obscure, but Lian has shown that the outline of the thyroid gland may be traced by the varying sensitiveness of the skin of the front of the neck—that is, over the thyroid area it becomes suddenly more

sensitive in the majority of cases of hyperthyroidism. This may be due to auto-suggestion in many neurotic patients who are aware of this thyroid hypertrophy. But in a certain number of cases, as frequently in Lian's hyperaesthesia as in the author's vasomotor reaction, the psychic factor may be eliminated. These phenomena may occur particularly in cases of simple hyperthyroidism without thyroid hypertrophy in which the patient does not suspect the origin of his troubles.

#### 48. Rubeola without a Rash.

G. FLÖYSTRUP (*Ugeskrift for Læger*, October 26th, 1922, p. 1461) considers the diagnostic value of tender swelling of the glands in the neck and occipital region in rubeola to be great. But he believes that rubeola can exist without a rash, although such an aberrant form of rubeola has apparently not hitherto been described. The cases inducing the author to take this view occurred in his own family. On April 20th a son aged 9, who had had measles but had not hitherto suffered from enlargement of the lymphatic glands, was found to have slightly tender, freely movable, and swollen glands in the neck. On April 23rd there was slight nasal catarrh with conjunctivitis; he vomited once and complained of headache and indefinite abdominal pains. Next day a few isolated pin-head spots appeared for a few hours on the cheeks and were of a pale red colour. This child had been a fortnight earlier in contact at school with cases of rubeola. Eight days after he fell ill his brother, aged 3, who had had measles two years earlier, fell ill with tender swelling of the cervical glands. Seven days later a rash, characteristic of rubeola, broke out. As there was no other source of infection it seems evident that the typical rubeola in the second case arose from contact with the atypical case.

#### 49. The Ultimate Prognosis of Lethargic Encephalitis.

S. TSCHUDI MADSEN (*Medicinsk Revue*, October, 1922, p. 470) has come to the conclusion that it is rare for the subjects of lethargic encephalitis to recover complete health. He has observed 19 cases, 4 of which terminated fatally at an early stage. Of the remaining 15, 10 were kept under observation for one year or more, and only in one case did the disease fail to leave any trace. Many patients showed slight mental disturbances; their memory was affected, and neurasthenic and psychasthenic symptoms were extraordinarily persistent. One of the patients was a boy, aged 13, who had previously been well behaved. After his discharge from hospital he was irritable and passionate, and, though he gradually regained his docile temperament, his capacity for concentration at school work was diminished. Some patients who retained their memory and intelligence lost all interest and initiative, being apathetic and performing every movement with a machine-like lack of individuality. Parkinson's disease supervened in two cases, and intention tremor and scanning speech were observed in one case a year after the onset of the disease. No satisfactory treatment has yet been devised.

## SURGERY.

#### 50. Enlarged Prostate in a Young Subject.

VAN DEN BRADEN (*Le Scalpel*, September 16th, 1922, p. 901) observes that retention of urine in a young man is not common except in those cases where it is due to a stricture or an acute prostatitis. As a general rule the symptoms due to enlarged prostate appear after 50 years of age. Guyon has stated that prostatic symptoms in the young subject may be due to alcoholism. The author records in detail a case of this nature. The patient, aged 25 years, was a wine merchant, and had indulged freely in alcohol since his youth; he complained of difficulty of micturition of several months' duration. The prostate was found to be slightly enlarged, of normal consistence, and not painful. After treatment with sounds and dilatation his condition was little improved; there was incontinence with overflow. Cystoscopic examination showed increased vascularity of the bladder and intravesical enlargement of the prostate. Treatment by local applications of heat to the posterior urethra with a metal sound gave satisfactory results, and the patient was subsequently able to resume his employment. Nine years later he returned with further difficulty of micturition and nocturnal frequency. The prostate felt very little enlarged, of soft consistency, and the urine was clear. The condition did not improve with treatment, and operation was advised. On opening the bladder the left lobe of the prostate was found much enlarged; the right lobe projected slightly. Prostatectomy was carried out, and when incised with the nail the enlarged left lobe ruptured, much blood escaping, and a prostatic tumour, weighing 10 grams, was enucleated with some difficulty. Microscopic examination of the portion

removed showed great vascular proliferation with a little adenomatous tissue. This case does not appear to have been one of true adenoma. The author compares the condition of the left lobe to a kind of cystic dilatation of the prostate, causing, by its mechanical effect, symptoms analogous to those due to an adenoma.

#### 51. Pain on Pressure over the Phrenic Nerve in Abdominal Diseases.

F. HÖGLER and K. KLENKHART (*Wien. Arch. f. inn. Med.*, Bd. v, H. 1, October 15th, 1922) record the results of their observations, in 200 cases, respecting the sensibility of the phrenic nerve to pressure in abdominal diseases. The nerve is lightly pressed upon between the two heads of the sternocleidomastoid muscle (Mussy's pressure point). Here the phrenic nerve winds round the anterior scalene muscle, and is most superficial. When the nerve is unduly sensitive a light pressure at this point causes intense pain. (Comparison with the opposite side should be made.) From their observations the authors conclude that in abdominal diseases the right phrenic nerve is sensitive to pressure only in inflammatory conditions in the region of the gall bladder. The most frequent cause was cholelithiasis with cholecystitis, very rarely ulcer of the intestinal tract; but then only when the latter had caused inflammatory adhesions with the gall bladder. In abdominal diseases pain on pressure over the left phrenic nerve was not detected. The right phrenic nerve contains both motor and sensory fibres, and supplies fibres to the diaphragmatic pleura, the mediastinal pleura, and the pericardium, and also to the peritoneum covering of the liver, gall bladder, and suspensory ligament of the liver. The importance of the pressure sensibility of the phrenic nerve in chest affections has been previously demonstrated by Neumann. Höglér and Klenkhart have shown in this paper that not only in thoracic affections, but also in diseases of the abdomen, this symptom is of diagnostic value. When the right phrenic nerve is found to be painful on pressure, and no sign of lung affection can be detected, this symptom especially points to inflammatory affections in the region of the gall bladder.

#### 52. Epidemic Encephalitis from the Ophthalmological Standpoint.

G. F. LIBBY (*Amer. Journ. Ophthalmol.*, October, 1922, p. 785) considers epidemic encephalitis from the point of view of the ophthalmologist, seeing that the ocular symptoms are often rapid in onset and may be the first, or even the only, symptom noticed, diplopia being frequently the first indication. Of other ocular symptoms paralysis of the eye muscles are transient and variable, and ptosis is often bilateral but seldom complete. Weakness or loss of convergence, insufficiency of accommodation, and inequality of the pupils occur, and in a large number of cases nystagmus is present, and occasionally optic neuritis in one or both eyes. If syphilis can be excluded, encephalitis may be diagnosed from the ocular symptoms alone, and an important differentiating point is the duration of the muscular palsies, the lesion in syphilis being generally long-standing before treatment avails, while in encephalitis the paralysis is fleeting and may shift from one muscle to another. Notes of five cases are given showing several varieties and degrees of ocular symptoms, from transient palsies to destructive optic neuritis. While it is possible to base a diagnosis on the ocular symptoms alone, the disease so almost invariably attacks the eye that a diagnosis in the absence of such symptoms is open to doubt. The evil effects of epidemic encephalitis may affect the general nervous system for years, and consequently the eyes may show persistent, or even permanent, damage to the structures seriously affected; but in these long-standing cases care must be taken not to confuse the pathological changes with those due to nerve syphilis. Clearly the disease is as much the concern of the ophthalmologist as of the neurologist or internist, and co-operation between all these is the ideal attitude in diagnosis and treatment.

#### 53. Malignant Disease of the Caecum and Chronic Appendicitis.

C. A. MORTON (*Bristol Med.-Chir. Journ.*, September, 1922, p. 82) states that it is sometimes impossible to make a definite diagnosis between a malignant growth of the caecum and a chronic or subacute appendix. Even on opening the abdomen the difficulty in distinguishing the one condition from the other may still be marked. The author reports three cases of malignant disease where it was not possible to make a certain diagnosis till adhesions had been broken down. Chronic appendicitis with abscess formation may be present with no pain, whilst malignant disease may simulate an attack of appendicitis with marked pyrexia. In both conditions the

lump will be found fixed in the right iliac fossa, and may be tender in either disease. In one case reported there was both a malignant growth and appendicitis, the latter condition being due to blockage of the lumen of the appendix by the growth. Carcinoma originating in the appendix may present the microscopic structure of alveolar carcinoma. In three cases recorded by Willie the patients were under 25 years of age. Several writers consider that these nodules are not really malignant. Such growths of the appendix are probably benign, and may threaten life more from the acute obstruction and inflammatory complications to which they may lead than from any intrinsically malignant properties.

#### 54. Treatment of Cancer of the Larynx.

L. J. MOURE (*Rev. de laryngol., d'otol. et de rhinol.*, October 15th, 1922, p. 755), in discussing the treatment of cancer of the larynx, considers that the first point to be emphasized is the confirmation of the diagnosis by a histological examination. Malignant tumours may be divided into intrinsic and extrinsic growths. Of the former, sarcomata and epitheliomata are found. Among the extrinsic growths are found those arising above the glottis, growths confined to the epiglottis, and those starting outside the laryngeal vestibule. In the case of intrinsic cancers limited to one vocal cord the neoplasm can be excised by thyrotomy, followed by immediate closure of the air passages. This is succeeded by x-ray treatment. If radium is employed great care must be taken to avoid necrosis, as it is difficult to control its effect. If the growth has started in the vocal cord but has spread beyond this to neighbouring structures, it should again be removed by thyrotomy, followed by local application of radium. In cases of an intrinsic growth arising outside the vocal cord on other parts of the mucous membrane, deep x-ray therapy should be tried. If this is not successful, complete laryngectomy is the operation of choice, followed by the application of x-rays to the scar. If the growth is limited to the epiglottis, the epiglottis may be removed after splitting the hyoid or thyroid cartilages. Should the growth arise outside the larynx and be accompanied by glandular enlargement, deep x-ray therapy should be tried. This may be followed by an apparent immediate cure, but recurrence is apt to take place after an interval of perhaps several months.

#### 55. Gastric Motility after Pyloric Obstruction.

B. S. VEEDER, M. B. CLOPTON, and R. W. MILLS (*Amer. Journ. Dis. of Children*, November, 1922, p. 404) studied the results of operation or non operation for pyloric obstruction in infancy upon gastric function and motility later in life (from 1½ to 8 years of age). The children were given a barium and milk meal on an empty stomach and its progress fluoroscoped, four cases which had been operated upon, and four which had not, being examined. No difference was noted between those cases treated medically and those treated surgically (Rammstedt operation), the gastric motility in all being normal, so that it may be concluded that end-results cannot be taken into consideration in deciding for or against operation in any given case of pyloric obstruction in infancy. In those operated upon a definite tumour was found, the four medically treated cases being classified as pylorospasm with symptoms of persistent projectile vomiting, small stools, visible peristalsis, and malnutrition. At the time of x-ray examination they were all in good condition of nutrition, and, with one exception, had developed normally after recovering from the trouble in early infancy. In five of the cases the stomach was empty in four and a half hours or less, and in the other three there was only a very slight amount remaining by that time, so that they all came well within the limits of normal gastric motility.

#### 56. Diathermic Treatment of Naso-pharyngeal Tumours.

L. SAMENGO (*La Semana Médica*, No. 36, 1922) records 5 cases of fibroma, 2 of fibrosarcoma, and one each of fibro-adenoma, fibromyxoma, and sarcoma of the nasopharynx, treated by diathermy followed by excision. The advantages claimed for this method are that electro-coagulation renders the operation bloodless and rapid, and leads to sterilization of the line of tissue cleavage; also that it is only by this means that certain extensive tumours can be extirpated *per vias naturales*. Unipolar or bipolar electrodes were used, one of the latter being introduced through the nostril and the other through the mouth. Except in aged subjects chloroform anaesthesia was employed as a rule. Glandular metastases were treated by bipolar electro-coagulation, a small cutaneous incision having previously been made. In the malignant cases post-operative applications of radium were made by means of the author's rigid apparatus fixed by bands, rods, and screws around the skull. Diathermic treatment of sarcomatous and epitheliomatous growths of the tonsil, palate, epiglottis, and floor of the mouth is also described.

## OBSTETRICS AND GYNAECOLOGY.

#### 57. Operation or Radiation for Cancer of the Uterus.

H. KÜSTNER (*Deut. med. Woch.*, December 8th, 1922, p. 1640) believes that in many German hospitals the pendulum is at present swinging in favour of operative treatment of uterine cancer and against treatment by radiation. At his hospital (the University Gynaecological Hospital in Breslau) the principle has consistently been adopted of operating when the disease is operable, the radical abdominal operation being practised for carcinoma of the lower sections of the uterus. When laparotomy reveals inoperable disease the abdomen is at once closed and treatment by radiation adopted. In the period from January 1st, 1911, to December 31st, 1917, there were 205 women operated on for cancer of the uterus. To ascertain their fate approximately five years or more after operation the author traced as many as he could. Only 15 cases had been operated on for cancer of the body of the uterus, and the number being too small for statistical investigation they were not included in the following results. Of 171 total abdominal extirpations there were 42 representing the primary mortality and 53 the late mortality. There were 30 patients still living and 46 who could not be traced. Total extirpation by the vaginal route was performed on only 18 patients, 6 of whom were still alive, and 3 could not be traced. There were 2 primary (operation) and 7 late deaths among the 18. The vaginal extirpations performed on these 18 patients concerned cases in the very earliest stage of the disease. The outstanding feature of these figures is the high operation mortality for the abdominal operation. This mortality has been greatly reduced of late, and during the past three years there has been only one operation fatality among 55 abdominal operations for cancer of the uterus. Of the 30 patients still alive 3 had developed late recurrences. The ultimate result was, therefore, recovery in 15.7 per cent. of all the cases of cancer of the cervix operated on by the abdominal route. As the operation mortality has been greatly reduced of late it would be fair to subtract the operation fatalities of the earlier period. This leaves 129 women, of whom 27, or 20.9 per cent., were cured by the operation. The author concludes that every fourth patient who survives the operation may expect complete recovery, and it is by this standard that the results of radiation should in the future be judged. At present, he holds, every operable case should be operated on, and treatment by radiation should be only supplementary and prophylactic.

#### 58. Pregnancy with Myoma and Placenta Praevia.

E. DEL SOLE (*Rivista d'Obstetricia e Ginecologia Pratica*, October, 1922, p. 533) records an unusual case of pregnancy with myoma and placenta praevia present. The patient, a 5-para aged 36, had had menorrhagia for three years; when, after twenty-six weeks' amenorrhoea, she was admitted to hospital complaining of slight haemorrhage per vaginam and of pain, the uterus corresponded in size to seven months' pregnancy and placental tissue was palpable through the cervix. In spite of two sharp haemorrhages, pregnancy continued to term and the patient was admitted to hospital in labour thirty-eight weeks after the last menstruation. Abdominal palpation showed the left portion of the uterus to be harder than the right; during performance of podalic version, on account of prolapse of the cord and haemorrhage, it was found that a voluminous myomatous mass to the left of the uterus had distorted and narrowed the uterine cavity. The delivery of the living and healthy foetus was followed by expulsion of a placental cotyledon which, implanted in the lower uterine segment, had caused the *ante-partum* haemorrhage; the main portion of the placenta was inserted on the left lateral surface, above and below the myomata. Signs of pelvic infection persisted during the puerperium and the ensuing months, and seven months after labour two partially necrotic myomata, weighing together 1,300 grams, were expelled per vaginam, together with much fetid pus. The subsequent recovery appeared complete, save that the uterus remained somewhat hard and large.

#### 59. Statistics of Eclampsia.

W. GESSNER (*Zentralbl. f. Gynäk.*, December 2nd, 1922, p. 1914) gives statistics of the number of births and the number of cases of eclampsia occurring in Baden during the years 1910-20. It is seen from these that during the war and especially during the years 1917-18 the number of cases of eclampsia was approximately only half as many per 1,000 births as in the years previous to the war. It is also noted that in the two years following the war the number of cases again approximates to the number before the war. This has been attributed to the nearly vegetarian diet indulged in

during the war years, a pregnant woman only receiving 1 lb. meat and 2 eggs a week and 1 litre of milk per diem. But, the author points out, the price of meat after the war made a vegetarian diet still necessary, yet the number of cases of eclampsia increased. Thus there must be some other factor involved. The author thinks that the decrease was also due to the hard work that had to be done during the war even by pregnant women up to the very day of their confinement. This helped metabolism and prevented the laying down of superfluous fat. He also blames the upright position, which, owing to the prominence of the abdomen, alters the centre of gravity of the body and causes a lordosis, which is especially marked in primiparae and has been shown by Jehle to be a cause of albuminuria, as it leads to circulatory disturbances in the kidney. It has also been shown by von Leyden that the progressive increase of the intra-abdominal pressure affected the kidney during pregnancy. Thus during the war hard work was indulged in, which caused the disappearance of most of the subcutaneous and subperitoneal fat, and thus increase of intra-abdominal pressure was not aggravated and there was no disturbance of renal function. After the war pregnant women, enjoying as before tranquillity not only of body but of mind, developed superfluous fat followed by eclampsia. The author advocates an hour's exercise morning and afternoon in the open air for every pregnant woman, and if she is obese and pasty he gives her thyroid extract three times a day to stimulate metabolism and accelerate the disappearance of fat. This treatment to be efficacious has to be begun early as it takes fourteen days before its maximum effect is reached.

## PATHOLOGY.

### 60. Blood Tests for Syphilis.

R. A. KILDUFFE (*Arch. of Derm. and Syph.*, December, 1922, p. 709) gives the results obtained at the Pittsburgh Hospital Laboratories from 1,014 serums tested both by the routine Wassermann method and the Kolmer modification. The same preserved complement was used in both tests. The Kolmer test involved serum dilutions of 0.1, 0.05, 0.025, 0.005, and 0.0025; primary ice-box incubation for eighteen hours; and the use of a special antigen—namely, a cholesterinized and lecithinized extract of heart muscle. Eight cases of known syphilis gave a negative Kolmer reaction. Seventeen serums from non-syphilitic conditions (pneumonia, diabetes, etc.) were all negative to Kolmer's test; two were positive and two doubtful by routine method. A positive Kolmer reaction was obtained in two cases where the primary lesion was only three and four days old respectively, routine method giving negative reaction. In 111 cases a positive Kolmer reaction was obtained where routine method gave a negative result; of these 50 per cent. had definite evidence of syphilis, and there was strong presumptive evidence in the remaining 50 per cent. (many being prostitutes) of the correctness of the positive findings. Thirty-one serums gave positive routine reaction and negative Kolmer reaction. The readings given by the Kolmer method are strictly quantitative; this last feature makes it a particularly useful method of estimating the results of treatment, and the author concludes that, although not infallible, it is superior to other methods now in use, and might well be adopted as the standard method of performing the Wassermann test. PALMER and GIBB (*Ibid.*) arrive at the same conclusions, based on examination of 362 serums. IDE and SMITH (*Ibid.*) report the results of an examination of 2,165 serums by the Wassermann and the Kahn precipitation tests. The results were practically identical from both tests. With spinal fluid, however, they found the Kahn method inferior to the Wassermann method.

### 61. The Viruses of Herpes and Epidemic Encephalitis.

C. KLING (*Hygiea*, November 30th, 1922, p. 913) has carried out experiments on rabbits to ascertain whether the viruses of herpes and of epidemic encephalitis are identical or not. The herpes virus was obtained from one case of pneumonia and from one case of herpes facialis. The virus of epidemic encephalitis was obtained from a district in the North of Sweden, where there had recently been a severe outbreak. The virus in each case was introduced into the cornea of a rabbit. The herpes virus provoked an intense purulent kerato-conjunctivitis in twenty-four to forty-eight hours, and an acute encephalitis followed, the changes in the brain differing in many respects from those associated with experimental epidemic encephalitis in rabbits. The inoculation of the virus of epidemic encephalitis into the cornea of a rabbit provoked a comparatively slight reaction, and it took about four to six months for charac-

teristic changes to occur in the brain. For these and other reasons the author has come to the conclusion that Levaditi is wrong in assuming that the viruses of herpes and of epidemic encephalitis are identical. In another series of experiments the author has found that the cerebro-spinal fluid of patients who have developed Parkinson's disease after contracting epidemic encephalitis is infectious to rabbits even a year to a year and a half after the onset of the encephalitis. Some rabbits appear to have a natural immunity to this disease, but 50 to 60 per cent. proved susceptible to inoculation with the cerebro-spinal fluid of the subjects of post-encephalitic paralysis agitans.

### 62. Coagulability of the Blood during Pregnancy and in the Newborn.

THE coagulability of the blood in women before, during, and after labour, as measured by the estimation of the coagulation, calcium, and pro-thrombin time, F. H. FALLS (*Journ. Amer. Med. Assoc.*, November 25th, 1922, p. 1816) asserts, is well within the limits of normal blood coagulability. Maternal and foetal blood at the time of birth of the baby have practically the same coagulation time. There is no evidence from the series of experiments performed by Falls that pregnancy tends to produce a haemophilic state in the mothers; hence post-partum haemorrhage can rarely, if ever, be ascribed to this cause. Foetal blood at birth clots with normal firmness and rapidity, so that subsequent haemorrhagic tendencies cannot be detected from coagulation tests at this time. Patients who took ether exhibited the same coagulation time as those delivered without ether. Post-partum haemorrhages, therefore, which are more common in these cases, cannot be explained on the basis of decreased blood coagulability.

### 63. The Number of Erythrocytes under Various Conditions.

E. J. RUD (*Acta Medica Scandinavica*, December 21st, 1922, p. 325) has investigated, at the Rigshospital in Copenhagen, the conditions under which the number of the erythrocytes in the blood is supposed to vary. He found, however, that such factors as a meal or muscular work did not show an appreciable or constant influence in this matter. He also failed to find any appreciable differences in the number of the erythrocytes at different times of the day or during menstruation. Their number was also strikingly uniform in the same person from day to day, week to week, and month to month; and it was immaterial whether the blood was taken from a capillary, vein, or artery. But during pregnancy there appears to be a certain physiological anaemia, as shown by a comparatively low erythrocyte count.

### 64. The Place of the Thyroid Gland in Anaphylaxis.

R. APPELMANS (*C. R. Soc. de Biologie*, December 9th, 1922, p. 1242) has endeavoured to confirm the statement of Képinow, who found that in animals from which the thyroid gland had been removed the injection of the dechaining dose after previous sensitization failed to bring about anaphylactic shock. On a series of eleven animals—presumably guinea-pigs—a sensitizing injection of 0.64 c.c.m. of human serum was made. In three of them thyroidectomy was performed 2, 7, and 11 days previous to the injection; in two of them thyroidectomy was carried out at the same time as the injection; in four of them thyroidectomy was performed 2, 2, 7, and 8 days after the injection; while the remaining two animals were used as non-thyroidectomized controls. At a period varying from 17 to 24 days after the sensitizing dose, the dechaining dose—0.5 to 3 c.c.m. in quantity—was injected into either the heart or the peritoneum. In every case typical shock occurred, and, with the exception of two of the animals in which the thyroid had been removed subsequent to the sensitizing injection and one of the controls, all of them died. All the animals were examined post mortem, and in only one was any vestige of the gland to be found—and this in one of the fatal cases. From these experiments it is concluded that the thyroid gland plays no part in the phenomenon of anaphylaxis. This conclusion, it may be noted, can only be held valid for the particular species of animal investigated.

### 65. Relation of the Diazo-Reaction to the Number of Leucocytes in the Blood.

NANNA SVARTZ (*Hygiea*, November 15th, 1922, p. 869) was so struck by the frequency with which she found the number of the leucocytes vary inversely with the intensity of the diazo-reaction in the urine in cases of tuberculosis and typhoid fever, that she undertook a special investigation of the subject, hoping to find some explanation for this inverse parallelism. Seventeen cases, represented chiefly by typhoid and paratyphoid infections, were investigated. But though confirmation was obtained of the inverse relationship of the two conditions, no explanation of it could be found.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## MEDICINE.

### 66. Action of Alcohol on the Acidity of the Gastric Juice.

K. FRIESE (*Dent. med. Week.*, January 5th, 1923, p. 11) has investigated the action of alcohol on the acidity of the gastric juice of 132 patients suffering from various diseases of the stomach. He first investigated the acidity forty-five minutes after a test meal without alcohol, and then gave a test meal containing 20 c.cm. of absolute alcohol in 200 c.cm. of tea, and on another occasion 5 c.cm. of alcohol in 200 c.cm. of tea. Thus the strength of the alcoholic solutions was 10 per cent. and 2.5 per cent. respectively. The patients were classified according as they suffered from (1) ulcer, (2) carcinoma, (3) achylia gastrica, (4) nervous dyspepsia, and (5) other diseases, such as atony, gastritis, and the digestive disturbances associated with cholecystitis and tabes. Both sexes and every age were represented in this material. Investigations with seven healthy controls showed that alcohol has, as a rule, no appreciable effect on the acidity of the gastric juice. But in the overwhelming majority of the 29 cases of gastric ulcer the acidity was reduced by the alcohol. Similar, but not so uniform, results were obtained in most of the 13 cases of carcinoma. In none of the 10 cases of achylia gastrica did the alcohol have any effect on the acidity of the gastric juice, but in nervous dyspepsia the acidity was usually increased. In the fifth class there was no uniformity in the reaction of gastric juice to alcohol. The author concludes that small quantities of alcohol promote the secretion of gastric juice largely by reason of its psychic action, and he discusses the possibility of the findings referred to being exploited in the differential diagnosis of various diseases of the stomach.

### 67. Diabetes Mellitus: Etiological Factors.

W. HOOGSLAG (*Nederl. Tijdschr. v. Geneesk.*, October 28th, 1922, p. 1934) records his observations on 250 cases of diabetes mellitus, 130 of which were males and 120 females; 42 were Semites (41 Jews and 1 Arab) and 208 non-Semites. The proportion of Jews affected, high as it was, was somewhat below the average, as all the patients came from the Hague and the neighbouring district, in which the Jewish population is by no means so large as at Amsterdam. The ages of the patients ranged from 10 to 79. In spite of careful treatment all the patients under 30 died in typical diabetic coma. Between 30 and 40 there were a few deaths from acid intoxication, but after 40 this cause of death was rare, and coma was usually due to a complication, such as gangrene, carbuncle, or bronchopneumonia, or to a sudden change to meat and fat diet. Occupation had much etiological importance, the disease being specially frequent among those who eat and drink in excess of their physiological requirements and neglect to take exercise and to take care of their skin, etc. Very many cases were found among butchers, restaurant keepers, captains of mail steamers, bankers, Indian planters, and clergymen leading a sedentary life. Hereditary and familial diabetes was common—among 207 cases 90, or about 43 per cent., gave a history of diabetes among their near relations (parents, grandparents, brothers and sisters, uncles and aunts). Diabetes among several children and adolescents in the same family was very uncommon. Hoogslag met with only 5 examples: 3 of these were rapidly fatal, and 2 occurred in Jewish youths whose disease had lasted for six years and showed no tendency to progress. It was as difficult as in the case of tuberculosis to say whether the factor of heredity was of favourable or unfavourable prognosis. In some cases the disease was fatal in every generation, while in others it ran a favourable course in all. Signs of mental degeneration, such as epilepsy and mental disease, were rare. Graves's disease was met with in 4 cases. On the other hand, evidence of the uric acid diathesis, such as gall stones, renal calculus, and obesity, were very frequent, being found in 115 out of 215 cases. Obesity was present in 85 cases. As regards the blood pressure, a low reading (below 110 Riva-Rocci) was of bad prognosis, and was only found in young patients or in middle-aged patients with clinical signs of pancreatic diabetes. A high blood pressure (above 200 Riva-Rocci) was found in patients with arterio-sclerosis or obesity of some years' duration. In this group the tension sometimes fell 20 or 30 mm. Hg when the sugar and fat were reduced. The great majority of the patients had a moderately high blood pressure (140 to 200), which was the best prognostic.

A normal reading (120 to 140) was very rare, in confirmation of the well known fact that the heart and vascular system are soon involved in diabetes.

### 68. Bismuth Salts in the Treatment of Syphilis.

ESCHER (*Ann. de l'Institut Pasteur*, December, 1922, p. 839) has used trepol and neo trepol in a large number of cases of syphilis in soldiers with very satisfactory results. In the present communication he analyses the results of treatment with trepol (tartaro-bismuthate of sodium and potassium) in 60 cases. At first he gave courses of ten to twelve intramuscular injections of 0.3 gram. But such doses frequently caused stomatitis and gingivitis, and occasionally albuminuria, and he therefore reduced the dose in later courses to 0.2 gram, given every fourth or fifth day. In 10 cases in the primary stage with a positive Wassermann reaction in the blood the parasite disappeared from the chancre in twenty-four to fifty-six hours after the first injection, and living spirochaetes were never found after forty-eight hours. The swelling of the inguinal glands subsided more rapidly than after any form of arsenical treatment, and parasites were not found in the serum aspirated from these glands six to eight days after the first injection. The chancres healed rapidly, and secondary rashes never appeared during the treatment. The Wassermann reaction became negative after the first course in 6 cases, in 2 at the end of the second, and in 2 between the second and third courses. Forty cases in the secondary period were treated. Mucous plaques began to heal on the fifth or sixth day, and parasites disappeared from them in thirty-six hours. Roscolar rashes disappeared in every case after the third injection. Pigmentation of the scars was much less frequent than after arsenical treatment. In 30 of these cases the Wassermann reaction became negative after one, two, or three courses of trepol. Pain at the site of injection was rarely met with after "painless trepol." Stomatitis and gingivitis could be controlled by thorough attention to the teeth and mouth-washes when doses of 0.2 gram were given. Albuminuria, which occurred in 9 cases, cleared up on cessation of the drug and a vegetarian diet. The presence of clusters of renal epithelial cells in the urinary deposit was a warning of the imminence of albuminuria.

### 69. Gastric Syphilis.

P. ÉMILE-WEIL (*Bull. Soc. de Thér.*, November 8th, 1922, p. 231) states that Leven has shown that syphilitic affection of the stomach is much more frequent and important than has hitherto been supposed. Without going so far as to adopt the opinion of Castex of Buenos Aires, that every gastric ulcer is due to syphilis, he maintains that a large number are due to this cause, and, as many cases of cancer of the stomach follow an ulcer, the possibility of syphilis should be considered in every organic lesion of the stomach. Gastric cancer may succeed syphilis of the stomach, as cancer of the tongue, oesophagus, or rectum may succeed syphilitic affection of these organs. From the practical standpoint, in every case of gastric disease it is important to make a complete examination, including the Wassermann reaction, of the patient himself and the members of his family. But even in the absence of any signs of syphilis the existence of an organic disease of the stomach should justify the trial of specific treatment, which is often followed by unexpected success, as in three out of four cases which the author records. The treatment consisted in injections of "914" alone, or in intravenous injections of soluble salts of mercury, followed by subcutaneous injection of arsenical preparations. Iodides were never given.

### 70. The Duration of Contagion in Whooping-cough.

BARBIER and RENARD (*Paris méd.*, December 9th, 1922, p. 531) have examined numerous children and adults before and during the paroxysmal stage of whooping-cough for Bordet's bacillus, and have come to the conclusion that whooping-cough patients are isolated for too long a period. In most cases children cease to be contagious after the paroxysms have lasted three weeks. They should, therefore, be allowed to return to school one month after the onset of the disease, instead of one month after the last paroxysm. The authors also maintain that abortive attacks occur, and that when a case of whooping-cough breaks out in a family the patient's brothers and sisters should also be examined, as they may be in the pre-paroxysmal stage, and thus constitute a source of infection in the school which they are attending.

## 71. Direct Muscle Testing in the Prognosis of Acute Poliomyelitis.

P. ERLACHER (*Klinische Wochenschrift*, December 2nd, 1922, p. 2415) describes a method of direct electrical examination of paralysed muscles by faradism in cases of acute poliomyelitis soon after the onset. On the results he bases his prognosis as regards the recovery of motor power in the muscles affected. It has been shown by Perthes that at the time of operation for nerve lesions the exposed paralysed muscle may react to a faradic current when it had ceased to react to faradism applied through the skin. Erlacher has tested the direct excitability of paralysed muscles in poliomyelitis by means of a fine needle introduced through the skin into the muscle. By this needle he applies the faradic current directly to the muscle. He states that this method of testing can be carried out even in infants, and that the pain is not greater than that caused by the needle when a hypodermic subcutaneous injection is given. He has found that paralysed muscles which present relatively good excitability when tested by the introduction of the fine needle recover their functions later. He gives examples of cases of acute poliomyelitis in which muscles not reacting to faradism applied in the ordinary way through the skin, but reacting distinctly to the faradic current applied by a fine needle recovered their motor power. The author's experience has been that recovery occurs in those paralysed muscles of which the direct excitability during the first month (after the onset of the paralysis) does not sink under one-third of the normal strength of current required for producing their contraction. But no useful recovery occurs in muscles which can only be directly excited by the full strength of the faradic current. If a relatively weak faradic current by direct needle testing gives a rapid and marked contraction the muscle is not seriously affected. If the direct faradic excitability does not sink under one-third of the normal, and if an increase of the strength of the current produces a strong contraction the prognosis is favourable.

## 72. The Pel-Ebstein Type of Hodgkin's Disease.

E. CAUTLEY (*Brit. Journ. Children's Dis.*, October-December, 1922, p. 185), who records an illustrative case, states that irregular pyrexia is common in Hodgkin's disease. One variety is the recurrent or relapsing type described by Pel and Ebstein in 1887. It is infrequent at all ages and decidedly rare in children. MacNalty reported one case in an infant aged 3 months and another in a child of 8 years of age; Murchison's patient was a girl aged 6 years. The fever is suggestive of an infectious origin of the disease, but so far no reliable evidence of this has been obtained. Cautley attributes the pyrexial bouts to localized necrosis of lymphadenomatous tissue and toxic absorption. His case, which occurred in a girl aged 8 years, was characterized by a prolonged local stage of glandular hyperplasia in the neck and a generalized stage of pyrexia which assumed a relapsing type, severe and progressive anaemia, a yellowish-grey tint of the skin, enlargement of the cervical glands, liver, and spleen, slight bronchitic attacks with breathlessness, sometimes semidelirium, erythropenia, and leucopenia. There was no evidence of tuberculosis, and the von Pirquet reaction was negative. No autopsy was obtained.

## 73. School Children and Spinal Curves.

E. H. BRADFORD (*Boston Med. and Surg. Journ.*, November 30th, 1922, p. 781) calls attention to the advantages of effective and not too irksome corrective measures in treating the curvatures of growing children, carried out through childhood and adolescence, as compared with spasmodic and expectant methods. Since faulty attitudes in children tend to develop into fixed spinal curves in adults, the importance of correcting flat chests and round shoulders is pointed out. When muscular weakness is present daily home exercises must be added to the class gymnastics and school drills, and in addition to the correcting of curves attention must be given to the strengthening of those muscles which hold the trunk normally. Where faulty attitudes have become firmly established corrective devices—braces, corsets, etc.—are needed in addition, but these should not be used so constantly as to weaken muscles or establish reliance. By means of properly adjusted appliances correcting pressure can be made on the projecting shoulder-blade, the drooping shoulder raised, and the side bend of the spinal column checked. It is during the period of rapid bone growth that treatment will be most successful, and each case requires individual judgement as to the extent and degree to which such correcting pressure should be applied. Clothing which restricts the normal play of muscles, and chairs which allow of faulty lounging attitudes, must be avoided, and since treatment is necessarily of long duration appliances should be as simply made as possible and suitable for domestic nursing.

## SURGERY.

## 74. Metastatic Carcinoma of the Choroid and Iris.

C. H. USHER (*Brit. Journ. Ophthalmol.*, January, 1923, p. 10) reports three cases of metastatic carcinoma of the choroid; the importance of recognizing such tumours is increased by the fact that a latent primary internal carcinoma may occur in which the diagnosis can be made only with the ophthalmoscope. The large majority occur in females and the primary growth is generally mammary, but two of the three cases reported were in males and the primary growth was not in the breast. In the first case, a man aged 36, autopsy was refused, and there was no evidence as to the site of the primary growth. In the second case, a woman aged 35, the primary tumour was in the breast and both eyes contained metastatic carcinomatous masses on the outer surface of each sclerotic; two growths were present in the choroid of the right eye, and both optic nerves were invaded. In the third case, a man aged 48, there were separate growths in the iris and choroid, that in the iris being cystic. Extensive growths were present in the thyroid, lymphatics, and lungs, the choroidal mass being probably metastatic from the scirrhous type of growth in the thyroid, lymphatic glands, and root of the lungs, while the cyst in the iris was probably metastatic from the softer papilliferous cysto-adenoma found in the lower lobe of the right lung. In about a third of the cases recorded in the literature both eyes were affected, and of 102 cases 73 were females and 29 males. Extraocular growths with destruction of the sclerotic are unusual, and growths passing from the optic disc into the optic nerve, as occurred in the second case, are rare. After the first onset of ocular symptoms duration of life averages only about eight months.

## 75. Congenital Scoliosis.

H.-L. ROSHER and R.-H. NOIRIT (*Journ. de Méd. de Bordeaux*, December 10th, 1922, p. 767), in reporting six cases of congenital scoliosis, remark that radiography has shown abnormalities in the vertebral column to be much more frequent in occurrence than was previously supposed. The commonest variety consists in a cuneiform or trapezoidal deformity of one or more vertebral bodies, often associated with abnormalities of the articular and spinous processes and of the ribs, and sometimes with spina bifida, occult or otherwise. The absence of one or more spinous processes often gives a valuable hint as to the congenital nature of the deformity, although the latter may not be noticed till adolescence. Slight cases may require no treatment. In severe cases a stiff corset should be worn, during the period of growth, to prevent increase of deformity. Moderate cases are treated in the same way as ordinary scoliosis, by hypercorrection and plaster jacket, followed by leather or celluloid corset, with gymnastic exercises. The cases in question presented the following conditions: (1) Male aged 2; right cervico-dorsal scoliosis from hemiatrophy of seventh cervical and of second dorsal vertebrae; absence of second left rib; torticollis since infancy. (2) Female, aged 13; dorsal right scoliosis with fusion of fourth and fifth dorsal vertebrae and atrophy of their left sides; oblique split in body of fourth dorsal vertebrae. (3) Female, aged 16; trapezoidal deformity of fifth dorsal, absence of fifth and sixth spinous processes; sixth right rib bifid. (4) Female, aged 9; left dorsal scoliosis from wedge-shaped sixth dorsal vertebra; fusion of sixth and seventh right ribs. (5) Female, aged 5; left dorso-lumbar scoliosis, with fusion of last four dorsal and first lumbar vertebrae, irregularity of lumbar vertebra, absence of twelfth right rib, spina bifida occulta, and dorso-lumbar hypertrichosis. (6) Male, aged 17; fifth lumbar vertebra wedge-shaped and fused with sacrum; atrophy of fourth lumbar, especially of its right side, giving secondary left dorsal scoliosis (compensatory).

## 76. Diptera causing Myiasis.

W. S. PATTON (*Journ. Laryngol. and Otol.*, January, 1923, p. 18) deals with the identification of the larvae of the tropical flies which cause naso-pharyngeal and aural myiasis in man, and studies the subject from the standpoint of the flies rather than from a classification of the organs invaded. Attracted by offensive discharges from the nose or ear, or following a nose bleeding, the eggs are laid, or larvae deposited, in the nostril or external auditory meatus, giving rise to intense irritation, swelling, and pain. The septum of the nose becomes perforated and the tissues rapidly break down; but in the ear the larvae are unable to eat their way through bone, and therefore cannot reach the brain. *Chrysomya bezziana* and *Wohlfahrtia magnifica* are typical of the oviparous and larviparous species causing myiasis; but many flies which normally lay their eggs or deposit their larvae in decaying vegetable and animal matter have acquired the

habit of doing so in or near diseased human tissues, as do also several flesh-flies of the genus *Sarcophaga*, and one or more species of the *Phoridae*. The larvae of either *Chrysomya*, *Sarcophaga*, or *Wohlfahrtia* can be recognized by the posterior stigmatic plates being large and enclosed in a shallow cleft or deep hollow, and by the overhanging lips of the ninth segment. In *Chrysomya* the plates are D-shaped, with three brown slits directed downwards and inwards, and they become visible on pressing the posterior end of the larva, while in *Sarcophaga* or *Wohlfahrtia* they are buried in a deep cleft and only just become visible on firm pressure. In *Calliphora* or *Lucilia* the plates are exposed without compression, and are relatively small, round or pear-shaped. The genera and species can only be determined with certainty by examining a caustic potash preparation of the posterior stigmata.

#### 77. Association of Bladder Symptoms with Ultra-Descent of the Right Testicle.

A. ADLER (*Deut. med. Woch.*, December 1st, 1922, p. 1612) has tested Ebstein's claims as to the diagnostic significance of the degree of descent of the testicles. Having many patients in hospital suffering from enuresis or other slight nervous disorders of the bladder, the author compared the incidence of these symptoms with that of ultra-descent of the right testicle. The coincidence of the two phenomena proved to be remarkably frequent, and when a patient was found to have ultra-descent of the right testicle he often gave a history of nocturnal enuresis. The author has collected 22 cases of ultra-descent of the right testicle, and he gives details of 12. Only in 4 out of the 22 did he fail to correlate the ultra-descent of the right testicle with functional disturbances of the bladder. He assumes that the ultra-descent of the right testicle betrays a slight functional deficiency in the lower segments of the cord; the right testicle hangs lower than the left because the tone of the right cremaster muscle is defective; and the lower position of the right testicle is not the cause of the bladder symptoms, but merely, like them, the result of a defect in the nervous system.

#### 78. Haematoma of the Rectus Abdominis in Typhoid Fever.

FRANZ ROST (*Acta Chirurgica Scandinavica*, December 22nd, 1922, p. 385) considers that in typhoid fever haematoma of the rectus abdominis muscle may give rise to symptoms which are very liable to be mistaken for those of perforation of the intestine. In typhoid fever the muscles sometimes undergo degeneration and rupture, a considerable quantity of blood being effused. The author has seen two cases in which haematoma of the rectus occurred under these conditions. In both cases the onset of abdominal pain was sudden, and it was associated with rigidity of the abdominal wall. The physician in charge diagnosed perforation of a typhoid ulcer and called for immediate operation. In the first case laparotomy was performed, but all that was found was a large haematoma of the rectus. In the second case the author declined to operate because the pain and rigidity of the abdominal wall were confined to the rectus muscle, and he realized that the symptoms were due to rupture of this muscle. With regard to the differential diagnosis, he suggests that it would be greatly facilitated simply by the surgeon bearing in mind the possibility of this complication of typhoid fever. It is very difficult to diagnose early peritonitis in typhoid because distension of the abdomen is common in typhoid before perforation and peritonitis have occurred. Considering the critical condition of the patient, it is most important that he should not have to undergo a laparotomy which would be superfluous if the symptoms were solely due to rupture of the rectus muscle.

#### 79. Plexus Anaesthesia.

E. PLATOU (*Norsk. Mag. for Lægevidenskaben*, September, 1922, p. 667) discusses the comparative merits of Kulenkampff's method of injecting a local anaesthetic into the brachial plexus for operations on the arm, and Mulley's modification. According to Kulenkampff's technique, the local anaesthetic is injected into the brachial plexus immediately above the clavicle. In some cases thus treated there have been signs of involvement of the pleura or apex of the lung, as well as other complications; to avoid these Mulley advocated anaesthetizing the plexus at a considerably higher level, the injecting needle being introduced three finger-breadths above the middle of the clavicle and 0.5 cm. behind the external jugular vein. The author has practised Kulenkampff's method in 26 cases, and it was successful in 25. Mulley's method was practised in 7 cases, but only in 3 did it prove satisfactory. Practising Mulley's method, the author found it very difficult to locate the plexus, and in one case he observed just those complications which Mulley's method, as compared with Kulenkampff's, should avoid. The

author used a 2 per cent. solution of novocain-adrenaline injecting, as a rule, about 20 c.cm., increasing the dosage in some cases to 30 or 40 c.cm. In some cases anaesthesia was induced in three to four minutes, but as a rule fifteen to twenty minutes were required, and in some cases half an hour. In 7 cases total anaesthesia of the arm was combined with complete paralysis of the muscles, the normal functions of which returned in two to four hours. The average duration of the anaesthesia was two hours, but in one case the sense of pain suddenly returned after eighty-five minutes. Though bilateral anaesthesia by Kulenkampff's method is considered dangerous, the author has successfully employed it in one case of severe electrical burns of all ten fingers; he allowed, however, an interval of an hour and a half between the two injections. He concludes that Kulenkampff's method is perfectly safe when carried out with care.

### OBSTETRICS AND GYNAECOLOGY.

#### 80. Etiology and Treatment of Tubal Gestation.

E. MAUTHER (*Zentralbl. f. Gynäk.*, December 16th, 1922, p. 2005), from his statistics of 437 cases (all operated upon), discourses on the various theories as to the causation of the condition. A previous history of acute salpingitis was only given in 17 per cent., but at operation the appendages were found to be inflamed in 36 per cent. The increase of gonorrhoea during the war years gave rise to no corresponding increase in the cases of tubal gestation. As regards the theory that tubal gestation usually occurs a long time after the last confinement, his statistics tend to show that this is not the case, 18 per cent. occurring less than a year after the last labour, and 30 per cent. between one and two years after. Definite external migration was found in three cases, one ovary and the opposite tube having been removed previously. As 32.2 per cent. of his cases showed no pathological causal factor, he is inclined to favour Poorten's theory that in many cases the condition is due to a diminished vitality of the ovum, and that this diminished vitality is due to some pathological condition in the ovary itself; 16.7 per cent. of his cases had ovaries which contained small cysts. "An absolutely degenerated ovary gives forth no ova; why (he asks) should a partially degenerated ovary not expel partially devitalized ova?" As regards treatment, the author advises immediate operation with removal of the gravid tube and ovary if necessary. He condemns all conservative measures of treatment of the tube, as the bleeding cannot be controlled with certainty. He also condemns the treatment advocated by Smith and Kulenkampff of prophylactic removal of the unaffected tube to prevent a second tubal gestation occurring, and only removes the other tube if markedly diseased. He points out that a second tubal gestation only occurred in 11.8 per cent. of his cases, and as the various symptoms were so well known to the patients they all reported early and were successfully operated on, whereas 33.4 per cent. became pregnant again, several having more than one child after the tubal gestation. It is interesting to note that in 6.7 per cent. a haematosalpinx was found on the opposite side to the gravid tube. His operative mortality was 2.5 per cent.

#### 81. Caesarean Section.

THE indications and technique of Caesarean section, based on 252 operations, are discussed by J. C. HIRST and W. W. VAN DOLSEN (*Journ. Amer. Med. Assoc.*, December 16th, 1922, p. 2047). The cases were unselected, and the patients were operated on just as they presented themselves. They varied from the ideal, clean case, in which operation was performed before labour, under ideal conditions and surroundings, to those in which operation was performed in unfavourable surroundings, in various stages of neglect. In one instance a patient with a rachitic funnel-shaped pelvis had been in labour five days, with four physicians making in all thirteen attempts at forceps delivery and one attempt at version; this patient recovered after hysterectomy and drainage of the stump, and the child is alive and well. In this series of 252 cases there have been five maternal deaths: one from haemorrhage from a ruptured varicose vein in the broad ligament, eight hours after operation (proved by *post-mortem* examination); one from mesenteric embolism of the transverse colon; three from septic peritonitis. Of the latter, two occurred before the days of extra-peritoneal Caesarean section. Had this technique been used the authors are confident one or both women might have been saved. This maternal mortality gives a percentage slightly less than 2. The foetal mortality, in any series of unselected cases, will run relatively high. In neglected cases the child is so often injured by prolonged pressure or ill advised attempts at instrumental delivery that

it is either stillborn or dies shortly after delivery. This can be in no way ascribed to the operation. Even in clean cases the child is not entirely safe. It is born anaesthetized in many cases, and inspiration pneumonia later claims some of these infants, though the risk is naturally many times less than in any other form of delivery in these particular cases. It is a mistake, however, to say that in a clean ideal case of Caesarean section the child runs no risk; it does, though a comparatively small one. In this series eighteen children were stillborn or died shortly after delivery; some of these deaths might have been avoided had the patient been brought to operation without needless delay. Two died of enlarged thymus, which would have occurred in any method of delivery. The authors emphasize the necessity for the operator to provide a competent assistant to receive the baby and attend to its resuscitation, if needed, rather than trust this important duty to anyone who happens to be present.

### 82. Treatment of Ovarian Carcinoma.

ACCORDING to E. ZWEIFEL (*Archivos de Medicina, Cirugia y Especialidades*, December 16th, 1922, p. 491) the operability in cases of carcinoma of the ovary is about 33 per cent., and the primary mortality is high—10 to 50 per cent. in various reports. The percentage of cures after operation is given as from 9 to 29, and no definitive cure has yet been recorded after irradiation alone. The author is in favour of prophylactic x-ray treatment after operation. He records the case of a patient in whom the uterus and adnexa were removed in April, 1913, for large ovarian carcinomatous tumour with microscopically confirmed nodular metastases on the peritoneum covering the uterus and bladder and that of the pouch of Douglas. In the same year the patient received two vaginal applications of mesothorium (50 mg. for twenty-four hours) and two exposures to x rays. She remained well for over seven years, and the metastases which then appeared in the abdominal scar and the pelvis have yielded to radiation.

### 83. Pyometra and Carcinoma of the Cervix.

R. ALAMANNI (*Rivista d'Ostetricia e Ginecologia Pratica*, October 29th, 1922, p. 12), in a communication to the Tuscan Obstetrical and Gynaecological Society, calculates the frequency of incidence of pyometra as a complication of cervical cancer to be 3.3 per cent. in cases observed at one clinic. In four cases seen by the author the age ranged from 55 to 70, and the growth was of the proliferative form and ulcerated; in two the pyometra was closed, and in two it emptied itself intermittently. The etiological factors concerned are: (1) obstruction by the tumour; (2) inflammatory infiltration of the cervical tissue; (3) endometritis in the body of the uterus. In none of these cases were pain, elevation of temperature, or compression signs present; and in one the diagnosis was only made after abdominal removal of an enlarged uterus, thought to be the site of myoma as well as of cancer of the cervix. Pyometra is not to be regarded as a contraindication to abdominal hysterectomy if the cervical growth is operable.

## PATHOLOGY.

### 81 The Nature of the Toxin of *B. dysenteriae* Shiga.

OLITSKY and Klinger stated that if *B. dysenteriae* Shiga were grown in a medium of egg bouillon, two distinct types of toxin were secreted. The one, an exotoxin, appears in the filtrate in five days; it is thermolabile, being destroyed by heat at 75° C. for one hour. Injected intravenously into a rabbit it gives rise to paralysis of the fore and hind limbs without any intestinal symptoms. The other, an endotoxin, does not appear for twenty-two to twenty-five days; it is thermostable, resisting heat at 90° for one hour. Inoculation of the heated filtrate—heated to 80° C. so as to destroy the exotoxin—causes intestinal symptoms without any nervous lesions. An antitoxic serum neutralizes the exotoxin but not the endotoxin, while a serum prepared against the endotoxin protects animals against several lethal doses of the endotoxin. C. DOPFER, J. DUMAS, and COMBESCO (*C. R. Soc. de Biologie*, December 2nd, 1922, p. 1140) have endeavoured to confirm this statement. They find that the five-day filtrate injected into rabbits produces paralysis of the limbs without any intestinal symptoms, but that on autopsy considerable oedema of the caecum is always noticeable. The twenty-two-day filtrate, heated to 80° C. for one hour and injected intravenously into rabbits, similarly gives rise to paralysis of the limbs without any intestinal symptoms, though on autopsy the same oedema of the caecum is found. They were able to produce the same phenomena by injection of the sodium sulphate toxin, and by the bodies of both living and dead bacilli. Finally, the ingestion of Shiga bacilli by the mouth,

either living or killed by heat for an hour at 60° to 75° C., produces the same syndrome with or without intestinal symptoms. On these grounds they feel unable to substantiate the duality of dysenteric toxin.

### 85. The Action of Lead and other Metals on Grafted Tumours in Rats.

A. BORREL, A. DE COULON, and L. BOEZ (*C. R. Soc. de Biologie*, November 25th, 1922, p. 1118), after noting in 1910 the effect of variations in the diet on the percentage of successful grafts in mice, and after obtaining, in particular, evidence of the growth-increasing properties of potassium, decided to take up the question again and study the action of different elements introduced, not by the alimentary canal but by means of ionization. Rats were selected as the most suitable animals, and the tumour used was a sarcoma—one which gives uniformly successful grafts without spontaneous regression. The treatment was commenced two to three weeks after inoculation, at a time when the tumour was already well developed. As regards the technique, they employed a battery of Leclanché cells, a resistance box to enable variations in the current to be made, and an ammeter to measure it. Knowing the electrochemical equivalent of the body they were using, the length of time the current was passed, and the intensity of the current, they were able to calculate the weight of the substance introduced. A carbon electrode was placed over the tumour, separated from it by a cotton compress soaked in a chemically pure solution of the electrolyte, while the cathode was in contact with the opposite side of the body. Of the various elements introduced lead gave by far the most promising results. Of ten tumours treated by this metal no fewer than eight retrogressed and disappeared completely within the space of two or three weeks. The animals were subsequently found to be refractory to a fresh inoculation. The total quantity of lead introduced varied from 16 to 47 grams, distributed over two to five sittings. Other metals, such as barium, silver, and copper, occasionally caused retrogression of the graft to occur, but not with the same frequency as lead. Though these experiments have only been performed on a small number of animals, and only one particular type of tumour studied, the results are certainly very suggestive and encouraging.

### 86. The Leucocyte Picture in Tuberculosis.

C. J. RAFFAUF and GRIMM (*Zeit. f. Tuberc.*, November, 1922, p. 107) examined the blood of 65 children, 25 of whom were boys and 40 girls, aged from 6 to 15 years, suffering from tuberculosis of the lungs or bronchial glands, and came to the following conclusions: (1) In well marked pulmonary tuberculosis in children the blood picture has the same significance as in adults, lymphocytosis and eosinophilia being signs of a favourable reaction. (2) In bronchial tuberculosis in the child lymphocytosis is also an undoubtedly favourable sign, and is frequently present when the disease pursues a relatively favourable course. (3) No distinction can be made between active and inactive hilus tuberculosis from a study of the blood picture. (4) The study of the leucocytes in tuberculosis of the lungs and bronchial glands in children appears to be, as in adults, a valuable therapeutic guide, especially as regards specific treatment. (5) A careful study of the blood picture appears to be specially important in tuberculosis of the bronchial glands when a focal reaction is produced by overdosage.

### 87. The Schick Reaction in Nasal Diphtheria.

VERNIEUWE (*Rev. de Laryngol., d'Otol. et de Rhinol.*, December 15th, 1922, p. 925) discusses the question of carriers and reviews the progress made since 1896, when Eeman and van Ermengem showed that virulent diphtheria bacilli might exist in a case presenting no other symptoms beyond excretion, increased nasal discharge, and, occasionally, epistaxis. Vernieuwe divides diphtheria "carriers" into four classes: (1) Convalescents from an acute attack, whether they have been given antitoxin or not, may still have bacilli, especially in the throat—that is, carriers by continuity of infection. (2) Carriers with no visible lesion (past or present). (3) Accidental carriers in whom are found diphtheria bacilli on a raw surface, such as follows an intranasal or naso-pharyngeal operation. (4) Carriers who have an active nasal diphtheria, often yielding an almost pure culture—a true local diphtheria with no constitutional invasion, which consequently is not diagnosed. The author records seven typical cases and describes his technique. He states that, by the use of Schick's method, laboratory work proves that nasal diphtheria does not produce immunization. The bacilli form a virulent focus, and in the majority if not in all of the cases continue to produce a positive Schick reaction. The significance of this fact and the recent work of Wolf on this subject are fully discussed.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## MEDICINE.

### 88. A Modification in the Routine Treatment of Syphilis.

M. SYDNEY THOMSON (*Brit. Journ. of Derm. and Syph.*, January, 1923, p. 1) has treated over 2,000 cases of syphilis by a special routine. This consists in giving at least three intravenous injections of 0.9 gram novarsenobillon with an interval of three weeks between each injection. These doses are continued until the Wassermann-reaction becomes negative. At the same time the patients take 1 grain of grey powder three daily continuously for at least a year unless gingivitis necessitates short remissions in the treatment. When the Wassermann reaction has remained negative for a year treatment is stopped, and the patient is watched for another year, a Wassermann test being done every six weeks. If this remains satisfactory at the end of the probation period the cerebro-spinal fluid is examined, and if all the tests for syphilis prove negative the patient is discharged as cured. The reasons given for this modification are (1) that death never occurs after a first dose of 0.9 gram novarsenobillon; (2) that this dose is not fully eliminated from the body for four weeks, but at three weeks only minute traces remain. There is therefore no danger of cumulative poisoning by the arsenic. Analysing 500 cases which have undergone this treatment fully, he finds that of primary cases 90 per cent. gave a persistently negative Wassermann reaction after their third injection, and a further 6.5 per cent. after four to eight injections, with a failure in 3 per cent. of cases. Of secondary cases 71 per cent. gave a persistently negative Wassermann reaction after the third injection, and 19 per cent. after four to seven injections; 10 per cent. were failures. He found the Wassermann test a very reliable standard of cure; a relapsing Wassermann reaction frequently presaged a clinical relapse. But during pregnancy the reaction almost constantly becomes negative, to relapse at once on parturition; it should therefore be disregarded during pregnancy, and treatment by injections and grey powder continued, if anything, more energetically than before. He had seen no ill results following arsenical intravenous injections continued up till the date of parturition, if the urine was carefully watched for albuminuria. This routine method was safe and convenient for the patient, and gave at least as good results as any other.

### 89. Ulcerative Endocarditis following Gonococcal Septicaemia.

N. GH. LUPU and P. STOINESCO (*Bull. et Mém. Soc. Méd. des Hôpitaux de Bucarest*, October 11th, 1922, p. 211) report a case in a woman of 21, admitted to hospital on February 15th, 1922, with a very painful acute arthritis of the right knee. Five days previously she had had a severe rigor with generalized articular pains. The articular fluid was greenish-yellow and viscid; dysuria and a vaginal discharge had been present for three weeks—the latter, as well as the synovial fluid from the knee, yielded a pure culture of gonococci; the blood culture was negative. Transient improvement followed hypodermic injections of polyvalent gonococcal vaccine, but after two weeks the temperature began to oscillate, rising to 38° or 39° C. at night, and the pulse rate rose to 136. A second course of vaccines produced a still shorter improvement; the patient developed right bronchopneumonia with bilateral pleural effusion, racking cough, and blood-stained sputum—over 500 grams of blood-stained purulent fluid were removed from the pleurae; neither this nor the sputum showed gonococci. Cultures from the pleural effusion remained sterile. Two months after admission a systolic bruit was heard for the first time; its maximum intensity was at the third left intercostal space; pericardial friction sounds were also heard. The pulmonary condition improved, but three weeks later the patient's state was very grave; a diastolic basal bruit, loudest in the pulmonary area, appeared, and an intense systolic thrill was felt. Intractable vomiting, followed by symptoms of acute parenchymatous nephritis, set in. The spleen was much enlarged and very tender, uraemic symptoms increased, and the patient died on May 27th. At the autopsy the following conditions were found: acute myocarditis, fibrinous pericarditis, vegetations on the pulmonary valve, double bronchopneumonia (pseudo-lobar), right pleuritic adhesions, parenchymatous degeneration of the myocardium and liver, acute nephritis, splenic enlargement with anaemic and suppurating infarcts, arthritis and peri-arthritis of right knee, with periostitis of the femoral condyles, and cervicitis of the uterus. The lesions of the pulmonary valve are described in detail, as well as those of the other viscera. Cultures on

blood agar, and ascites agar from the heart, pulmonary valve, purulent synovial fluid, lung, and cervical canal, yielded gonococci. The authors observe that, after streptococcal, staphylococcal, and pneumococcal infections, gonococci most frequently produce metastatic lesions. Gonococcal septicaemia has been described by several authors, whose statistics are quoted. Gonococcal infection often produces arthritis, rarely endocarditis, and exceptionally pleural, pericardial, and pulmonary complications. The infection of the pulmonary orifice, the multiplicity of the secondary foci, and the failure of vaccine therapy are remarkable. The authors conclude by analysing the localizations of previously recorded valvular lesions of gonorrhoeal origin, emphasizing the rarity of infections of the right side of the heart.

### 90. Epidemic Polio-encephalitis Simulating Food Poisoning.

P. KRAUSE (*Deut. med. Woch.*, December 22nd, 1922, p. 1715) reported at a medical meeting at Bonn an epidemic which broke out in a training establishment, where ten women between the ages of 18 and 25 developed alarming symptoms. There was great dysphagia, with dyspnoea, diplopia, and paralysis of accommodation. There were no gastrointestinal symptoms. Nine, all of whom lived in the same room, died within two and a half days. The tenth patient, who lived apart from the rest, recovered. Of 13 patients, who fell ill several days later, 4 died with similar symptoms. The patients examined by the author showed a variety of ocular symptoms; there was paralysis of accommodation and of the movements of the eyeball, in 2 cases there was horizontal nystagmus, in 1 there was vertical nystagmus, and in 2 there was bilateral ptosis. All experienced difficulty in swallowing, and in one case there was complete paralysis of the palate. The tendon reflexes were normal or slightly increased, and in some cases they were less lively than normal. There was no evidence of poisoning by meat, fish, or cheese, and an examination of sweets, which some of the patients had eaten, proved negative. Tests for arsenic also proved negative, as did certain bacteriological and serological investigations. The post-mortem examinations showed no signs of an inflammatory process or of gastro-intestinal disease. A doctor who had attended the patients developed similar symptoms about eight days later. The author noticed that all his patients showed slight redness and moderate swelling of the lining of the throat, and some suffered from gingivitis. Three other patients were seen, all of whom showed slight catarrhal angina, transitory dysphagia, and protracted accommodation paralysis. In two of these cases the poisoning was traced to a ham, but in the third case there was no evidence of food poisoning. The conclusion drawn from these cases is that the symptoms of food poisoning and of epidemic polio-encephalitis may be remarkably similar.

### 91. Melanomata of the Skin.

HENRI HALKIN (*Ann. de Méd.*, September, 1922, p. 189) discusses fully the various views regarding the origin of these tumours, and then describes his own researches. He explains his methods of hardening and staining, and insists on the differences in structure which the specimens present. These show a type of evolution of a naevus from that of a localized benign tumour; this evolution may be arrested or become so slow that one finds in adults very slightly developed naevi which have existed for a long period; the process is independent of that malignant change which, as clinical observation shows, may be produced as much in a small, smooth naevus as in one which is projecting and horny. Histological details of fourteen specimens are then given, with numerous plates. Halkin concludes that melanomata are naevi undergoing rapid evolution; like them they are of mesoblastic origin, and may be termed melanosarcomata. This confirms Virchow's opinion; he considered naevi to be potential sarcomata. As in naevi, all connective tissue cells may become the point of origin of proliferation. Proliferation without pigmentation may occur; non-pigmented naevi are analogous to the melanotic form, and may result in sarcomata by malignant degeneration. Melanotic pigmentation, however it may arise, is a proliferating agent and an element of malignity. Proliferation is particularly rapid, and metastases occur very early when pigmentation is most marked. Epidermal pigmentation and the proliferation resulting therefrom are accessory only. The epidermis takes no active part in naevus formation, nor in its malignant transformation, nor in metastases. Pigmented connective tissue cells (chromatophores) are not the only source of the

tumours (chromatophoromata of Ribbert). Non-pigmented cells are developed in the same manner; they are not derived from chromatophores. The chromatophores are not old pigmented cells (Unna); they are young cells with all their proliferating power. Melanosarcomata do not originate in a nucleus, an embryonic inclusion; they result from tissue change, probably under the influence of a substance circulating in the blood, if not derived from it, and becoming deposited in the cells in the form of melanin.

## 92. A New Eruptive Fever?

A. M. STEVENS and F. C. JOHNSON (*Amer. Journ. Dis. Children*, December, 1922, p. 526) report two cases of eruptive fever, which they consider entirely unlike any previously recorded condition, and associated with stomatitis and ophthalmia. Both occurred in boys, living so far apart as to preclude any possibility of contact, and in both there were high continuous fever, great prostration, and purulent conjunctivitis. Commencing with fever, the rash appeared the next day on the back of the neck and on the chest, spreading during the next eighteen days to the face, arms, trunk, and legs, and finally to the soles and palms, by which time resolution in order of appearance had begun. The eruption consisted of oval, dark red to purplish macules, separated by normal areas of skin, and becoming in a few days raised brownish-purple papules, without pustules or vesicles, and without pain or itching, and ending in horny crusts. The mouth and tongue were inflamed and raw, and the eyelids swollen, with pus streaming from the eyes. Both were diagnosed at first as haemorrhagic measles, but this was negated by the subsequent distinctive development of the rash, and, though a toxic erythema multiforme was suggested, the character and distribution of the lesions, absence of subjective symptoms, prolonged high fever, and terminal heavy crusting negated this view also. The serious effects of the disease were shown by one of the boys becoming totally blind and the other only escaping with impairment of vision in one eye. The syndrome suggested to the authors an infectious disease of unknown etiology.

## 93. Familial Haemolytic Splenomegaly.

S. O. COWEN (*Med. Journ. of Australia*, November 11th, 1922, p. 545) investigated a remarkable series of cases of splenic enlargement associated with anaemia and jaundice occurring in one family, now 48 in number spread over three generations, of whom 19 were examined. The majority were only mildly affected, but in two advanced cases, aged respectively 1 year and 4 months and 44 years, splenomegaly, anaemia, increased corpuscular fragility, and jaundice were prominent. Enlargement of the spleen commences early but is never extreme, and anaemia is constant, the red cell count becoming lower and the colour index rising as the disease progresses. The fundamental pathogenic feature of the disease is the persistent excessive haemolysis, and this and the specific activity of the spleen are regarded as essential factors in its causation, and may both be due to the action of some toxic substance as yet unidentified. Splenectomy, by removing the splenic factor permanently, relieves symptoms, since excessive haemolysis is prevented. The familial and acquired forms of the disease are, the author believes, closely related, and in the family under observation the disease may have been introduced by an acquired case among its members; the familial factor is apparently transmitted by a toxin causing an inborn error of metabolism manifested by corpuscular fragility and splenic activity, the age of onset of symptoms varying as the balance between blood destruction and blood regeneration varies.

## 94. Peptic Ulcer.

MAX EINHORN (*New York Med. Journ. and Med. Record*, December 6th, 1922, p. 613), from an experience of twelve cases of peptic ulcer with deformities of the viscus as shown by x rays, considers that such cases can be successfully treated medically with a restoration of almost normal configuration of the stomach and duodenum. Five of the cases showed penetrating ulcers of the lesser curvature of the stomach, one of the pylorus, and in six there were duodenal ulcers with constant deformities of the cap. Under duodenal alimentation treatment the pathological findings were improved, the niche formation almost entirely disappearing, and the cap deformities becoming normal, with a general return of well-being and health. That the possibility of curing peptic ulcers by medical means is not a rare event is shown by the fact that these twelve cases were taken serially, and only one later case occurred in which duodenal alimentation failed to relieve, and in which a gastro-enterostomy was needed. By such medical measures rest to the affected part is secured, and the general nutrition provided for.

## SURGERY.

95.

### Goitre

N. J. MACLEAN (*Canadian Med. Assoc. Journ.*, December, 1922, p. 847) considers that in the treatment of goitre bilateral resection affords the best results, provided that the patient be placed in the best possible position for operation by preventive and early active medical treatment, the actual operation being regarded as one of the steps in treatment. The importance of pre-operative and post-operative rest is insisted upon, and it is claimed that the exophthalmic or toxic patient can be made as safe for operation as in simple goitre. R. E. McKECHNIE (*Ibid.*, p. 854) urges basal metabolism as the best guide in deciding when to operate, and under such guidance early operation is advocated. While treatment by rest and drugs is important, operation, undertaken before extensive myocardial degenerations have taken place, offers the only positive treatment, and both forms of toxic goitre (the exophthalmic and the toxic adenoma) should be treated alike. F. N. G. STARR (*Ibid.*, p. 258) considers that most of the cases seen in childhood can be cured before the age of 20 by medical treatment, but that later surgery alone can effect a cure, provided that no permanent cardiac mischief has arisen. The estimation of the basal metabolism is important, and in extreme cases one pole should be ligated under local anaesthesia, followed in a week or two by ligation of the other pole, the whole operation being completed after about three months' complete rest and change. J. K. MCGREGOR (*Ibid.*, p. 860) relies upon the basal metabolic test in diagnosis and also in estimating the course of the disease. Surgery is inadvisable in the early stages, which should be treated by complete rest. Ligations are of value in preparing for a thyroidectomy and for testing whether a radical operation is likely to produce an attack of acute hyperthyroidism. Extirpation of four-fifths of the gland affords the only certain means of cure. In severe cases ligations and thyroidectomies may be done in bed, as advised by Crile, in order so far as possible to eliminate disturbance of the patient.

96.

### Maxillary Sinusitis in Young Children.

INFLAMMATION of the maxillary sinus in the newborn and young children is a somewhat unusual condition. F. J. COLLET (*Arch. Internat. de Laryngol.-Otol.-Rhinol.*, November, 1922, p. 1041) records a case of this nature in a child a few weeks old. The symptoms of the condition are fairly typical. The child at first shows the signs of a feverish attack with rise in the temperature, refusal to take the breast, and nasal obstruction. There is redness around the eye and progressive swelling and redness in the suborbicular region with oedema and perhaps fluctuation. Finally, there is a discharge of pus from the corresponding nostril. Recorded cases show that the prognosis is bad, and the suppuration severe in spite of operative treatment, which may be necessary on repeated occasions. In two cases death was due to an abscess of the lung and abscess of the brain. The maxillary sinus in the child differs from that in the adult, in that in the child it opens into the nasal fossa by a large orifice; further, the cavity itself is of small dimensions, for the anterior part of the maxilla does not contain the sinus but is occupied by the tooth germs. This renders an infection of nasal origin unlikely. The author considers that the condition starts as a generalized infection which becomes localized in the maxilla and then affects the sinus, the infection being by way of the blood stream. In one case it followed injury at birth. The treatment of the condition raises several points. It is not advisable to approach the small cavity via the nasal fossa, as it is both difficult and dangerous owing to the proximity of the orbit. If it is approached from the alveolus the incision should be slanted to avoid damaging the teeth; further, if the disease starts in the maxilla the incision is best made at the border of the alveolus, as this allows sequestra to be cast off later should they form.

97.

### Middle-ear Infection in the Newborn.

MAHU and E. CHOMÉ (*Gynéc. et Obstét.*, 1922, vi, 5, p. 313), at autopsy on a stillborn child born after prolonged infected labour, demonstrated the presence of staphylococci, streptococci, and other organisms in the middle ear. They point out that pus has been found in this situation by Renaud in post-mortem examination of each of 70 sucklings, and that Veillard found pus, together with evidence of local suppuration in bone or in mucous lining, in 35 per cent. of cases. As may be shown by animal experiment, foetal distress causes intra-amniotic inspiration followed by deglutition; by these movements infection of the foetal middle ear may, it is said, be readily produced. The authors are inclined

to agree with Renaud in considering chronic latent middle-ear infection as a common cause of marasmus and as playing an important part in early infant mortality; like him they have found middle-ear suppuration to be the only demonstrable morbid finding at autopsy on certain atrophic infants. They believe that shortly after birth prophylactic applications of silver solutions should be made to the nose and nasopharynx as well as to the eyes, and suggest instillation into the nostrils of two or three drops of 10 per cent. argyrol in glycerin, or injection of 1 in 300 watery solution of protargol.

### 93. Prostatectomy.

S. H. HARRIS (*Med. Journ. of Australia*, October 7th, 1922, p. 401) records a death rate of 3.5 per cent. in 146 cases of prostatectomy. The average age of these patients was 69 years, nine being over 80 years. Preliminary treatment was carried out by retention catheter in over one hundred of the cases, whilst a preliminary cystotomy was performed in thirty-four. The one-stage operation was performed as follows: After vertical incision of the aponeurosis the bladder was segregated with gauze; the bladder was then incised to the highest point of the fundus, and after bimanual enucleation the bladder was drained with a glass tube. For the control of operative haemorrhage, bimanual compression was generally found sufficient. Either is the anaesthetic of choice, by the intrapharyngeal method. A saline is given per rectum immediately after the operation, and a suspensory bandage fixed to support the scrotum. The drainage tube is removed about the sixth day, and the majority of patients pass urine within ten days; complete closure of the fistula occurs three to seven days later. Hexamine and sodium benzoate are given, and no bladder irrigation used, at any rate during the first fortnight. Epididymitis occurred in 10 per cent. of the cases; the early onset of urination acts as a prophylactic in this regard. The author considers that the glass drainage tube contributes in no small degree to the exclusion of unpleasant sequelae. So far as recurrence of symptoms is concerned, practically all the patients consider themselves cured of the prostatic trouble. The modern operation of prostatectomy in competent hands should entail little greater risk than that of any average series of abdominal sections.

### 99. X Rays in the Treatment of Salivary Fistula.

F. W. KAESS (*Zentralbl. f. Chir.*, January 6th, 1923, p. 14) reports two cases of parotid fistula in which healing took place after the parotid gland had been put out of action temporarily by a strong dose of x rays. He was led to make a trial of the method through noticing that patients under x-ray treatment for cervical adenitis frequently complained of dryness of the mouth. One case, in which the fistula resulted from a gunshot wound received in 1917, was operated upon on January 23rd, 1920, the fistula being excised and the thermo-cautery applied to the deep communication; on removal of the sutures a week later a brisk flow of saliva reappeared. Thereupon a strong x-ray exposure was made, the dose being 120 F. at 24 cm. distance of anode from skin, with 3 mm. of aluminium filtering. After this no saliva came from the wound, and complete healing had taken place by March 2nd, 1920. The second case was that of a man aged 44, suffering from parotid fistula, the result of a gunshot wound, with marked eczema of the surrounding skin. Division of the auriculo-temporal nerve was first tried, and was followed by temporary improvement, then relapse. A dose of 150 F. of x rays was then applied. Two weeks later the fistula had closed, and the eczema disappeared soon after. The author considers that such x-ray exposure may of itself cause many such fistulae to heal, and also that the method should be used as an adjunct to any form of operative treatment.

### 100. Recurrent Renal Calculi.

J. D. BARNEY (*Surg., Gyn., and Obstet.*, December, 1922, p. 743) considers that it is impossible to say whether the stones found in a kidney a year or more after operation are actual recurrences or stones left in the kidney at the first operative procedure. He is convinced that many cases fall into the latter class. An x-ray examination should be the rule after convalescence to ensure accuracy in finding if these stones are recurrences. Actual recurrence of stone is unquestionably very frequent. It appears strange that removal of stones from so comparatively small a cavity as the renal pelvis should be so uncertain a matter, whilst nephrotomy yields equally unsatisfactory results. However, the complex character of the interior of the kidney, haemorrhage, and the comparative inaccessibility of the organ in many cases contribute to the difficulties in removing all stones. X-ray examination may show one fairly large shadow, but this may cover other smaller shadows lying in

front of or behind it. Further, a small stone may become surrounded with fibrin so that it is not detected. It would appear that the fluoroscope offers the most promising prospects of success. After delivering the kidney from the wound the x-ray apparatus is brought up and stones may be readily seen. When the rays subsequently show that a stone has been left behind a second operation is advisable and should be done soon after the first. For removal of stones pyelotomy is unquestionably the operation of choice, and may often be advantageously combined with partial nephrotomy. One of the most common causes of recurrence of stone has been attempts to conserve a badly damaged kidney. The mortality following nephrotomy is about 5 to 6 per cent., whilst in pyelotomy it is practically negligible. Haemorrhage and post-operative fistulae are rarely seen after the latter procedure, which, though perhaps more difficult, should always be selected if possible.

## OBSTETRICS AND GYNAECOLOGY.

### 101. Pregnancy in the Tuberculous.

C. C. NORRIS and D. P. MURPHY (*Amer. Journ. of Obstet. and Gynecol.*, December, 1922, p. 597), from a series of cases of their own and also collected from the literature, evolve some important statistics. In their own cases 51 per cent. became worse or died after pregnancy, the prognosis becoming worse the more advanced the stage of the disease. Thus, 30.5 per cent. in the first stage got worse and 1.5 per cent. died, 46.6 per cent. in the second stage got worse and 3.6 per cent. died, whereas 84.5 per cent. got worse in the third stage and 31.5 per cent. died. From the cases collected from the literature therapeutic abortion seems to be beneficial, for in 630 cases 44 per cent. became worse with pregnancy, whereas in 44 cases in which abortion was induced only 9 per cent. deteriorated. The infantile mortality in 1,500 infants was 58.83 per cent. From the study of their cases the authors give the following recommendations: (1) Unless pulmonary lesions have been quiescent for some time tuberculous women should not marry, but, if married, should not become pregnant unless disease is in the first stage and has been quiescent for at least two years. (2) If acute exacerbations manifest themselves before the fifth month of pregnancy, abortion should be induced at once, the delay of a week even affecting the prognosis considerably; 70 per cent. will benefit by such treatment. (3) If after the fifth month, expectant treatment should be adopted and labour made as easy as possible. The patient should never be allowed to go over time, but rather premature labour should be induced a week or two before time. (4) A tuberculous mother should never be allowed to nurse her child, and the infant should be specially protected against post-natal infection, as it is very rare indeed for a child to be born tuberculous.

### 102. The Toxaemias of Pregnancy and Anti-anaphylaxis.

LOUIS CHARRON (*Journ. de méd. de Bordeaux*, December 25th, 1922, p. 787) observes that the uncontrollable vomiting of pregnancy has given rise to an infinity of etiological interpretations, and consequently to a like variety of remedies. The author records two cases which he thinks may throw light on the problem: (1) A patient, aged 30, complained that for two months she had vomited incessantly. She had not menstruated for two months, but stated that she did not know if she were pregnant; in her two previous pregnancies she had not suffered in this way. Her doctor suspected pregnancy and tried to relieve the vomiting, without success. He gave (among other treatment) a few injections of horse serum. The patient became worse, slight jaundice appeared, with rapid pulse and progressive emaciation. Ultimately the uterus was explored, but the cavity was empty, except that on the anterior wall there was a placental fragment as large as a small nut. The patient recovered, and admitted that abortion had been induced. The retention of that small portion of placenta after the bulk of the ovum had escaped apparently caused the persistence of vomiting; this suggested that the toxins are of placental origin. (2) A war widow, aged 24, with one child aged 5, was about two and a half months pregnant. Her doctor had treated her for two months for severe vomiting. The patient refused food, the vomit became fetid and blood-stained, and when seen by the author cachexia was advanced. After administration of various drugs and injections of horse serum, with no benefit, the author curetted the uterus, and the patient completely recovered. Two years later the patient married again, and fifteen days after the last period blood-stained vomiting suddenly commenced. The previous symptoms recurred, the vomit was extremely fetid and incessant, and the patient's weight fell from 58 to 41 kg. The urine was normal, except that it contained 0.96 gram of acetone to the

litre, much indican, urobilin, leucocytes, and a trace of serum-albumin. With her doctor's consent, Charron decided to try the effect of injection of the husband's serum. He was quite healthy; the Wassermann reaction was negative, and there were no signs of malaria. If the patient's toxæmia were due to a "male" antigen, a second and progressive injection of that antigen should, asserts the author, desensibilize the patient's system. After five injections of 5 c.cm. of the husband's serum the patient completely recovered, and her pregnancy is stated to be progressing normally. Charron considers that the fact that in this pregnancy the patient commenced suddenly to vomit while yet ignorant that she was pregnant disposes of the theory of auto-suggestion; further, none but Charron and his colleague knew the source of the serum.

### 103. Action of Mammary Extracts on the Uterus.

M. DAL COLLO BONARETTI (*Archivio di Ostetricia e Ginecologia*, December, 1922, p. 73) reviews the somewhat discordant results which have been reported concerning the action of mammary extracts on the uterine muscle. In her own experimental investigations she has found that mammary extracts made with saline solution or Ringer's fluid exercise an effect which varies with the dosage; small amounts increase the tone of surviving uterine muscle and lead to increased frequency and amplitude of its contractions, while larger amounts produce the contrary effects. The results are the same on the gravid as on the empty uterus, and are produced by extracts of secreting or inactive breast tissue; no specificity is demonstrable, the uterus of one species responding to mammary extracts derived from another species. The experiments included trial of human uterine muscle and human mammary extracts, but the latter appeared less active than extracts of animal breast tissue. The active principle is destroyed by boiling, but resists a temperature of 60° C.

### 104. Treatment of Abortion.

J. A. VAN DONGEN (*Nederl. Tijdschr. v. Geneesk.*, November 25th, 1922, p. 2346), in the second part of his paper (see EPITOME, December 23rd, 1922, para. 492), discusses whether digital or instrumental removal of the residues of abortion is preferable. First, as regards pain, instrumental treatment is in most cases possible when the os admits a No. 12 dilator and sometimes even a No. 10, or No. 8, whereas proper digital treatment can only be carried out when a No. 18—or better, a No. 20—can be passed. This in itself is in many cases so painful that an anaesthetic is necessary. In manual treatment, therefore, the patient has to choose between suffering much pain and the dangers connected with an anaesthetic. On the other hand, curetting can be carried out in most cases without an anaesthetic and with little or no pain. Secondly, as regards the results, manual treatment, even under an anaesthetic, is more fatiguing for the operator, as the cervix, if it is not considerably dilated, grips the manipulating finger, and interferes with the separating of the residues of abortion. Moreover, the finger, which is short in comparison with the curette, may have difficulty in reaching the fundus, so that the operation loses in completeness and accuracy. Van Dongen has frequently had to remove with a curette large pieces of the placenta from patients who had been treated elsewhere by the digital method. Thirdly, infection of the genital organs and general infection are much more likely to occur under digital treatment, owing to damage to the cervix of fundus, than when a curette is used. Fourthly, as regards perforation, provided a proper instrument is used and suitable care is taken, this accident is not likely to occur. Van Dongen has never had a case among the 1,590 curettings for abortion performed by him. He concludes that curetting is less painful for the patients, saves an anaesthetic, is more readily carried out, and is less likely to give rise to local or general infection, while there is only more chance of perforation if it is performed by an inexperienced and careless operator. Medical students should occasionally perform the operation under supervision, so that after they are qualified they may be of greater help to their patients than if they employed the digital method.

## PATHOLOGY.

### 105. Pancreatic Extracts.

J. R. MURLIN, B. KRAMER, and J. E. SWEET (*Journ. Metabol. Research*, July, 1922, p. 19) discuss the influence of pancreatic extracts without the aid of alkali upon the metabolism of the depancreatized animal, and record experimental support of the presence in pancreatic tissue of a substance capable of restoring to the diabetic animal the ability to utilize glucose. Success in its preparation depends upon the reaction of the

extracting medium. A mixed extract of pancreas and duodenal mucosa, neutralized but not made alkaline and administered intravenously, not only stopped the sugar elimination, but the blood sugar markedly declined and the animal showed the power to burn glucose. These experiments, though conducted in 1913 to 1916, are presented in confirmation of the hormone previously recorded by Banting and Best. While these latter consider that the hormone is of the nature of an enzyme, because heating to 57° C. kills it, the present authors have no doubt that in certain circumstances the hormone will withstand boiling in an acid medium, thus showing that its exact nature is as yet undetermined. That the extract has some effect on combustion is seen by the rise in respiratory quotient, and removal of the thyroids some weeks previously in no way altered the handling of carbohydrates or prejudiced the result.

### 106. The Cerebro-spinal Fluid in Trypanosomiasis.

LEFROU and OUZILLEAU (*Ann. de l'Institut Pasteur*, December, 1922, p. 834) have studied the cerebro-spinal fluid in trypanosomiasis for evidence of meningeal invasion other than the demonstration of the parasite in the centrifugized deposit of the cerebro-spinal fluid. Two hundred and forty samples of cerebro-spinal fluid were examined; trypanosomes were proved to be present in 100 of these, but absent from the remainder. The parasites were never found in cerebro-spinal fluids which contained less than 50 cells per cubic millimetre, or less than 0.02 per cent. of protein. Their presence in fluids giving cell and albumin counts above these levels was frequently but not constantly demonstrated; nor were parasites always easily found in fluids which contained a very large number of cells, or a high percentage of vacuolated cells, or other abnormal cell forms. But the authors considered that a cell and protein examination of the cerebro-spinal fluid gave presumptive evidence that the parasite had invaded the central nervous system if more than 50 cells per cubic millimetre and 0.02 per cent. of protein were present.

### 107. Method of Testing Liver Function with Phenoltetrachlorophthalein.

The principle of the method devised by S. M. ROSENTHAL (*Journ. Amer. Med. Assoc.*, December 23rd, 1922, p. 2151) is as follows: Five mg. of phenoltetrachlorophthalein per kilogram (2.2 lb.) of body weight are injected intravenously. This dosage is normally removed from the blood stream very rapidly; in normal human beings, from 2 to 6 per cent. is present in the plasma fifteen minutes after injection, and complete disappearance takes place within from forty to sixty minutes. In cases of liver disease, high percentages may be found in the plasma for many hours after injection. Clinical results have fully borne out experimental work. Following the intravenous injection of the dye, strikingly high degrees of retention in the plasma have been found to occur in cases of hepatic disease. Results by this method are quantitative, and it is believed that they give an index of the fundamental capacity of the liver.

### 108. A New Diagnostic Serum Test for Cancer.

A METHOD of serum diagnosis in cancer, studied by Botelho, is reported by A. WILBOUCHEVITCH, together with the results obtained from its use (*C. R. Soc. de Biologie*, December 23rd, 1922, p. 1339). The technique is as follows: To 2 c.cm. of a 5 per cent. solution of citric acid, containing 1 per cent. formal, is added 0.5 c.cm. of a 1 in 2 dilution of the serum to be tested, followed by 0.7 c.cm. of a test solution containing 1 gram of iodine and 2 grams of potassium iodide in 210 c.cm. of distilled water. A precipitate appears which rapidly dissolves in the case of a normal serum, but which persists—even after shaking—in the case of a cancerous serum. If the serum clarifies, 0.2 c.cm. of the iodine solution is added; this gives rise to a fresh precipitate, which remains solely in the presence of a cancerous serum. To obtain a persistent precipitate with a normal serum it is necessary to use at least 1 c.cm. of the iodine solution. Applying this test to 52 cases of cancer he obtained 39 positive reactions, 5 doubtful ones, and 8 negative ones. With 107 control serums sent up for the purpose of a Wassermann reaction, 1 positive and 1 doubtful reaction were obtained; information as to the condition of the individuals from which they were derived was not available. In comparing the results obtained by this method with those furnished by a study of the haemolytic and anti-tryptic titres, it was found that the majority of the serums which gave a positive Botelho test had only a low quantum of haemolysis—for sheep red cells—while, with few exceptions, their antitryptic content was high. He concludes that it would be well in doubtful cases to perform both the Botelho and the antitryptic tests, as the correlation between them appears to be fairly close.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## MEDICINE.

### 109. The Causes and Prognosis of Tuberculosis in Infancy.

L. RIBAUDEAU-DUMAS (*Journ. de Méd. et de Chir. Prat.*, December 25th, 1922, p. 885) gives a brief review of our present knowledge of the factors which lead to the development of tuberculosis in infancy. Apparently he considers the question merely from the point of view of infection with the human type of tubercle bacillus, omitting all reference to the bovine type, and not even mentioning the possibility of milk infection. He finds that in a large proportion of cases it is possible to trace the source of infection usually to one of the family. The mother is more dangerous than the father; the mortality of children with a phthisical mother is 33.5 per cent., while that of children with a phthisical father is only 14.7 per cent. After being infected the children show an incubation period which can be roughly given as thirty days; this may be determined either by the careful observation of the first signs of disease or by the appearance of a positive von Pirquet reaction, following exposure to a known infectious individual. The danger of tuberculosis to the child seems to depend largely on the period at which infection occurs: thus infants infected under 3 months of age almost invariably die; under 1 year the mortality may be given as 86 per cent.; from 1 to 2 years as 10.8 per cent.; and from 2 to 3 years as 2.7 per cent. Whether the lesion remains latent or whether it advances rapidly has been referred to the heaviness of the infection; the more bacilli there are taken in the greater is the danger of active spread. But on this point the evidence is confusing. There is much to suggest that a single big dose of virulent material is more harmful than repeated doses of smaller quantities. The latter may have an immunizing effect, as has been demonstrated in animals. If this be so, it might be justifiable to allow children of tuberculous patients to be reared at home, but as one has no control over the actual doses they receive it is obvious that the procedure is at best highly unscientific. It has been shown that if such children are separated from their parents shortly after birth and brought up under hygienic conditions their mortality is only 2.7 per cent., of which a half can be attributed solely to tuberculosis. The author's thesis, therefore, is that the greatest care should be taken during pregnancy to ascertain the extent of the danger to which the newborn infant will be submitted, and that if this danger is sufficiently great steps should be taken to ensure the removal of the child, so as to permit of its upbringing in healthy surroundings.

### 110. Prophylaxis of Measles by the Serum of Convalescents.

L. ZIMMERMANN (*Deut. med. Woch.*, December 22nd, 1922, p. 1701) is very favourably impressed by his experience in aborting measles by injecting into exposed children serum obtained from convalescents. In a children's hospital prophylactic injections were given to 32 children after the admission of a child who developed measles on the day after he reached hospital. This child was at once isolated. There were 4 cases in which the prophylactic injection of serum could not be considered suitable for testing its claims as it was given too late. Of the remaining 28 children given prophylactic injections only 2 developed measles. No ill effects from the injections were observed. The author agrees with Degkwitz that the convalescent serum should be obtained from children over the age of 3 years, who show no sign of syphilis or tuberculosis, who are in other respects healthy, and who are in the seventh to the tenth day of convalescence from uncomplicated measles. To every 10 c.cm. of serum one drop of carbolic acid should be added, and it is best to give a mixture of three different serums. Up to the sixth or seventh day of the incubation period the injection can almost invariably be relied on to abort the disease. This procedure is particularly useful in children's hospitals housing cachectic and tuberculous children, who must be protected at all costs from measles.

### 111. The Use of Adrenaline in the Stokes-Adams Syndrome.

H. FEIL (*Journ. Amer. Med. Assoc.*, January 6th, 1923, p. 26) presents clinical evidence that the subcutaneous injection of adrenaline in cases of partial heart-block may overcome the delay in conduction, restoring it to normal; in 2-1 block the

mechanism may be restored to normal or dissociation may follow. In complete block normal sequence may result or no change occur. In the latter event acceleration of the auricles and the ventricles usually results. In cases of frequently recurring attacks of the Stokes-Adams syndrome the attacks of syncope may be abolished. The effect of the subcutaneous injection may be said to last about twelve hours. The dose administered to adults of average weight is from 0.3 to 0.6 c.cm. of a 1 in 1,000 solution, injected subcutaneously. The danger in administration of adrenaline to patients with a considerable degree of arterio-sclerosis or with hypertension (and in many cases of complete heart-block there is an elevated systolic maximum pressure) must be weighed against the dangers and the discomfort of the syncopal attacks. Doubtless adrenaline therapy is justified in the treatment of patients with frequently recurring syncopal attacks, in view of the usual urgency of the patient's condition and because of the satisfactory results obtained in the reported cases. In no event should adrenaline be administered intravenously. Injected subcutaneously it offers relief from Stokes-Adams attacks. The supposition is that it stimulates the new centre of impulse formation in complete heart-block by way of the sympathetic endings. There appears to be little or no danger in the use of adrenaline in this type of case when it is properly administered. Intravenous injection results in greater concentration of adrenaline in the blood stream, and it is this factor that is probably responsible for the grave reactions reported in the literature.

### 112. The Association of Enteric and Malta Fever.

L. AURICCHIO (*La Pediatria*, December 15th, 1922, p. 1155) records five cases of the association of various forms of enteric with Malta fever in patients aged 21, 22, 7, 56, and 8 years respectively. The symptoms in all the cases corresponded to the clinical picture of the association of the two diseases described by Maggiore and Tupputi. The typhoid infection dominated the scene at first. In two cases the diagnosis of typhoid fever was made by the agglutination test, and later, when the symptoms of typhoid subsided, and the temperature assumed the characteristic features of Malta fever, the blood culture showed the presence of the melitococcus. In the third case the serum agglutination test was positive for the typhoid bacillus only after the disease had lasted ten days, but when the fever persisted in spite of repeated injections of antityphoid vaccine a blood culture was made on the twenty-third day and showed the melitococcus. The agglutination test was also positive for this organism. In another case, although there was a history of only eight days' illness, Malta fever infection had probably been present much longer. The agglutination test in this case was positive, both for the paratyphoid B bacillus and the melitococcus; the paratyphoid B bacillus was found in the blood and the melitococcus in the urine. Treatment with antityphoid vaccine acted almost exclusively on the typhoid symptoms, and had little or no effect on the course of Malta fever, which had to be treated with a specific vaccine.

### 113. Arterial Hypertension.

E. HARTWIG (*Zentralbl. f. inn. Med.*, December 23rd, 1922, p. 825) mentions the diseases which may cause high blood pressure, and discusses the cases of high blood pressure in elderly people which are not associated with disease of the kidneys or heart. This last form is described as essential hypertension; it is regarded by some authors as a sign of commencing kidney affection, since in course of time in some of these cases albuminuria is detected. But the author shares the view of those who consider the subsequent kidney condition to be the result of the high blood pressure. The condition is caused by primary vascular constriction, and as a result of the high blood pressure both arterio-sclerosis and granular kidney may develop. Chronic abuse of tobacco is very often the exciting cause of the high blood pressure. Assuming these views to be correct, the author points out the importance of the treatment of high arterial tension. In addition to physical, dietetic, and psychical treatment, the employment of vaso-dilators is indicated, and of these the author thinks yohimbine deserves special mention. It dilates the peripheral arterial system and neutralizes vascular spasm of sympathetic origin. Through the use of this drug the development of arterio-sclerosis and granular kidney is thought to be prevented or at least postponed. The author states that his experience confirms this view.

## 114. Cardiac Murmurs in Young Children.

G. BLECKMANN (*Paris méd.*, December 30th, 1922, p. 588) remarks that in young children the diagnosis of a murmur due to a valvular lesion or to an abnormal communication between the various cavities of the heart from a non-organic intra- or extra-cardiac murmur may be a matter of great difficulty. In the child, as in the adult, no criterion can be derived from auscultation. As regards radiological examination, although the orthodiagram may not reveal the characteristic deformities of congenital heart disease, the absence of radiological signs does not absolutely negative the existence of congenital heart disease. Moreover, this method of examination is particularly difficult in the infant, and is therefore not generally employed. Time is the only real diagnostic criterion. If the murmur becomes permanent it is the sign of an organic lesion, while if it disappears within a year it may be regarded as not organic.

## 115. Treatment of Epidemic Cerebro-spinal Meningitis.

CIOPPA (*Rif. Med.*, January 1st, 1923, p. 7) gives his experiences in a small epidemic of cerebro-spinal fever. He lays stress on the importance of looking out for carriers and for evidence of adenoids and chronic naso-pharyngeal catarrh. Bad hygienic conditions, whether of the dwelling place or the person, should be corrected where possible and attempts made to establish health. Unfavourable conditions causing naso-pharyngeal catarrh. Intra-spinal serotherapy in big doses (30 to 40 c.cm.) proved efficacious, as 9 out of 10 cases reported were cured. Inhaling the vapour of iodine developed from a 1 per cent. ethereal solution, and painting the nasopharynx with iodine in glycerin (3 to 5 per cent.), were found useful, especially in carriers.

## 116. Radiology in Pulmonary Disease.

COVA (*Il Morgagni*, Nos. 8 and 9, An. 64, Part 1), writing as a physician and not as a radiologist, discusses the value of radiology in lung disease. In the initial stage of pulmonary tuberculosis he says that somatic examination gives more trustworthy and earlier results than radiology. In affections of the hilus glands radiology may sometimes be useful, but in many cases it is unreliable and inconstant. In diagnosing the site and extension of pulmonary disease radiology is valuable, and for the clinical form of pulmonary tuberculosis not only useful but essential. Even in acute types it may give much help. As regards the prognosis and control of the results of treatment radiology has not so far given important data. In the complications of tuberculosis and in pleuritic types it is useful as a control. In the treatment by artificial pneumothorax or certain surgical measures it is indispensable. In the differential diagnosis of other pulmonary affections radiology may be extremely useful.

## 117. Large Doses of Trypaflavine in Endocarditis.

H. MARK and L. OLESKER (*Deut. med. Woch.*, January 5th, 1923, p. 17) have achieved dramatic successes in the treatment of endocarditis with large doses of trypaflavine. Their conversion to a heroic dosage was due to a mistake. Intending to give 0.2 gram by intravenous injection, they gave ten times this dose by mistake. Nausea, vomiting, and a sense of heat in the head began even before the injection was completed, and after about half an hour intense yellow discoloration of the skin appeared, but the pulse rate was normal, and the general condition not disturbed. The temperature, which was 102.5° F. on the day of the injection, fell in the evening of the following day to normal, and when the patient was discharged from hospital less than a month later she felt perfectly well. After recording another case, in which three injections, each of 0.4 gram, were given, and the temperature was reduced to normal, the authors suggest that a suitable dosage is 0.01 gram per kilogram of body weight. They dissolve the drug in 20 c.cm. of distilled water, injecting it very slowly, and taking great care not to let any escape into the subcutaneous tissues for fear of necrosis.

## 118. Vitamins in Ice-cream.

VITAMIN A was present in the typical samples of ice-cream examined by A. H. SMITH (*Journ. Amer. Med. Assoc.*, December 30th, 1922), in such concentration that he concludes that no noteworthy alteration in its potency is caused by pasteurizing or freezing. Normal growth was induced by 1 gram of the ice-cream, and ophthalmia was cured by 0.25 gram containing 25 mg. of butter fat. The vitamin B of the ice-cream can be accounted for by the equivalent quantity of milk used therein. Freezing had no effect on the vitamin B in the ice-cream used. The ice-cream, which was made from pasteurized products, contained no significant quantity of vitamin C.

## SURGERY.

## 119. Hirschsprung's Disease.

R. BENSANDE and P. HILLEMANN (*Ann. de méd.*, December, 1922, p. 425) say that Hirschsprung's disease, a case of which was recently shown to the Cardiff Medical Society by Mr. Alwyn Smith (*BRITISH MEDICAL JOURNAL*, 1922, vol. ii, p. 1268), is more common than is usually described. It is found more often in boys than girls, in men than women, and in infants than in adults. Two theories have been advanced to explain the nature of the disease—the first by Hirschsprung, who considered it an idiopathic congenital condition analogous to other hypertrophies, such as are found in the liver, spleen, breast, or bladder; the second regards it as a secondary condition due to some obstruction to the passage of the faeces. The chief symptoms are obstinate constipation, distension of the abdomen, and the presence of a tumour with visible peristalsis. The course of the disease is essentially chronic, with acute exacerbations of faecal retention and violent peristalsis, ending in the passage of the accumulated faecal matter. Occasionally the condition undergoes spontaneous cure; more often the patient goes progressively downhill and succumbs to cachexia. The prognosis is bad, and the younger the child the worse the outlook. In the child the diagnosis is not difficult, but such conditions as tuberculous peritonitis and congenital occlusion of the intestine must be considered. The treatment should be medical in the first instance: a diet poor in indigestible residue, lavage of the intestine, and mild laxatives, whilst flatus must be evacuated by a rectal tube. If the condition does not improve, one of two operations must be carried out. Resection of the sigmoid, which is easy, quick, and safe, and has little risk attached to it, or colectomy, which is a long and difficult operation, but ensures a cure. The latter is the operation of choice, and has a lower mortality when carried out in two stages.

## 120. Chronic Duodenal Stenosis.

W. KOENNECKE and H. MEYER (*Deut. Zeit. f. Chir.*, November, 1922, p. 179) describe three cases of chronic duodenal stasis which have come under their observation since August, 1921. All were adults (one male and two female), who complained of pain in the upper abdomen, coming on half an hour to an hour after food, and of eructations and occasional vomiting. In each case radiography showed rapid passage of the opaque meal into a dilated duodenum, marked peristalsis of duodenum, with to-and-fro movement of contents and holding up of duodenal contents for about twenty minutes before gradual passage into the jejunum. In one case it was noted that these phenomena were less pronounced when the patient was placed in the prone position and disappeared in the knee-elbow position. (Reference is made to a case described by Zoepffel, where the appearances of duodenal stenosis vanished in the prone and knee-elbow positions.) Operation was performed in two cases: in one of these duodeno-jejunal anastomosis gave relief; in the other, although laparotomy was performed, there is no account of the procedure adopted. It was noted in this case that, on lifting up the root of the mesentery, the distended duodenum collapsed. Diagnosis is made by x rays, the contrast with the normal condition, in which the opaque meal passes along the duodenum very quickly, being marked. The authors have made a series of experiments on dogs, in which the duodenum was constricted at its terminal end by a band of fascia sufficiently to reduce the lumen to the diameter of a lead pencil. Several weeks later radiography has revealed a state of affairs very similar to that observed in the above cases—namely, duodenal peristalsis and holding up of contents for a quarter of an hour. In two of these experiments the gastric branches of the vagus were divided, in one at operation, in the other some weeks later; no marked differences in the phenomena resulted. The experiments proved that a partial obstruction at the duodeno-jejunal flexure can cause the appearances observed in the cases under discussion, and the authors conclude that the cause of chronic duodenal stenosis is a mechanical compression, probably exercised by the root of the mesentery or the superior mesenteric artery, and secondary to loss of support or changes in abdominal pressure or in the position of other organs. Reference is made to the work of Wilkie and others in this country on the same subject.

## 121. Treatment of Perforated Gastric and Duodenal Ulcer.

E. R. SCHMIDT (*Acta Chirurgica Scandinavica*, December 22nd, 1922, p. 314) considers that gastro-enterostomy is unnecessary in the treatment of a perforated ulcer, and he advocates excision of the ulcer and the establishment of a Witzel fistula through which the patient can be fed and

irrigated very soon after the operation. The material on which these views are based consists of 44 cases of perforation treated in hospital in the period 1908-21. There were 11 immediate deaths and 2 late deaths. Twenty-two cases were subsequently investigated, and all but one were found to be still fit for work. In no case did a simple ulcer subsequently show signs of malignant degeneration. In 39 cases the abdomen was closed without drainage, and in 42 the abdominal cavity was irrigated with normal saline solution at 40° C. The author is of the opinion that when peritonitis is more or less generalized, systematic mechanical cleansing should be effected by irrigation. It was notable that in 5 of the 44 cases there was no history of gastric or duodenal symptoms before the perforation occurred. The author's objection to gastro-enterostomy is partly based on the principle that operative interference should be strictly limited to absolutely essential measures.

## 122. Hypertrophied Anal Papillae.

C. J. DRUECK (*New York Med. Journ. and Med. Record*, October 18th, 1922, p. 448) discusses the etiology, symptoms, and treatment of hypertrophied anal papillae (papillitis). In the intermediate zone at the anus, where the transition from mucous membrane to external skin occurs, from ten to fourteen dermoid papillae exist, and it is these which hypertrophy as the result of traumatism or irritation, so that at each evacuation they become engorged and are dragged down to extrude externally. Symptomatically they cause a feeling of fullness and tickling within the anal canal, and a sensation of incomplete evacuation. When, with the subsidence of their engorgement, they recede a sensation as though worms were being voided or were crawling on the skin about the anus is produced, with a consciousness of the anal sphincter being unduly contracted, and such symptoms last from a few minutes to an hour or even become constant. Occasionally the sphincter may be so spasmodically contracted as to prevent complete evacuation without enema, the administration of which is painful. There may be accompanying symptoms of lumbar or sacral aching.

If untreated the papilla or, from the venous congestion, consists in amputation under local anaesthesia, and when only a few papillae require removal the infiltration may be confined to the diseased area, the needle being inserted into the mucous membrane at the base of the tumour and gradually advanced towards the apex while injecting, ten drops being usually sufficient. The papilla is then drawn down and cut off well below its base and the wound is not sutured, careful cleansing after each defaecation and a warm sitz bath each day being all the after-treatment necessary. Notes of a case are given—a woman, aged 45, in whom five hypertrophied papillae and one haemorrhoid were removed under local anaesthesia, with complete relief to all distressing symptoms.

## 123. Endoscopic Examination in Young Children.

F. LE MAÎTRE and A. AUBIN (*Arch. Internat. de laryngol., otol., rhinol.*, September-October, 1922, p. 968) emphasize the importance of endoscopic examination in young children. Endoscopy of the upper respiratory tracts and the oesophagus is easy at this age owing to the absence of teeth and the high position of the larynx. The narrowness of the pharynx and larynx causes no obstacle to the progress of the tube when a view is obtained of the landmarks, the epiglottis in particular. It is not a dangerous procedure, and can be carried out without a general or local anaesthetic. The indications for its employment are the same in the child as in the adult, and it is a method of diagnosis and treatment which should be more generally recognized. The authors have adopted this procedure in a case of a cyst of the epiglottis which was punctured through the tube, in the extraction of foreign bodies from the pharynx, and in cases of congenital stridor in young children.

## 124. Congenital Osteo-sclerosis.

R. K. GHORNLEY (*Johns Hopkins Hosp. Bull.*, December, 1922, p. 444) reports a case of congenital osteo-sclerosis which seems unique in its characteristics. The patient, a male aged 8 years, complained of pain in his left hip and a limp. The left foot was held rotated outwards and atrophy of the calf and leg was present on this side. There was apparent shortening of 1/2 cm. and some limitation of movement of the left hip. The condition suggested a beginning epiphyseal separation of the head of the left femur. Radiograms showed a curious dense appearance of the bones of the pelvis; this condition was found throughout the skeleton. The vertebrae showed marked density at either pole and thickening of the cortex of the long bones. The skull was thicker than normal. Radiographs of the parents showed the mother's bones to be normal, but that practically the same condition existed in the father as in the child. These changes are well illustrated in

a series of radiograms which are reproduced with the paper. A search through the literature has failed to locate any similar cases in the living person. Several cases have been described at autopsy, and a report of these cases is given. The general view is that the sclerosis is secondary to an irritation which goes with a morbid process in the blood. In this case the condition appeared to be definitely inherited and not related to any demonstrable metabolic disturbance, except possibly some increase in the blood phosphorus. It is possible that secondary blood changes may come as a coincidence, or as a failure of the blood-forming mechanism to respond to the excessive demands placed upon it.

## 125. Pulmonary Fat Embolism.

G. E. SUTTON (*Annals of Surgery*, November, 1922, p. 581) states that pulmonary fat embolism has most often been noted in cases of fracture. Fat embolism is a potential factor in the cause of death following any operation in which fatty tissue has been injured. In order to permit the entrance of increased amounts of fat into the blood there must be injury to the fatty tissue and a break in the continuity of the blood stream. Partial haemostasis is of importance, likewise mobility of the injured part. In fatal cases haematomas filled with fat droplets have been found at necropsy. Probably mobility of the injured tissue is the most important factor, as shown in the war cases of fracture which were transported long distances and suffered from pulmonary fat embolism. The symptoms may be pulmonary or cerebral. The respiration is increased in frequency and shallow; dyspnoea develops, followed by cough and cyanosis; blood-stained expectoration may be seen, and the pulse is increased and the temperature raised. Cerebral symptoms are ushered in with headache, restlessness, and delirium; convulsions or paralysis may occur. Pulmonary oedema is found on examination and fat droplets in the sputum. Lipuria is detected if the urine is held up to the light. The involvement of the nervous system is a later phase of pulmonary fat embolism. As to treatment, injured limbs should be kept at rest. If transportation is necessary all fractures should be fixed on an extension splint. Complete haemostasis is important where fatty tissue has been injured, and the wound drained at its dependent point. Active treatment has not met with much success. The injection of normal saline into the veins is recommended, and also of a 2 per cent. solution of sodium bicarbonate. Stimulants and heat should be applied to keep the blood flowing at as high a rate as can be maintained.

## OBSTETRICS AND GYNAECOLOGY.

### 126. Obstetric Shock.

ACCORDING to A. TURENNE (*Annales de la Faculté de Médecine, Monte Video*, October, 1922, p. 409), Wallich in 1908 was the first to draw a definite clinical picture of obstetric shock. From a review of the cases described in the literature and from a number of personal cases the author concludes that obstetric shock is a term which has been applied to a number of conditions of widely divergent etiology and pathology. In one group the condition of shock occurs during or after labour as a consequence of some morbid maternal condition which may be extragenital (for example, acute dilatation of the stomach, mitral stenosis, peritonitis, abrupt release of a Momburg's ligature, minute pulmonary fat embolus, among some of recorded causative factors), or may be located in the uterus or adnexa—for example, small incomplete uterine tears demonstrable only at autopsy or grosser lesions with grave haemorrhage. In a second group there have been antecedent pathological conditions the timely recognition of which might have pointed the way of prophylaxis—acidosis, hyperemesis, or other toxæmic condition of pregnancy. In a third group no etiological factor is apparent, at any rate in the absence of autopsy. Such cases of shock may be reflexly produced by afferent stimuli acting on over-sensitive nerve centres, and are comparable with the cases of sudden death or acute shock which have occurred after simple dilatation of the cervix or skillful introduction of the uterine curette. Obstetric shock and grave obstetric haemorrhage are both characterized by pallor, cold and moist skin, small pulse, and subnormal temperature; the frequent advent of shock after haemorrhage detracts somewhat from the value of the differential diagnostic signs as described by Berkeley and Bonney, but in general Turenne holds it true that in shock the superficial veins are full, the patient is quiet and indifferent, respiration is rapid and superficial, and there is no sensation of giddiness. With regard to treatment of shock cardiac stimulants are ineffective, if not prejudicial, and in general hypnotics are more useful—morphine in adequate doses, nitrous oxide, and possibly ether, but not chloroform on account of its toxic action on the liver.

**127. Radium Treatment of Inoperable Cancer of the Cervix.**

ACCORDING to C. JACOBS (*Gynecol. et Obstet.*, 1922, vi, 5, p. 354), palliative radium treatment of inoperable cervical carcinoma, as compared with palliative operative treatment, is fraught with considerably less risk and gives results which are both more satisfactory immediately and more lasting. In the most advanced growths and in extensive and apparently hopeless recurrences after hysterectomy the author has found radium therapy to be followed by cessation of pain, disappearance for a time of haemorrhage and discharge, notable improvement in general health, and survival of the patient in comparative comfort for long periods. The effect of the applications is the formation in the cervical mucosa of an adherent scar, the separation of which takes about eleven weeks; in addition to a caustic effect on the cells of the mucous membrane radium produces a quasi-fibrinous, vascular, and perivascular degeneration. Jacobs employs relatively small amounts of radium—for example, 75 mg. of the bromide for twenty-four hours—and repeats the applications on one or more occasions with any return of the haemorrhage; the treatment is preceded during several days by daily antiseptic douches, followed by tamponnage with gauze soaked in tincture of iodine. Clinical details are given of eight cases, in one of which symptoms of the malady were still in abeyance thirteen months after application of 50 mg. of radium bromide for the recurrence of a growth after vaginal hysterectomy.

**128 Myoma of the Cervix.**

IN the experience of SCHEFFZEK (*Zentralbl. f. Gynäk.*, November 4th, 1922, p. 1776), who records six illustrative cases, myoma of the cervix uteri not infrequently evades diagnosis, being confused with adnexal tumour or with corporeal myoma developing within the broad ligament. Cervical myoma shows the most varied anatomical relations, according as its greater growth is towards or away from the endometrium, and the anterior, posterior, or lateral regions are the site of its commencement. Compression of the bladder and other viscera may lead at an early stage to pain and other symptoms, and the cervical canal may show lengthening, displacement, and considerable distortion. The external os in such cases is of crescentic form and accessible with difficulty from the vagina, through which the tumour may be palpable below the level of the os. At an early stage considerable upward displacement of the peritoneum occurs, so that in one case it was found impossible to complete by the vaginal route a hysterectomy already begun. To shell out a cervical myoma which has developed in the sub-peritoneal direction is impossible (although there is usually a well defined capsule) on account of the complicated wound-bed which would be left behind. X-radiation is contra-indicated, and treatment consists in total hysterectomy after laparotomy, special care being taken to avoid wounding the bladder. For cervical myoma constituting an obstruction to labour in the pregnant uterus the author recommends Caesarean section, followed after a considerable interval by operation for the myoma.

**PATHOLOGY.****129. Infection and Immunity in Anthrax.**

L. BALTEANO (*Ann. de l'Institut Pasteur*, November, 1922, p. 805) has been successful in confirming Besredka's work on the mode of infection of rabbits and guinea-pigs with anthrax. These animals, he has shown, are refractory to all paths of infection except that of the skin. So long as proper care be taken not to contaminate the skin, virulent anthrax bacilli may be injected into any part of the body without any deleterious effect. In the present communication experiments are recorded in which twenty-four-hour broth or agar cultures were inoculated intravenously, intraperitoneally, intrapleurally, and subcutaneously into rabbits; in only one case—that of a rabbit in which three attempts were made before successful introduction of the emulsion into a vein—did fatal anthrax ensue. Two control rabbits, however, which were infected, one by rubbing the culture on the freshly shaven skin, and the other by intradermal injection, each died after four days with positive blood cultures. Similarly, guinea-pigs submitted to intracardiac, intraperitoneal, and subcutaneous inoculations with young bacilli failed to develop anthrax, while those inoculated on or into the skin died of the disease after three days. If the skin alone be susceptible to infection, it is reasonable to suppose that immunity to anthrax may be related to the functions of this structure. It is known that Pasteur's method of vaccination is comparatively valueless for small animals, however successful it may be in the case of larger ones: To immunize rabbits and guinea-pigs Besredka directed his attention to the skin, and found that if the organisms were injected into the skin,

instead of intraperitoneally or subcutaneously, it was quite easy to obtain complete protection after the usual interval had been allowed to elapse before the critical tests were made. The author here confirms this in respect to guinea-pigs. The first vaccine was rubbed into the skin of the abdominal wall by means of a cotton tampon; the second vaccine was similarly applied six or seven days later, and after eighteen days young living bacilli were employed. Afterwards virulent bacilli were injected in increasing doses into different parts of the body, without precautions being taken to protect the skin; both the original strain and three other virulent strains were employed. The protected guinea-pigs remained perfectly well, while the controls died in three days of anthrax septicaemia.

**130. The Colloidal Gold Reaction in Acute Poliomyelitis.**

J. C. REGAN, A. LITVAK, and C. REGAN (*Amer. Journ. Dis. of Children*, January, 1923, p. 76) made an examination of 132 cerebro-spinal fluids taken from 42 cases of acute poliomyelitis admitted to hospital between June and November, 1921. In every instance during the acute stage of the disease a positive reaction was obtained with colloidal gold solution. It was found that the average curve was highest during the first and second weeks, after which it gradually declined, to become normal in 65 per cent. of the cases by the eighth week. The reduction occurred constantly in the zone of low dilutions; in 88 per cent. of the fluids examined the reaction was present between the dilutions of 1 in 10 to 1 in 320, though in fourteen fluids it extended up to the seventh dilution—that is, 1 in 640. Those cases in which a normal reduction occurred early were affected with a mild type of the disease, while those in which the curve remained elevated beyond the eighth week were generally victims of the more severe forms, with extensive and slowly improving paralysis and with moderate or marked neuritis. There was nothing characteristic in the nature of the reaction seen in cases which proved fatal, so that the test was of no value in the prognosis of a fatal issue. No correlation could be established between the amount of globulin in the fluid and the height of the colloidal gold curve; nor was there any definite relation between the latter and the number of cells per cubic millimetre. The use of the test in the differential diagnosis of poliomyelitis is discussed, and the conclusion reached that, taken in conjunction with the history, symptoms, and other laboratory data, it is one of the most valuable tests we have for the recognition of the disease.

**131. Prognostic Value of the Wassermann Reaction in Tabes.**

T. E. HESS-THAYSEN (*Ugeskrift for Læger*, November 23rd, 1922, p. 1617) has investigated the behaviour of the Wassermann reaction in the blood and cerebro-spinal fluid of 111 cases of tabes, represented by 54 men and 57 women. Among them were as many as 18 cases of oligo-symptomatic abortive tabes, the chief symptom in most of these cases being sluggishness of the ocular reflexes. The author comes to the conclusion that, as a rule, the prognosis is practically unaffected by the Wassermann reaction in the blood. Even when a positive reaction has been replaced by a negative it does not follow that the prognosis is improved. Nor is the prognosis appreciably better for patients whose tabes first appears when the reaction is negative than for patients whose reaction is positive both early and late in the disease. Syphilitic complications of tabes were indeed somewhat more frequent when the reaction was positive than when it was negative, but the difference was not great. The prognosis for mono- or oligo-symptomatic tabes is comparatively good, particularly when the Wassermann reaction in the cerebro-spinal fluid is negative. On the whole, the serological evidence must be regarded as disappointing from the prognostic point of view.

**132. The Blood in the Aged.**

TERZANI (*Rif. Med.*, September 11th, 1922, p. 871) has examined the blood in old people with especial reference to the haemoglobin content and red corpuscles, as in these points authors differ considerably. The ages varied from 60 to 99, and blood diseases were excluded. In men the author found that the haemoglobin varied between 0.45 and 0.84, and in women between 0.35 and 0.80 (Fleisch apparatus). As regards the red corpuscles, a slight hyperglobulia was noted in men (in one old man of 99 it reached 6,190,000). In women this hyperglobulia was rather more marked. Poikilocytosis was seldom seen, anisocytosis was rather more frequent. There seemed no constant relation between hyperglobulia and high blood pressure. Probably this hyperglobulia in old people is not a primary fact, but secondary—a reaction against the diminishing function of the haematopoietic organs. The contrary state of hypochromæmia and hypoglobulia is of bad augury.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## MEDICINE.

### 133. The Relation of Chorea to Rheumatism.

R. NORDGREN (*Acta Paediatrica*, December 16th, 1922, p. 159) has made a statistical study of the incidence of rheumatic lesions and of chorea in children's hospitals in Stockholm between October 1st, 1908, and the end of 1921. As a table shows, the incidence of the two was remarkably uniform, and the author quotes Roger as saying that chorea, rheumatism, and endocarditis are three names for one and the same condition. Among the 345 cases of chorea there were 26 with a history of rheumatic fever, with or without valvular lesions, 161 with valvular lesions which could be traced to no other disease, and 6 with a history of endocarditis during residence in hospital. Thus 193, or more than half, showed definite signs of rheumatism. Other possible causes of the chorea were seldom found; there were only 6 cases with a history of scarlatina, and 6 others with a history of psychic shock. It was significant that during the epidemic of influenza in 1918 and 1919 there were very few cases treated in hospital. With regard to the sex distribution of chorea and other rheumatic affections, it was found that there were only 125 boys to 218 girls suffering from chorea. In the case of other rheumatic affections, however, the sex incidence was almost equal; there were 177 boys to 190 girls. The age for which chorea showed the greatest preference was between 8 and 10, and there were as many as 43 boys and 77 girls within this age limit.

### 134. Treatment of Disseminated Sclerosis.

L. MANN (*Klinische Wochenschrift*, December 23rd, 1922, p. 2573) records the results in the treatment of eight cases of disseminated sclerosis with tetraphan, a derivative of atophan. He points out the great difficulty in estimating the value of drug treatment in disseminated sclerosis owing to the spontaneous improvement which often occurs, and to the occasional occurrence of periods in which the disease is for the time latent. Also we have no means of definitely expressing and measuring the degree of many of the prominent symptoms. Notwithstanding these difficulties the author records eight cases in which improvement followed treatment with tetraphan. In three cases the results were prompt and marked, and consisted chiefly in a great diminution of the spastic paraplegia and great improvement in the gait. In five other cases similar but less striking improvement followed the use of the drug. In all of the cases the spasticity of the gait was diminished and walking became less difficult.

### 135. The Differential Diagnosis of Gastric Ulcer.

TORRACA (*Rif. Med.*, December 11th, 1922, p. 1190), discussing the differential diagnosis of gastric and duodenal ulcers, says that in the early stages the clinical signs and symptoms are for the most part common to either localization; continuous and progressive accentuation of symptoms favours the diagnosis of pyloric ulcer, whilst inequality and variability are more like duodenal or small curvature ulcer. Serial radiography is particularly useful in duodenal ulcer. The commonest site for ulcer is the smaller curvature, then the pylorus and duodenal bulb, and lastly, the second part of the duodenum. In 9 per cent. the ulcers are multiple. Haematemesis is most frequent in small curvature, melaena in duodenal, and stenosis in pyloric ulcer. In ulcer of the small curvature, radiology shows permanent hollowing of the greater curvature, diverticula of the small, mediogastric stenosis and *enroulement* of the smaller curvature. In pyloric ulcer the most certain sign is antiperistalsis. In duodenal ulcer diverticula and hollowing are the most usual signs. Pyloric ulcers usually have a sudden onset, slight tendency to haemorrhage, augmented stomach contents, late pain, and indirect radiographic signs.

### 136. The Therapeutic Properties of Luminal.

J. RIISING (*Ugeskrift for Læger*, November 30th, 1922, p. 1671) is greatly impressed by the hypnotic and analgesic action of luminal, the chief objection to which is its cost. The dose is 10 cg., and it is the only known remedy, he states, that invariably cures hiccups. But it is in epilepsy that its sphere of usefulness is greatest. Given in doses of 10 cg. two or three times a day it arrests the fits completely or renders them less severe and frequent. In some cases the fits are confined to the night after the administration of luminal,

which must not be discontinued suddenly for fear of provoking status epilepticus. The action of the drug is merely symptomatic, and while it is being gradually discontinued in epilepsy it is advisable to give bromides. There are no contraindications, and with the ordinary dosage no signs of poisoning have been observed. Eclampsia, tetanus, and delirium tremens are some of the many conditions which react satisfactorily to the drug.

### 137. Artificial Pneumothorax.

N. BARLOW (*New York Med. Journ. and Med. Record*, January 3rd, 1923, p. 9) discusses some principles of immunology applied to treatment of tuberculosis by artificial pneumothorax as a means of obtaining much more permanent benefit than the present temporary success obtained by artificial pneumothorax alone, which latter must be regarded more as an adjunct to treatment than as a treatment in itself. Since the clinical symptoms of tuberculosis are suppressed after pneumothorax before any real progress towards cure occurs they are apt to be misleading as guides to treatment, and, since the signs of activity both on the compressed side and in the compensating lung may not reappear until the disease has made more progress than would be required to cause marked signs in an ordinary patient, it is essential that such treatment should be continued as would be indicated were the physical signs and symptoms not masked by the pneumothorax. From the experience already gained such principles of treatment produce a greatly increased proportion of permanent benefit from artificial pneumothorax, so that while the lung is re-expanding the patient should be closely watched and tested, and placed at rest upon the slightest indications of toxæmia, such as nervousness, cardiac irritability, anorexia, insomnia.

### 138. The Heart in Influenza.

S. MENTI (*Zentralbl. f. inn. Med.*, January 6th, 1923, p. 10), from his observations on 106 cases of influenza, came to the conclusion that this disease has a definitely injurious action upon the heart. Circulatory disturbances developed which had hitherto been latent, or in the case of valvular defect had been well compensated, and caused no symptoms. Diseases of the heart and vessels which had already caused some symptoms before the attack of influenza underwent a considerable aggravation. In a second group showing cardiac disturbance without any anatomical lesion a general asthenia was noted. In both groups there was a disturbance of pulse rhythm which Menti attributes to a change in the conductivity of the heart muscle similar to that which occurs in convalescence from diphtheria. The symptoms in both groups were very slow in disappearing, and ordinary treatment, especially digitalis, failed, so that Menti came to the conclusion that cases which did not react promptly to digitalis were due to influenza. If digitalis had to be given at all it was administered only in combination with quinine, caffeine, theobromine, belladonna, etc.

### 139. Postural Treatment for Congestion of the Lungs.

E. RAUTENBERG (*Deut. med. Woch.*, January 5th, 1923, p. 1) notes that the rational treatment for cases of drowning is to place the body in such a position that water will run out of the lungs. Why, he asks, should not the same principles apply to the patient who is suffering from pneumonia or bronchitis and is drowning in his own bronchial secretion? Even as a prophylactic measure it would be wise in cases of pneumonia to tip up the foot of the bed 20 to 30 cm. and to turn the patient on to his abdomen. The author has had three years' experience of this simple measure, and he has come to the conclusion that it does not harm even very ill patients, and on the other hand it is positively life-saving in many cases. In one case as much as 500 c.cm. of fluid ran out of the patient's mouth and nose in the course of two hours. The result was great improvement in the respiration, which became slower and deeper. The author records in detail the case of a woman, aged 24, suffering from influenzal pneumonia with great dyspnoea, cyanosis, and weakness of the heart. The tracheal râles disappeared after she was turned over on to the abdomen, and she ultimately recovered, although the prognosis had been exceptionally bad. When the patient is unconscious great care must, of course, be taken to prevent the mouth and nose being obstructed by the pillow on which the head rests.

## 140. Immunization against Measles.

GALLI (*La Pediatria*, October 1st, 1922, p. 898), struck by the fact that 5 children exposed to measles did not develop it after a prophylactic injection of diphtherial antitoxin, has followed up the suggestion by further researches. In a group of 24 children exposed to measles and unprotected by previous attacks he injected 5 c.cm. of horse serum; only 3 of these developed measles three to five days after injection. Reference is made to similar attempts by other physicians, with various serums. Not less than 5 c.cm. of horse serum should be given, and the earlier it is given the better. In 2 out of the 3 cases which developed measles in spite of the injection the disease must have been well on in the incubation period, for the rash appeared only two or three days after injection.

## 141. Treatment of Cutaneous Anthrax.

ACCORDING to J. SEGOVIA (*Archivos de Medicina, Cirugía y Especialidades*, December 16th, 1922), surgical intervention in cutaneous anthrax is not to be recommended, total excision of the diseased focus usually being impracticable and a considerable danger existing of promoting extension of the infection. A much more effective treatment is a combination of intravenous injections of neo-salvarsan (60 cg.) with similar injections of anti-anthrax serum, which in Spain is given in doses of 10 to 15 c.cm., in contrast to the much larger amounts recommended by American writers. The serum may also be applied locally in compresses. The author records a case in which treatment on these lines was successful in a patient in whom a blood culture showed the presence of the anthrax bacillus.

## SURGERY.

## 142. The Dangers of Ethyl Chloride Anaesthesia in Children.

SEIFFERT (*Deut. med. Woch.*, January 12th, 1923, p. 55) records the two following alarming experiences. A well developed child, aged 2 years, suffered from a cold abscess of the knee, requiring aspiration. On a small ether mask 25 drops of ethyl chloride were covered by a cloth. The child soon fell asleep, then respiration became irregular and the face pale. The pulse became weaker and weaker, and at last the respiration ceased. The second patient was a child, aged 2½ years, with a small abscess at the angle of the jaw. Ethyl chloride was given as in the first case. An incision had been made, when the child collapsed suddenly; it was pale and livid, there was an outbreak of sweat, the pulse was not palpable, and the respiration ceased. In both cases oxygen was given, and artificial respiration and massage of the heart instituted. The skin was stimulated with cold water, and oil of camphor injected. In three to four minutes both children rallied, and fifteen minutes later neither of them showed any ill effects. Since these two experiences the author has not dared to use even transitory ethyl chloride inhalations in his children's hospital. He refers to an ethyl chloride fatality, published in 1922 by Hofmann, and suggests that the number of ethyl chloride accidents is considerably greater than is commonly supposed to be the case.

## 143. The Teres Minor Muscle.

D. M. GREIG (*Edinburgh Med. Journ.*, January, 1923, p. 16) points out that the teres minor muscle is phylogenetically inseparable from the deltoid. The strongest reason for regarding the teres minor as part of the deltoid is the common nerve supply from the circumflex. The pseudoganglion on the nerve is a vestigial structure in the course of phylogenetic obliteration; it is universally present in man and varies in size; it is the abortive remnant of the cutaneous distribution of the nerve. The function of the muscle is generally stated to be a lateral rotator of the humerus—the teres major rotates it inwards, the minor outwards. The author tests the validity of these opinions by clinical means. If the circumflex nerve is paralysed, lateral rotation of the humerus is not interfered with. In cases of paralysis of the teres minor itself—a rare condition—the humerus is drawn upwards until the head comes into contact with the acromion and the coracoid, then when abduction begins the head becomes moulded to this surface and an alteration in shape of both surfaces takes place. In a specimen described by the author this condition was found whilst lateral rotation of the humerus was not interfered with. In paralysis of the infraspinatus the patient is unable to rotate the humerus outwards. With the elbow to the side it is impossible to rotate the humerus; when abducted other muscles come into play and make good the deficiency. In conclusion, the author states that the teres minor is not a muscle of lateral rotation—this movement is caused mainly by the infraspinatus; the teres minor steadies the head of the humerus in the glenoid during contraction of the deltoid.

## 144. Paraplegia Four Years after a Wound of the Spine.

L. SENCERT and G. FERRY (*Bull. et Mém. Soc. Chir. de Paris*, December 19th, 1922, p. 1404) find that, in spite of the very large number of wounds of the spine and spinal cord received in the war, the number of cases of paraplegia cured after removal of the foreign body is very small. They record a case where a bullet was removed from the spine of a man with paraplegia two years ago, and the cure has been complete. The patient was wounded in 1915, and it was not till four years later that spinal symptoms, both motor and sensory, in the lower limbs appeared. Four months later the patient was completely paralysed. The case is of further interest owing to the slow appearance of the spinal symptoms. It is impossible to tell whether the bullet penetrated the spinal canal secondarily or lay against the dura mater, perhaps in a fold of the meninges. It produced no cord symptoms at the time of injury nor in the following months. Subsequently, after a latent interval of four years, symptoms of a slow and progressive compression supervened, resulting in paraplegia with complete paralysis of the sphincters. It is difficult to explain this long interval and the gradual onset of the symptoms of compression. It was perhaps the result of the fibrous reaction around the bullet found at the operation, or was possibly due to the lighting up of a latent and attenuated infection, the cause of which may have been accidental. Whatever may have been the reason, the authors emphasize the importance of giving a guarded prognosis in cases of foreign body in the central nervous system.

## 145. Submaxillary Salivary Calculus.

B. F. BUZBY (*Annals of Surgery*, December, 1922, p. 778) points out that salivary calculi, although comparatively often encountered, still go unrecognized in many instances. The submaxillary gland is the most frequent seat of calculus formation, as the saliva from this gland is more viscid and concentrated. Males are more frequently affected than females, perhaps because infection of the mouth is more common in men on account of the use of tobacco. Calculi vary in size, being large when in the gland itself, whereas in the duct small stones can cause obstruction. The stones are usually solitary. When the stone is in the duct the patient complains of a very painful and tender swelling appearing coincidentally with mastication; this disappears when the causative agent has passed away. This swelling interferes with the movements of the tongue, deglutition, and talking. The stone in the duct acts as a sort of stop-valve, causing partial obstruction to the flow of saliva. When the stone is in the gland there is no intermittent swelling, but a steadily growing tumour not influenced by the flow of saliva. Diagnosis is not difficult, and bidental examination enables the stone to be felt in the duct or in the gland. An x-ray picture always shows the calculus. Differential diagnosis is made from bone tumour and malignancy and submaxillary lymphadenitis. The treatment of a stone in the duct is removal under general anaesthesia. A longitudinal incision is made down to the stone, which is then lifted out. If the calculus is in the gland the whole gland should be removed because of the pain and possible abscess formation.

## 146. Deformity after Supracondylar Fracture of Humerus.

H. KÄLIN (*Deut. Zeit. für Chirurgie*, November, 1922, p. 45) has followed up 23 cases of supracondylar fracture of humerus occurring during the last twenty years, with a view to ascertaining the cause of the alteration, frequently seen after this accident, of the angle which the upper arm normally forms with the forearm when the elbow is extended. The angle of the sound arm was taken as the standard by which the amount of adduction or abduction was estimated. Clinically, particular attention was paid to the triangle formed by joining the tip of the olecranon and the epicondyles by straight lines. This triangle, normally equilateral, was frequently found to be altered. Union with uncorrected deformity would not account for this, at the level in question. The radiographs were examined with respect to the point in the transepicondylar line which the axis of the humerus crossed, and the angle which it made therewith. Normally the humeral axis crosses the middle of that line at right angles. After union of a supracondylar fracture with lateral displacement, the lines will still be at right angles; if union has taken place with angular deformity, viewed anteroposteriorly, the axial line will not be at right angles to the transverse; in neither case will the humeral axis cut the transverse line at its mid-point. In many cases it was found, however, that the normal angle of the arm was altered, although the humeral axis cut the transepicondylar line at its mid-point. There was evidence to show that the alteration had supervened or increased in many cases long after union of the fracture. These considerations

lead the author to conclude that, although cubitus valgus or varus may be due to union with angular deformity, it is liable to occur even after perfect reduction of fragments, and is then due to disturbance of growth at the epiphyseal line, most commonly taking the form of hypertrophy on the radial side, giving adduction deformity. Of the 23 cases, 20 were between the ages of 5 and 10 years, and none over 18, at the time of the injury. Adduction deformity was present in 15, abduction in 3; 6 showed no deformity; the remaining case was double, and any deformity was too slight to be assessed, in view of the absence of a sound angle for purposes of comparison. The deformity, when present, is not amenable to treatment.

#### 147. Spastic Intestinal Obstruction.

H. JACOBSEN (*Hospitalstidende*, November 8th, 1922, p. 753) notes that some surgeons are inclined to deny the very existence of spastic ileus. Though it certainly does exist they are wise in thrusting it in the background, for if this diagnosis were to be freely indulged in many a life-saving laparotomy might be omitted. By 1920 Sohn was able to collect 30 definite cases, and in the same year Nagel collected 45 cases in which the diagnosis was confirmed either by biopsy or necropsy. The chief interest of the case recorded by the author lies in the fact that laparotomy was performed twice, with an interval of only a day and a half; on neither occasion was there found any explanation for the obstruction other than spasm of the gut. The patient was a girl aged 7, who was admitted to hospital with violent pain under and to the left of the umbilicus. The pain was colicky, there was retention of flatus and faeces, and she vomited mucus frequently. The abdomen was slightly distended, and during a bout of colic the contour of a coil of gut was demonstrable in the right abdomen. Laparotomy revealed coils of small intestine, some of which were distended with gas, while others were completely collapsed and contracted, the transition from the one condition to the other being abrupt. But there was no stricture or furrow at this point. As the symptoms became most alarming after the operation it was repeated, but again nothing was found to explain the symptoms. Complete recovery ultimately followed after treatment with gastric lavage, enemas, and castor oil.

#### 148. Splenectomy for Pernicious Anæmia.

E. HOLM (*Lægeskrift for Læger*, December 21st, 1922, p. 1781) has investigated the records of splenectomy for pernicious anaemia, and has been struck by the unanimity with which the authors of these reports hesitate to claim permanent cures. The behaviour of this disease is notoriously capricious, and the marked improvement often observed after splenectomy is apt to end in the relapses which frequently follow periods of spontaneous arrest of the disease. It should be noted that, even in an advanced stage, the disease may suddenly and unaccountably take a turn for the better, and that this improvement may be maintained for a considerable period. With these reservations, the author publishes a dramatically successful case of splenectomy for pernicious anaemia. The operation was performed on August 5th, 1921, and when the patient was last examined, on July 7th, 1922, her improvement was well maintained, she could work all day, and continued to gain weight. But the blood picture was still that of pernicious anaemia, and the red cells, which had numbered 760,000 before the operation, had increased only to 1,725,000. In the same period the haemoglobin had risen from 35 to 65 per cent. (Sahli). The author concludes that though splenectomy does not deserve the place of honour in the treatment of pernicious anaemia, it may yet be indicated in those cases in which more conservative measures have failed.

#### 149. Salicylates in Ocular Diseases.

S. R. GIFFORD (*Amer. Journ. Ophthalmol.*, December, 1922, p. 948) summarizes the way in which salicylates and similar drugs produce benefit in ocular inflammations. Their effect is not directly bactericidal, since the concentration required could never be obtained in the living body; and, although leucocytosis has been observed after their administration, this is due to the infection rather than the drug, and there is but little evidence in support of the theory that by producing a general vasodilatation the engorged vessels of the inflamed part are depleted. Large doses are needed, and one grain of sodium salicylate per pound of body weight a day is a convenient formula, pushed to 175 to 200 grains a day if necessary; such doses do not damage the kidneys, and are not contraindicated unless albumin is present. There does not appear to be any advantage in using it in combination with sodium bicarbonate, though this latter renders cinchophen (atophan) and acetyl-salicylic acid less irritating. Such toxic symptoms as ringing in the ears, nausea, and malaise are no indication for stopping the drug if otherwise still needed. When the salicylates are contraindicated, cinchophen and

neo-cinchophen are useful and less toxic. In severe cases 100 grains a day of neo-cinchophen may be given for two or three days, reducing to 80 and 60 grains, and continuing 30 to 45 grains a day for some time after the eye is quiet. While in cases of non-specific iritis, irido-cyclitis, optic neuritis, congestion after cataract extraction, and sympathetic ophthalmia the respective causes require treatment, the salicylates are most useful in lessening the reaction and preventing permanent inflammatory changes until the effect of such causal treatment is secured.

## OBSTETRICS AND GYNAECOLOGY.

#### 150. Early Diagnosis of Pregnancy by the Induction of Glycosuria.

S. LESKINEN (*Finska Läkarsällskapets Handlingar*, November-December, 1922, p. 584) has used the phloridzin test, as described by Kamnitzer and Joseph. The solution contained phloridzin 0.03, novocain 0.015, and distilled water 30.5 parts. Of this solution 2 c.cm. were given by intragluteal injection, the quantity of phloridzin injected being 0.002 gram. The test was carried out in the morning, the patient being given 200 c.cm. of water to drink at the time of the injection, and again half an hour later. The urine was tested for sugar at the time of the injection and every half-hour after it. An hour and a half after an injection there was never any artificial glycosuria, and the critical time for determining the presence or absence of glycosuria proved to be an hour after the injection. The women tested included 13 in the first three months of pregnancy, 4 who had just aborted, and 31 who were not pregnant. Among these controls there were cases of myoma and inflammation of the appendages of the uterus and various other conditions. All but one of the 13 showed glycosuria, and the one exception showed glycosuria four weeks later. Glycosuria was present in only 2 of the 4 cases of abortion. Of the controls 5 showed glycosuria and 26 did not. It would thus appear that a positive reaction is less instructive than a negative; the reaction is always positive at a comparatively early stage in pregnancy, and may be so only six or eight days after menstruation is overdue.

#### 151. Wounds of the Gravid Uterus.

C. DANIEL (*Gynéc. et Obstét.*, 1922, vi, 5, p. 376), from a study of 47 cases of wounds of the gravid uterus, comes to the following conclusions: Penetrating wounds affecting the uterine wall and foetal membranes are usually characterized clinically by slight vaginal haemorrhage and passage of liquor amnii; in about half the recorded cases, corresponding in general to the larger uterine wounds, a part or the whole of the foetus passes into the abdominal cavity. The uterus may be the only viscus to be wounded, and the probability that this is so is proportional to the degree of advancement of pregnancy, the intestines being pushed upwards during the later months by the uterus, whose walls are in direct contact with the abdominal wall. The prognosis is better in wounds of the gravid than of the empty uterus, the total mortality being 22 per cent. Interruption of pregnancy is the rule in extensive wounds, expulsion of the foetus taking place *per vias naturales* in the case of small scab wounds or those caused by firearms. In about half the cases the foetus is directly injured by the wound, but in 40 per cent. of cases its survival has been reported. Treatment is surgical (laparotomy) except in the case of certain small punctured wounds, for which expectant treatment may be adopted, in the first instance at any rate. Simple uterine wounds may be treated conservatively by suture, but hysterectomy is called for if the wound is large or irregular, or in the case of multiple wounds, or if the foetus has partially or wholly escaped into the abdominal cavity.

#### 152. X Rays in Uterine Fibroids and Climacteric Bleeding.

J. B. KOUWER (*Gynéc. et Obstét.*, No. 6, 1922, p. 25) opposes the use of x rays for uterine fibroids on the following grounds: (1) The haemorrhage is stopped chiefly by the action of the rays on the ovaries, which become atrophied, and thus the woman suffers from an artificial menopause; whereas if operation is undertaken one or both ovaries can usually be conserved. (2) With the x rays the woman has no further chance of child-bearing, whereas in some cases, in which the abdomen is opened, myomectomy can be done and the uterus conserved. (3) There are numerous conditions, often present and unable to be diagnosed with certainty, on which x rays have little effect or are even harmful—for example, submucous fibroids, necrosis and gangrene in a fibroid, carcinomatous or sarcomatous changes, inflamed appendages. (4) The mortality and morbidity following operations are

slight in comparison with the damage that may be caused by x-rays, if the diagnosis is at all at fault. The author considers x-ray therapy unnecessary for menopausal bleeding except in very exceptional cases. He states that the great majority are cured if, after a diagnostic curettage has shown no signs of malignancy, the uterus is thoroughly curetted and the patient is then treated for the next few months with hot vaginal douches. He prefers hysterectomy to x-ray therapy for the few cases in which bleeding still continues, as the x-rays seem to upset the working of the endocrine system.

#### 153. The Ductless Glands during Pregnancy.

FROM animal experiments SCAGLIONE (*Rivista d'Ostetricia e Ginecologia Pratica*, October, 1922, p. xv) finds that during pregnancy signs of increased function of the pineal are to be found in unusual abundance of lipid granules, of vacuolated cells, and of quasi-colloid substance in the intercellular spaces. Pineal tissue administered orally to gravid animals is without toxic effect and appears to determine an increase of foetal weight. Pineal extracts are without influence on the gravid or non-gravid uterus, modifying neither the rhythm nor the depth of the automatic contraction of the former. D. CESARE (*Ibid.*, p. xxviii), in experiments on cows, has found that the content, as measured by Antencielli's colorimetric method, of adrenaline in the adrenal gland does not show any characteristic modification during pregnancy. He concludes that any increase in the functional activity of the gland during pregnancy is confined to the cortex. By similar experiments he has failed to note more than a slight and inconstant increase in the iodine of the thyroid gland in the pregnant condition.

#### 154. Radium in Metrorrhagia.

P. W. SIEGEL (*Deut. med. Woch.*, January 12th, 1923, p. 47) gives an account of treatment of metrorrhagia in Giessen at the University Maternity Hospital, which was fortunate enough to possess 150 mg. of radium bromide before the outbreak of the war. Since 1918, 28 cases of metrorrhagia have been treated, and 2 of myoma of the uterus. In every case amenorrhoea was induced, and in three-quarters of all the cases it was induced at once. In the remaining quarter there was one more menstrual haemorrhage after the treatment before amenorrhoea set in. Complications due to the treatment were rare, and only once did the temperature rise to 38.7°C. Senile shrinking of the vagina was never seen, but occasionally slight adhesions formed in the posterior fornix of the vagina, requiring blunt detachment by a finger. But no haematocolpos or haematometra followed. The observation period of these cases averaged twenty-five months, during which no serious ill effects occurred. The technique was exceedingly simple. Exploratory curetting was first performed, and then a capsule, containing 50 mg. of radium bromide, was inserted. If the length of the cavity of the uterus exceeded 8 cm. two capsules were inserted, each containing 50 mg. A 1 mm. silver filter was used, but no covering of rubber. The uterus was dilated with Hegar's dilators up to No. 4½, the cavity of the uterus being made just large enough to hold the capsule in its filter. The vagina was then packed with sterile gauze, and the radium left in place for twenty to forty-eight hours. The author considers this treatment a notable advance on x-ray treatment, which in Germany has become exorbitantly expensive.

## PATHOLOGY.

#### 155. Pathology of the Gall Bladder.

W. BOYD (*Brit. Journ. of Surg.*, January, 1923, p. 337), in discussing the pathological problems presented in the etiology of cholelithiasis, points out that a gall stone is composed of the several constituents of the bile combined in varying proportions. In the strawberry gall bladder, where tiny yellow specks are scattered over the mucous membrane, it has been found that the yellow material is lipid in nature, for it stains with Scharlach R. The author has investigated the nature of this lipid. With the dissecting microscope the lipid was seen on the folds and ridges of the mucosa and could be removed for further examination. It gives the usual reaction for fat and stains like an ordinary neutral fat with Scharlach R, Sudan III, and osmic acid. With Nile blue the reaction showed that the lipid was certainly not neutral fat, but left undecided whether it consisted of fatty acids or cholesterol. The polarizing microscope showed the yellow material of the strawberry gall bladder to be the ester of cholesterol with a fatty acid. Quantitative estimation showed that there was a real increase of the amount of cholesterol in the strawberry gall bladder compared with the normal organ. These deposits are found in the surface epithelium, connective tissue stroma, and possibly in the lymphatics, and the author considers that the first step in the development

of gall stones may consist in this formation of cholesterol deposits. The most probable cause of the deposit of this substance is inflammation, but it will only be possible to state with certainty the factors which govern its formation after deposition has been produced in animals.

#### 156.

#### Basal Metabolism in Obesity.

TO determine the basal metabolism in obesity LABBÉ and H. STEVENIN (*C. R. Soc. de P.*, 1923, p. 9) made experiments on 46 patients, both male and female, whose weights varied from 35 to 136 kilos, and whose ages were between 9 and 64 years. Of these 27 presented a normal basic figure, in 13 the metabolic rate was decreased, while in 6 it was above the normal. Those possessing a normal basal metabolism were nearly all large eaters, living a sedentary existence, and reacting well to a reduction in the amount of food taken. Of those presenting an increased basal metabolism, 2 were suffering from Graves's disease; the rest simply appeared to be addicted to over-feeding, and it is known how the alimentary régime may lead to modifications of metabolism. Amongst those with diminished basal metabolism were 3 cases of myxoedema and 2 of dystrophia adiposo genitalis; the others of this group displayed a disturbance of the ductless glands, which responded well to thyroid treatment. It was the sole manifestation of a thyroid disease. From these results the authors feel justified in dividing patients suffering from obesity into two classes: one in which the basal metabolism is normal or increased, and in which treatment by thyroid extract is contraindicated and often dangerous; and one in which basal metabolism is diminished, and in which thyroid treatment gives excellent results.

#### 157. The Wildbolz Auto-Urine Reaction in Tuberculosis.

R. KIPFER (*Schweiz. med. Woch.*, December 30th, 1922, p. 1241) describes fully the most recent modifications in the technique of the Wildbolz test, which is based on the assumption that the urine in tuberculosis contains certain tuberculous antigens which give rise to a specific reaction when the urine is introduced into the skin by intracutaneous injection. The author has tested this reaction in 200 cases, 103 of which were cases of active tuberculosis. In 104 of these 109 cases the reaction was positive, and it was again positive when the test was repeated. Only in 5 was the reaction negative. In a second class there were 25 cases in which the tuberculosis had ceased to be active, according to the clinical evidence. In 12 of these cases the reaction was positive, and in 13 it was negative. A third class was represented by 66 persons without clinical signs of tuberculosis; most of them suffered from other diseases. The reaction was positive in 12 and negative in 54. After reviewing the findings of forty-two other workers who have published their results, the author notes that twenty-six have reported favourably and sixteen unfavourably on the reaction. He has come to the conclusion that many of the unfavourable results may be traced to errors of technique, and though there remains a small proportion of cases in which this defence of the reaction cannot be put forward he is convinced that it is specific and is likely to prove of great value.

#### 158. Inoculation of Guinea-pigs with Contaminated Tuberculous Material.

IN order to overcome the difficulty caused by the contamination of suspected tuberculous material with pathogenic micro-organisms, E. AUBERTIN and A. FONTAN (*C. R. Soc. de Biologie*, January 20th, 1923, p. 118) have applied the same treatment to their inocula as Petrof does to products from which he desires to cultivate the tubercle bacillus. Their technique consists in adding to the material to be examined twice its volume of a 4 per cent. solution of sodium hydrate, shaking vigorously, incubating for half an hour at 37°C., and neutralizing with 10 per cent. hydrochloric acid. To the fluid resulting from this homogenization a 1 per cent. aqueous or alcoholic solution of gentian violet is added in such a quantity as will raise it to a concentration of 1 in 5,000. The mixture is now centrifuged for fifteen minutes, the sediment mixed with a little sterile saline, and used for animal injections. With the exception of certain resistant organisms contained in human faeces this process seems to destroy the usual secondary invading bacteria which are likely to gain access to tuberculous material. Such products as septic pleural fluids, sputum, urine, and pus can be injected intraperitoneally into guinea-pigs after this treatment without the risk of the animals dying of peritonitis due to pyogenic organisms. The process does not seem to have any deleterious action on the tubercle bacilli themselves, and the results recorded by the authors show that the development of tuberculosis in the guinea-pig proceeds in the usual manner.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## MEDICINE.

### 159. "Glandular Fever."

W. T. LONGCOPE (*Amer. Journ. Med. Sci.*, December, 1922, p. 781) points out that under the terms "glandular fever," "infectious mononucleosis," and "acute benign lymphoblastosis" cases have been described which present somewhat similar symptoms. He records ten cases which he describes by the term "infectious mononucleosis." The clinical features resemble those of "glandular fever" (described long ago by McEiffer, Dawson Williams, and others), but at present the exact relation, he says, is not settled. The onset is gradual, with headache and irregular fever, and often with pharyngitis, tonsillitis, or tracheitis. The cervical glands become enlarged, firm, and tender; frequently the axillary and inguinal glands are also affected; sometimes the spleen becomes enlarged and tender. The leucocytes in the blood increase in number from the seventh to the tenth or eighteenth day. The change is a mononuclear leucocytosis—an absolute and relative increase in the mononuclear non-granular leucocytes, with a decrease of the total number of granular leucocytes. Three forms of mononuclear leucocytes are found in all of these cases: (1) small mononuclear leucocytes, (2) large mononuclear leucocytes (both similar to those seen in normal blood), and (3) mononuclear leucocytes of a type not usually seen in normal blood. The third type predominates. These cells are somewhat larger than the small lymphocytes, and contain oval, kidney-shaped, or slightly lobulated nuclei, usually without definite nucleoli, and often eccentrically situated in the cell. Sometimes the nucleus almost filled the cell; at other times it was surrounded by a considerable amount of basophilic non-granular protoplasm. The absence of the oxidase reaction differentiated these cells from myeloblasts. There is no anaemia. The fever rarely exceeds 102° or 103°; it continues irregularly until the tenth or twentieth day, and then gradually subsides, and the symptoms and blood changes then disappear. The uniform character of this febrile disease and the association of enlargement of lymph glands with a striking increase of mononuclear leucocytes of an abnormal type in the blood serve to differentiate the condition from other acute infectious diseases. The cause is unknown. The disease is of short duration, and recovery is the rule. It resembles most closely acute leukaemia, but may be differentiated by many characteristics—anaemia and purpuric spots are absent, and the abnormal mononuclear cells in the blood are different in their histological and biological characteristics from those in leukaemia.

### 160. Broncho-pulmonary Spirochaetosis.

CH. GARIN and L. MORENAS (*Journ. de Méd. de Lyon*, December 20th, 1922, p. 759) state that broncho-pulmonary spirochaetosis typically resembles acute or chronic haemorrhagic bronchitis, but also assumes less typical but not exceptional forms. Some non-haemorrhagic broncho-spirochaetosis, resembling bronchopneumonia, fetid bronchitis, or pulmonary tuberculosis, are only recognizable by the often accidental discovery of Castellani's spirochaetes in abundance in the sputum, and by the absence of pathogenic microbes. Associated forms (spirochaetes and fusospirilli, or spirochaetes and tubercle bacilli) do not appear to produce distinctive symptoms, at least in their earlier stages. The authors state that prior to 1914, although the area of spirochaetosis was gradually extending, it appeared always to be confined to the tropics. The war brought it to Europe, the earliest cases being discovered in Switzerland, afterwards in Serbia, Dalmatia (where Castellani found some cases, erroneously diagnosed as tuberculosis, in a military sanatorium), and in 1917 an outbreak of nearly 50 cases occurred at Toulon, the majority being Annamese. Since that date, apparently under the influence of the great influenza pandemic of 1918-19, sporadic cases, or small local epidemics, have been reported in France, Salonica, Italy, England, and even in North America. Although rare, the disease must now be considered an integral part of European pathology. The authors describe in detail the antiseptic precautions which are required before the collection of suspected sputum—lavage of the mouth and fauces, and brushing the teeth with antiseptic solutions. The technique is then described. They recognize two main types: (1) The typical form, or haemorrhagic broncho-spirochaetosis, and (2) the atypical, habitually non-haemorrhagic form; intermediate or mixed forms also occur. In

the typical form the onset is sudden, with headache, moderate fever (lasting two to six days), and at first mucous or mucopurulent sputum. Examination of the lungs reveals only a few slight scattered râles. The symptoms may subside, but more frequently bronchitis persists for a long period, and a new and important symptom occurs—blood-stained sputum, homogeneous red masses resembling red-currant jelly. The chronic form may follow this, or it may commence with "influenza" symptoms. The authors describe in detail (a) the pneumonic and bronchopneumonic forms, (b) the "fetid" type, and (c) the pseudo-tuberculous variety, which clinically closely resembles pulmonary tuberculosis. Spirochaetosis may, however, be associated with true pulmonary tuberculosis, and also with enteric fever and malaria; such complications are, however, rare. The absence of the typical sputum ought not to eliminate the diagnosis of spirochaetosis, and a careful examination for spirochaetes should always be made in doubtful cases.

### 161. The Treatment of Chronic Dyspepsia in Infancy.

C. E. BLOCH (*Ugeskrift for Læger*, January 4th, 1923, p. 1) has given test meals containing barley water to 64 infants treated at the Rigshospital in Copenhagen for chronic dyspepsia and atrophica infantilis. In 31 cases the acidity of the gastric juice was normal. In the remaining 33 there was achylia or hypochylia, and in 15 of these 33 cases there was almost complete achylia, persisting for many weeks in spite of severe dietetic restrictions. In the remaining 18 cases of defective gastric secretion marked and rapid improvement followed treatment. This was based on the assumption that the chronic dyspepsia of infancy is merely the result of a simple insufficiency of the digestive glands. This insufficiency results from congenital weakness, the weakness following acute or chronic diseases, and overloading with food. Hence the author's advocacy of treatment by starvation. If the infant is already much debilitated, it cannot stand even a twenty-four hour régime, with only water or tea to drink. To avoid the collapse of absolute starvation, the author gives thin barley water, containing 2 per cent. cane sugar. After this dietary has been given for a day or two he adds increasing quantities of milk, but is careful to limit it on account of its tendency to promote fermentation. His discussion of the modern conceptions of the etiology of dyspepsia in infancy shows that opinions still differ widely.

### 162. Narcosis and Acidosis.

P. GYÖRGY and H. VOLLMER (*Klinische Wochenschrift*, November 18th, 1922, p. 2317) discuss the indications which urine examination may afford of acidosis or increased acid excretion. Freudenberg and György have recently shown that in tetany the acid excretion is markedly diminished; and György has shown that in rickets it is markedly increased. Retarded metabolism leads to acidosis; accelerated metabolism combats the acidosis, and may lead to alkalosis. In their further observations, to determine if every retarding of metabolism leads to increased acid excretion in the urine, the authors made careful examinations of the urine before and after chloroform narcosis or mixed chloroform and ether narcosis in 11 cases. The results of these examinations are given in detail. The authors conclude that this narcosis leads to an absolute and considerable increase of the acid excretion, and that the retarded metabolism due to the narcosis produces a tendency to acidosis, which is indicated by the increased acid excretion.

### 163. Infantile Eczema.

WHITE (*Arch. Dermatol. and Syphilol.*, January, 1923, p. 50) reports 22 cases of infantile eczema, and emphasizes the importance of examining the stools in obstinate cases. By the application of crude coal tar in combination with zinc oxide, two parts each, and sixteen parts each of corn starch and petrolatum, to form a black paste, the great majority of cases can be quickly cured; but in obstinate cases it was found that the stools were abnormal, excessive fat occurring in 60 per cent., excessive starch in 40 per cent., excessive sugar in 20 per cent., and excessive protein in 10 per cent. Distinct success resulted from a regulation of the diet. Of the reported cases males predominated, and all were breast-fed, the eczema appearing soon after weaning and attacking the face most frequently. No soap or water should be used to the affected parts, and night and morning the paste should be spread on and not bandaged, all remnants of the previousunction being removed with sterilized oiled gauze prior to each fresh application.

**164. Electro-cardiograms and Myocardial Disease.**

THE coronary arteries and ventricular heart muscle of eleven patients who died of heart failure were carefully examined by H. E. B. PARDEE and A. M. MASTER (*Journ. Amer. Med. Assoc.*, January 13th, 1923, p. 98), and it was found that muscle disease occurred but rarely in the absence of disease of the coronaries. The outstanding lesion was always a fibrosis, though it varied much in degree and distribution. The ventricular waves of the electro-cardiogram taken shortly before death were normal in four cases; three of these had normal ventricular muscle, and the other showed but insignificant changes. The ventricular waves were abnormal in seven cases; one of these hearts had a moderate fibrosis, and the remainder had various sorts of marked abnormality of the ventricular muscle. Though admitting the small number of their cases, the authors strongly suggest that an electro-cardiogram with the special abnormalities described will indicate disease of a ventricular muscle to a definite degree, which the microscope, if not the naked eye, can discover, and which might well be expected to interfere with its function. If the ventricular waves do not show any of these special abnormalities the indication is less clear, but it is likely that the ventricular muscle is normal, or at least affected with but the slightest degree of abnormality. It seems that ventricular muscle disease is a far more important deduction from the finding of abnormal ventricular waves than has been heretofore considered, so that the clinical importance of abnormal electro-cardiograms becomes more apparent.

**165. Calcium Chloride in Pulmonary Tuberculosis.**

R. MONTELEONE (*Il Policlinico*, Sez. Prat., January 8th, 1923, p. 48) alludes to the recent work of French clinicians on the use of intravenous injections of calcium chloride in the treatment of diarrhoea and vomiting in pulmonary tuberculosis, and records the results of his experiences with this method. Unlike the French writers, however, who used strong solutions (50 per cent.), he employed a solution of 10 per cent. Out of 10 patients suffering from vomiting following attacks of coughing, or independent of this cause, this symptom was completely cured in 5, considerably improved in 3, and in 2 not affected, while in 4 other patients diarrhoea was completely cured. Monteleone's results thus agree with those of the French as regards the great advantage of this method of treating two of the most troublesome symptoms of pulmonary tuberculosis.

**SURGERY.****166. Diverticula of the Bladder in Children.**

A. HYMAN (*Surg., Gyn., and Obstet.*, January, 1923, p. 27) points out that vesical diverticula are more frequently present in children than would be inferred, many being overlooked because the proper examination had not been made. Two types are described—true where all the coats of the bladder are present, false when formed by mucous membrane alone. The true diverticula are described as congenital or acquired, and uncertainty exists as to their origin. They are usually found in the neighbourhood of the ureteric orifice, and three reported cases were all in males; a marked pyuria was present in all cases, and all showed presence of residual urine. The symptoms do not usually appear till infection supervenes. A distended bladder is found and should focus attention on the condition, and if symmetrical a diverticulum should be suspected. Cystoscopy may be used, but is difficult in the young, and the opening, being small, may be overlooked. Radiograms are valuable in making a diagnosis. The prognosis is favourable, and children stand the operation well. Radical extirpation of the sac by an extraperitoneal route is the best procedure. Care must be taken to avoid the ureter, and it should not be interfered with if possible. The presence of diverticula in young children without evidence of obstruction leads to the conclusion that they are congenital in origin.

**167. Acute Symptoms following Gastro-enterostomy.**

HADEN and ORR (*Johns Hopkins Hosp. Bulletin*, January, 1923, p. 26) investigated the cause of certain acute symptoms following gastro-enterostomy, and record three cases which showed a considerable increase in the non-protein nitrogen of the blood proportional to the severity of the intoxication, low blood chlorides, and suppression of chloride excretion. All three presented clinical symptoms of a severe intoxication associated with much tissue destruction which, together with the chemical findings in the blood and urine, were characteristic of intestinal obstruction, although there was no reason to suspect (as confirmed in one of the cases by x ray) any actual interruption of continuity below the gastro-enterostomy stoma. The acute symptoms—fever, abdominal

pain, and in two cases nausea and vomiting—appeared to be caused by an intoxication arising in the upper intestinal tract, probably due to a duodenal obstruction at the site of the gastro-enterostomy interfering with drainage of the duodenal loop, and thus producing a condition favourable to the formation of toxic substances in a portion of the intestine from which rapid and complete absorption takes place. One case showed a marked alkalosis, evidenced by the very high CO<sub>2</sub> combining power of the plasma, and clinically by sighing respirations. In two cases in which the urine was examined there was a striking suppression of chloride excretion with a very low chloride content of both plasma and whole blood. The alkalosis is closely related to the chloride metabolism, and is probably merely an incident in the general intoxication.

**168.****Salivary Calculi.**

A. FALLAS (*Le Scalpel*, December 30th, 1922, p. 1264) remarks on the comparative rarity of salivary calculi. Men are more frequently affected than women, and adults rather than children. Irritants in the mouth, such as tobacco, dental caries, and spices, appear to exert some influence on their formation. It is generally believed that micro-organisms play a part in their formation. Staphylococci, pneumococci, and streptococci, and even the yellow grains of actinomycosis, have been found in the calculi. It is possible that some foreign body, such as bacteria or cellular debris, forms a nucleus around which the stone forms; the obstruction thereby produced assists in the deposit of crystals around the stone, though ligature of the duct alone does not result in calculus formation. The calculus is generally single, though multiple stones are not uncommon. They are small when multiple, larger when single—the size of a pea or an almond—and are generally oval in shape when formed in the duct; they are usually soft in the centre, with a harder covering. The presence of a calculus leads to stasis of the saliva and the ducts and the glands are distended with secretion; this leads to sclerosis and destruction of the secretory tissue. Inflammation with abscess formation may ensue and sometimes results in a salivary fistula; the inflammation may even spread to the teeth and the jaw, setting up a periostitis. Their formation is usually slow and may take up a dozen years or so. The symptoms are pain and swelling after food and a tumour situated in the course of the duct interfering with the movements of mastication. Salivary colic has been described with pain similar to renal and biliary colic. Probing of the duct with a fine stylet enables the stone to be felt; most calculi are opaque to the x rays. These calculi are most often found in Wharton's duct. Treatment consists in incision of the duct and removal of the stone.

**169. Operative Treatment of Chronic Intestinal Stasis.**

G. A. CASALIS DU PURY (*Med. Journ. of South Africa*, September, 1922, p. 27) discusses the operative treatment of chronic intestinal stasis associated with "typhlatony," caecum mobile, ptosis of the ascending colon, typhilitis, perityphilitis, chronic appendicitis, and the megacolon; he regards intestinal stasis in the right side of the large bowel as a frequent cause of chronic constipation. A mobile caecum is often dilated, prolapsed, and almost always associated with chronic typhilitis, perityphilitis, and appendicitis. Caecorrhaphy, with the destruction of adhesions and the performance of a caecopexy if necessary, by reducing the caecal sac and the dilated ascending colon, is the operation of choice in typhlatony and prolapse of the right colon. In other conditions giving rise to chronic intestinal stasis and necessitating either temporary or permanent drainage of the large bowel caeco-sigmoidostomy is preferable to other short-circuiting operations, because of its rapidity, simplicity, and safety, and the fact that the ileo-caecal valve is retained. For complete success in its performance the mesenteries of each colon must be lax, so that there is easy apposition of one bowel to the other without tension on the suture, and the anastomosis must be large.

**170. Respiratory Exercises for Adenoids.**

BRISOTTO (*Rif. Med.*, December 18th, 1922, p. 1206) says that the value of respiratory exercises both before and after operation for adenoids is not sufficiently recognized. He gives some figures showing, as tested by the spirometer, the great improvement in respiration which follows a course of special respiratory gymnastics. He describes the technique followed by him. Before starting the exercises he instils a few drops of mentholated oil into the nostrils. Although the value of these exercises is recognized by all, it is too often forgotten in practice, and the author's chief aim is to draw attention to the necessity of carrying them out if the best results are to be got from the removal of adenoids. It is especially between the ages of 6 and 12 years that the necessity arises.

## 171. The Cause and Treatment of Perforating Ulcer.

M. KAPIS (*Klinische Wochenschrift*, December 23rd, 1922, p. 2558) discusses the cause and treatment of perforating ulcers, and records his results in 31 cases of perforating ulcer on the foot. The ulcers were due in 13 cases to injuries of the peripheral nerves, in 4 to syringomyelia, in 5 to tabes, in 3 to syphilis, in 1 to spina bifida, in 1 to pes cavus (probably spina bifida), and in 4 to sensory disturbances not definitely due to spinal cord diseases. The author concludes that perforating ulcer is a bed sore in regions in which sensation is lost or diminished, and in tissues lacking the normal power of resistance and regeneration. The first duty in the treatment is the attempt to restore the nerve connexions; local treatment is necessary. In perforating ulcers on the balls of the toes a joint fistula usually exists, whether the joint presents arthropathic changes or not. These perforating ulcers are healed in the most simple manner by resection of the bones of the affected joints. For perforating ulcers of the heel no certain successful method of treatment has, so far, been found. The influence of sympathectomy is possible, but doubtful; removal of a neuroma appears less important. The performance of these operations is permissible in an attempt to heal an ulcer on the heel.

## 172. Treatment of Paralysis by the Grafting of Tendons.

G. L. REGARD (*Bull. Soc. de Chir.*, December 26th, 1922, p. 1496) has performed some experiments on dogs, in which calf tendons, preserved in 60 per cent. alcohol, were grafted to restore movements which had been abolished by nerve section, removal of muscles, etc. The essential feature was to connect the proximal end of the graft to a portion of an active muscle whose function was more or less in co-ordination with the paralysed muscles. Thus, after paralysis of the extensors of the digits of the hind leg, the graft was attached above to a portion of the vastus externus, separated distally just above the knee and below to the extensor tendons at the ankle. It was found that the best results were obtained if the graft was allowed to lie superficial to the deep fascia and covered by folding the latter over it, making an artificial sheath. Early movements were encouraged. An animal treated in this way and which had previously, owing to its extensor paralysis, walked on the dorsum of its foot, was walking normally within a few days. The fusion of the graft at its extremities becomes in time so complete that the exact site of union is not recognizable. REGARD considers that the method should be tried in preference to tendon transplantations, as it gives better results experimentally and is a less severe operation. Methods of performing the operation on the human subject for various forms of paralysis are suggested, but no actual cases are reported in which it has so far been attempted.

## OBSTETRICS AND GYNAECOLOGY.

## 173. Infections of Cervix, Body of Uterus, and Fallopian Tubes.

INASMUCH as it has been shown that the body of the uterus seldom harbours bacteria for a long period of time, A. H. CURTIS (*Journ. Amer. Med. Assoc.*, January 20th, 1923, p. 161) states emphatically that discontinuance of uterine curettage in attempts to relieve chronic infection marks a decided advance in methods. In most instances leucorrhoea arises from the cervix and from glandular tissues in the vicinity of the urethra. Treatment directed to eradication of these diseased areas yields very satisfactory results. Gonorrhoeal infection of the Fallopian tubes is naturally a quickly self-limited disease. So-called chronic gonorrhoeal salpingitis is usually a recurrence from an external source or repeated invasion from the chronically infected lower genital tract. Streptococcus infection of the tubes occurs usually as a complication of abortion or intrauterine manipulation, and is commonly only a part of more widespread pelvic infection. Streptococci, in contrast with gonococci, may remain viable in the tubes for many months or even for years. Even the most prolonged and most severe gonorrhoeal disease of the tubes is characterized by adhesions amenable to blunt dissection. Adhesions which require cutting or tearing are due to streptococcus or tuberculous infection. In any given case, if there is any doubt whether it is advisable to remove the ovaries at the time of operation, more radical measures are indicated in streptococcal or tuberculous infection than in gonococcal disease of equal severity, because viable bacteria probably remain buried in the tissues, and there is likelihood of post-operative chronic ovarian infection.

## 174. Radium in Cancer of the Uterus.

O. BEUTNER (*Schweiz. med. Woch.*, February 1st, 1923, p. 105) reviews the results obtained in treatment of cancer of the cervix by radium at the Swiss Radium Institute in Geneva. Till 1914 the treatment of carcinoma of the cervix in Geneva was operative. Since the establishment of the Radium Institute surgical interference has been abandoned even in operable cases. The author has had two series, each of 63 cases, and is now engaged on a third series. He classifies his cases according as the disease was (1) operable, (2) "borderland," (3) associated with excavation and slight infiltration of the structures adjoining the cervix, and (4) more advanced cases. In the first series of 63 cases there were 11 patients (4 belonging to the first group, 4 to the second, and 3 to the third) who were still alive. The remaining 52 were dead—that is, there was a mortality of 82.5 per cent. It should be borne in mind in connexion with this high mortality that only 14.3 per cent. of these 63 patients were operable—that is, in the first class. In this class there were only 9 cases, and 5 of them terminated fatally. In the second class there were 8 cases and 4 terminated fatally. Discussing the reasons why, in these two classes, the treatment was successful in some cases and unsuccessful in others, the author suggests that less depended on the microscopic character of the disease and the dosage of the radium than on the general health of the patient and her age; the best results were obtained in comparatively elderly patients. Turning to the inoperable cases, the author shows that, as judged by duration of life after the institution of treatment, by the relief from pain, haemorrhage, and discharge, radium treatment is remarkably superior to the old palliative treatment consisting of applications of zinc chloride and the like. He concludes that in inoperable cases radium is supreme; in operable cases the comparative merits of radium and operative treatment are still debatable, but it is significant that, whereas operative treatment has reached the limits of technical perfection, radium treatment is only in its infancy. While the Wertheim operation still has a primary mortality of 20 per cent., the author has not yet seen a single radium fatality among his patients.

## 175. Criminal Abortion.

J. A. VAN DONGEN (*Nederl. Tijdschr. v. Geneesk.*, January 6th, 1923, p. 24) remarks that it has always been held that the real number of cases of criminal abortion is much greater than the number admitted by the patients themselves. Olsbausen stated that about 80 per cent. of his cases of abortion were of criminal origin, and Kistner's experience at Breslau was the same. Boerma in 1908 was of the opinion that from half to three-quarters of all abortions in Groningen were of this character. In the 1,193 cases of abortion studied by van Dongen criminal abortion was admitted in 99, or 8.3 per cent. The real proportion was naturally much higher. It is probable that in Holland, as in other countries, criminal abortion has become much more frequent in recent years owing to economic depression. The proportion of unmarried to married women in van Dongen's series of criminal abortion was 1 to 0.8, while among the total number of abortions the proportion of unmarried to married was 1 to 5.9. It was thus obvious how frequently the unmarried state was the reason for criminal abortion. A study of the patients' ages showed that criminal abortion occurred at an earlier period of life than abortion in general. Nearly 50 per cent. of the patients were under 25 years of age, and only about 2 per cent. were over 40. The stage of pregnancy at which criminal abortion was induced was as a rule earlier than in abortion in general; in a large proportion of cases (36.49 per cent.) the duration of pregnancy was less than two months. In many cases attempts at abortion were made shortly after the first period had been missed. In a large proportion of cases the abortion was brought about by the patients themselves by ingestion of drugs, such as preparations of ergot, quinine pills, saffron, etc., hot baths, vaginal and intruterine injections, cycling, dancing, and gymnastic exercises. The complications of criminal abortion were lesions due to instruments used, infection of the sexual organs, toxæmia, and air embolism. Whereas among 1,193 cases of abortion due to all causes 296, or 24.86 per cent., had fever—that is, an axillary temperature of 100.4° or above—of 99 cases of criminal abortion 51.8 per cent., or about twice as many, had fever. The mortality among the 1,193 cases was 1.4 per cent., the afebrile cases having a mortality of 0.4 per cent. and the uncomplicated febrile cases a mortality of 1.09 per cent.

## 176. Injections of Turpentine in Diseases of the Uterine Appendages.

B. NYSTRÖM (*Läk. Med.*, November-December, 1922, p. 63) reports on 63 cases of uterine appendages. As turpentine in olive oil is apt to cause pain, he used

a preparation containing turpentine, quinine, and anaesthesia, given by intragluteal injection; in no case did it cause pain, swelling, or discomfort. The injections were given at intervals of a day or two, and the average number given to each patient was six. Among the patients there were 39 with acute or subacute disease and 24 with chronic disease; in all the cases of pyovarium and pyosalpinx the diagnosis was confirmed by puncture or operation. The results varied greatly. Several patients felt no change; others, often after the first injection or two, were rid of their symptoms. Others, again, felt much worse, and in these cases their complaints were substantiated on palpation, which showed increased tenderness or enlargement of the swellings. It was, however, just in these cases that the ultimate results were often best. The author is cautious in passing judgement on this treatment because it was supplemented by residential treatment in hospital, and it was therefore difficult to decide how much of the improvement should be credited to simple rest and dieting. But the general impression left on him by these cases was that their improvement was frequently hastened by the injections. This was particularly the case when the disease was acute or subacute.

#### 177. Tuberculosis and Pregnancy.

G. WINTER and W. OPPERMAN (Deut. med. Woch., January 5th and 12th, 1923, pp. 1 and 45) have investigated the cases in which tuberculosis was complicated by pregnancy at Winter's hospital in Königsberg. Of 139 cases carefully investigated after pregnancy the disease progressed in 93, or 67 per cent. Of 45 patients with latent tuberculosis, 33 showed no aggravation of the disease six months after pregnancy. Of 96 patients with active tuberculosis, 28 went to term; in the remaining 68 cases the pregnancy was interrupted. In 86 per cent. of the 96 the disease progressed. The authors consider that while latent tuberculosis is no indication for abortion, this ought to be induced when the disease is active and progressive. They admit that the distinction between latency and activity is often difficult. But fever is a definite indication for inducing abortion, and they have known 30 cases in which the disease was progressive, although the patients appeared to be afebrile. They found that when pulmonary disease was complicated by tuberculosis of the larynx as well as by pregnancy the prognosis was practically hopeless; of 16 patients in this class 15 died, and only one appeared to pass through pregnancy without any ill effects.

### PATHOLOGY.

#### 178. The Recognition of Pneumococcal Types.

R. R. ARMSTRONG (Brit. Journ. of Exper. Path., December, 1922, p. 287) has shown, by applying the absorption of agglutinin test to the serological study of pneumococci, that agglutination by specific pneumococcal serums is not invariably sufficient for recognition of types. Type II pneumococcus serum is not only capable of agglutinating the standard coccus but is also rich in subagglutinins which react with atypical cocci; these atypical cocci are sharply differentiated by failure to absorb the standard agglutinin. Some of the strains isolated from cases belonging to Subtype II appear to be intermediate between pneumococci and the salivary streptococci, but salivary streptococci are sharply differentiated from pneumococci by their vigorous agglutinogenic properties. These results are similar to those obtained by Avery, who, in an investigation of ten strains of aberrant Type II pneumococci, showed that saturation of the standard serum by its homologous coccus removes all the agglutinins and protective bodies, while absorption by a related subtype does not materially affect these. Subtype strains exhibit limited specificity within the group to which they belong; in no case was it found that a serum prepared against a subtype pneumococcus agglutinated the standard type strain. The numerous non-agglutinating strains of pneumococcus variously described as Group IV, and sometimes improperly as Type IV, are conspicuously deficient in antigen for rabbits, and only the feeblest agglutinating power can be produced by injections.

#### 179. Herpetic Encephalitis.

C. DA FANO (Journ. of Path. and Bact., January, 1923, p. 85) gives an account of the experimental investigation of herpetic meningo-encephalitis in animals and of the evidence that has been collected establishing its close resemblance to encephalitis lethargica. Inoculation with the vesicular fluid from all forms of herpes, with the possible exception of herpes zoster, gives rise in certain animals to a fatal infec-

tion, which displays a marked affinity for the central nervous system, spreading within a few days to the brain of the animal independently of the material used for inoculation or the site selected for transmission. The cerebral lesion thus produced consists of an extensive small-cell infiltration and marked degeneration of the nerve cells, which ultimately break down into a necrotic debris. Only by assuming the presence of a virus consisting of living micro-organisms able to multiply within the central nervous system of the animal affected does the above condition appear explicable. The process is almost identical with that observed in human cases of encephalitis lethargica, and the regions affected are the same. Still greater is the similarity that exists between the lesions of herpetic encephalitis and those produced in animals by inoculation into them of the virus of encephalitis lethargica. The author considers it probable, therefore, that the viruses of herpetic and lethargic encephalitis belong to the same pathogenic group. In the central nervous system of animals suffering from the former condition granular structures occur closely resembling certain "minute bodies" which have been described in the latter, and the suggestion is made that the smallest of these granular structures (herpetic minute bodies) may be the virus itself, or, at any rate, particles of organic matter to which the virus closely adheres. Whether the latter is of the filter-passing variety and whether it can be grown in culture media are as yet uncertain.

#### 180. A System of Tubules in Secreting Epithelia?

G. SCOTT WILLIAMSON and INNES PEARCE (Journ. of Anatomy, January, 1923, p. 193) describe a system of tubular structures which they have found existing in secreting epithelia, in particular of the thyroid gland, but also of portions of the kidneys and bile ducts. It consists, they say, of a network of tubules widely distributed and occupying a definite position in relation to the cells of the epithelium. In segmental section of the follicles the observers note short rods and dots with the appearance of a fence situated in a more or less central plane between the nuclei and the colloid substance within the vesicle, or, more plainly, stretched beneath the free surface of the epithelium. They state also that a layer of cytoplasm, no matter what may be the degree of distension of the latter, always separates the network from the contents of the follicle. Occasionally isolated branches, larger in calibre than the main system of tubules, have been observed running radially towards the base of the epithelium. The tubules are extremely fine—not exceeding  $2\mu$  in diameter—and when empty appear as dark-staining lines; when full they are pale and hollow, enclosing either a clear homogeneous or a granular substance. The observers claim no knowledge of the functional significance of the system, but feel justified in considering it a definite structure peculiar to secreting epithelium. They profess themselves satisfied that it is of a tubular nature, and consider it possible that it may be a type of auxiliary circulation carrying lymph, blood plasma, and the contents of parenchyma or gland ducts, connected with the complicated processes of excretion and absorption.

#### 181. Physical Properties of the Neurotropic Ultra-viruses.

C. LEVADITI and S. NICOLAU (C. R. Soc. de Biologie, January 20th, 1923, p. 66) have been investigating some of the physical properties of the viruses of vaccinia, encephalitis, and rabies. They find, in the case of the first two, that if an emulsion of the virus be mixed with animal charcoal, and centrifuged after twenty hours' contact in the ice-chest, the supernatant fluid is no longer able to produce disease when injected into a rabbit, while the deposit, on the contrary, is highly active. With rabies, not only does the charcoal adsorb the virus, but it actually destroys it, so that the injection of both the supernatant fluid and the deposit is without pathogenic effect. Similarly they find that this adsorption of the virus can be attained by the use of powdered kaolin, tricalcium phosphate, or the cellular material of yeasts—by the same bodies, in fact, which fix *in vitro* the soluble ferments, bacterial toxins, and certain colouring matters. Further, on dialysing an extract of neuro-vaccine, made by emulsifying a piece of brain in rabbit serum with subsequent clarification by prolonged centrifugalization, the virus was found to be adsorbed by the precipitated globulins. The same adsorption was shown to occur when the globulins were thrown down by ammonium or magnesium sulphate. It therefore appears that these viruses are composed of aggregations of living protein matter whose dimensions are not greatly in excess of those of the albuminoid particles which serve as nuclei for the adsorption of diastases and bacterial toxins. The authors promise to show presently that these viruses can be made to pass through collodion membranes which hold back albumins, toxins, haemolytic amoebocytes, and complements, but which allow the passage of peptones, amino-acids, and—curiously enough—the bac. criophage of d'Herelle.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## MEDICINE.

### 2. The Therapeutic Properties of Cod-liver Oil.

E. POULSEN (*Norsk Mag. for Lægevidenskaben*, January, 1923, p. 35) gives a preliminary account of the investigations into the composition of cod-liver oil proceeding at the Pharmacological Institute in Christiania. He found that even after heating the cod-liver oil for sixteen hours at a temperature of 98°C. its vitamin content was practically unimpaired. But bubbling air through warm cod-liver oil deprived it of its vitamin content in a few hours. Exposure to air at ordinary temperatures proved injurious, and when a thin layer of cod-liver oil was poured out on a glass plate it was found to be inert after fourteen days. But time alone appears to have little effect, and one of the most vitamin-rich samples examined was one which had been bottled for three years. With regard to prescribing cod-liver oil in the form of an emulsion it should be noted that, the oil being distributed in small drops, more of its surface is exposed than under ordinary conditions, and thus the chances of air contamination and loss of vitamin are considerably enhanced. As emulsions contain only 35 to 45 per cent. of cod-liver oil they must be given in much larger doses than pure cod-liver oil. The liver oil of certain other fishes besides the cod was found to be as rich in vitamin A as cod-liver oil. The liver of the male cod contains more oil than that of the female, and is just as vitamin-rich. The author refers to a case illustrating the value of giving cod-liver oil to the suckling mother. A poor mother, aged 39, had not been able to afford much fresh milk and butter. Most of her first nine children had suffered from rickets. Her tenth child, born on January 11th, 1922, weighed 3,500 grams at birth. Eighteen days later its weight had increased by only 50 grams. During the next fifteen days its weight was stationary, it looked flabby, and suffered from slight diarrhoea. The fat content of the mother's milk was normal. Her dietary was not changed, but she was given one tablespoonful of cod-liver oil three times a day. The weight curve, published by the author, showed a most dramatic rise. Fifteen days later the mother was given butter and fresh milk without stint, but they did not affect the infant's weight curve. What had been lacking had evidently already been supplied by the cod-liver oil.

### 163. After-care of Cases of Infantile Paralysis.

H. G. DUNHAM (*Journ. Amer. Med. Assoc.*, January 27th, 1923, p. 224) urges that, during an epidemic of infantile paralysis of any size, children with obscure indisposition should be kept at rest in bed for several days until the exact nature of their condition can be determined. When paralysis supervenes, it usually appears within a very short time after the initial upset, the average in a series which was investigated being three days after the first manifestation of illness; but often the paralysis comes on twenty-four or forty-eight hours after, so that the patient with a malaise of no consequence need not be incapacitated over a long period of expectancy. In every obscure acute illness during childhood the diagnosis of infantile paralysis should always be a mental reservation, since sporadic cases occur in the community every year. Obviously, to obtain the best results and maximum functional return, these patients must have intelligent care from the outset of their illness. Correct treatment for a definite stage applied at the wrong time is far worse than none.

### 161. Treatment of Unilateral Pulmonary Tuberculosis.

G. CAUSSE and DERVILLE (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, December 21st, 1922, p. 1766) remark that it is frequently thought that numerous pleural adhesions in the neighbourhood of a tuberculous cavity, too thick and resistant to permit collapse of the lung, must exist. Recorded cases have shown that while unsuspected adhesions sometimes bar the way, in others, in which radiological and clinical examination show pleuritic adhesions, the pleural separation is effected quite easily. Their patient, a married woman aged 20, had all the symptoms of acute pulmonary tuberculosis confined to the right lung: constant cough, profuse sputum containing numerous tubercle bacilli, fever, and profuse sweats. The physical signs and skiagrams showed a large cavity in the right middle lobe. Diagrams show the condition of the lungs at seven examinations made between September 8th and December 1st, 1922, each examination taking place within a few days of the seven nitrogen inflations of the right pleura, details of which are

given. Two days after the last inflation a right hydro-pneumothorax was found; this was sero-fibrinous only. The result of the treatment has been that the patient has gained in weight, the cough, sputum, and number of tubercle bacilli have all decreased, the right lung has collapsed, except where it is adherent to the mediastinum, and with that collapse the cavity has almost disappeared. The authors admit that the ultimate issue of the case cannot be predicted as yet, but they claim that the artificial pneumothorax has given great relief to a patient whose condition was very serious.

185

### Tuberculosis in Infancy.

P. NOBÉCOURT and J. PARAF (*Paris méd.*, January 6th, 1923, p. 18) in the course of two years have observed 60 cases of tuberculosis, or a proportion of 4.6 per cent., among 1,296 infants, aged from 1 to 17 months, admitted to the crèche of the Hôpital des Enfants Malades, Paris. In most of the cases the clinical diagnosis of tuberculosis was at first impossible, and the infants were admitted for gastro-intestinal affections or marasmus. In many cases the rapid course of the disease enabled a correct diagnosis to be made, as 21 infants died of meningitis less than a fortnight after admission, and 5 of bronchopneumonia or rapidly fatal miliary tuberculosis. The cuti-reaction was the only means of establishing a rapid and certain diagnosis. Among 40 cases in which the source of contagion could be determined the father was responsible in 16 cases, the mother in 19, the grandfather in 1, and nurses in 4. Of 36 children who had been infected by other members of their family, 16 appeared to have been contaminated in the first weeks of life by a tuberculous parent.

186.

### Calcium Lactate for Nervous Headaches.

C. I. BAASTRUP (*Lægeskrift for Læger*, February 1st, 1923, p. 75) describes a well defined type of headache in which he has found calcium lactate dramatically successful. The patient suffers concurrently from attacks of slight oedema affecting the eyelids, upper lip, or one hand. Apparently there is no fever, and while complaining of the headache the patient hardly notices the associated oedema. This condition appears to run in families, and in one family the mother and two daughters were subject to these attacks. One of the daughters knew when one of the others was suffering whenever she observed a slight swelling under the eyes. Another patient suffered from Quincke's oedema—a condition which the author has found to be remarkably common in Denmark. The association of headache with these cases suggests that it may be due to oedema of the meninges. The dose of calcium lactate recommended by the author is 1 gram once to thrice a day for a period of three weeks. This drug not only relieves the headache, but may also banish such troublesome symptoms as those of vasomotor rhinitis.

187.

### Simple Acroparaesthesia.

F. HEISSEN (*Klinische Wochenschrift*, December 9th, 1922, p. 2473) describes the clinical features of simple acroparaesthesia, and records two severe cases. In both cases severe attacks of a sensation of pricking and numbness in the legs, below the knees, occurred daily early in the morning. The author discusses the symptoms and etiology of the simple form of the affection, which, though not very rare, is not well known to medical practitioners. The application of warmth (warm bath or hot air) has a beneficial effect, and the patient is very sensitive to cold. The attacks are definitely related to excess of alcohol or coffee; the patients are less sensitive to tea and nicotine. Frequent associated symptoms are morning headache, superacidity, periodic attacks of diarrhoea alternating with constipation, attacks simulating migraine or angina pectoris, tendency to sweating, urticaria, oedema fugax, acrocyanosis. Two forms of acroparaesthesia have been described—the simple form (Schultze's type) and the vasomotor or angiospastic form (Nothnagel's type). The terminal stage of the simple form of acroparaesthesia is vascular paresis—acrocyanosis, with cessation of the paraesthesia. The vasomotor or vaso-constrictor form may terminate in recovery, or gangrene may develop. In the simple form the symptoms are temporarily relieved by warm baths, whilst in the vaso-constrictor form the symptoms are increased thereby. The two forms are two diseases of different nature and etiology. The vaso-constrictor form is allied to Raynaud's disease, and may be regarded as the first stage of this affection.

## 188. The Effect of Olive Oil on Gastric Function.

B. C. LOCKWOOD and H. G. CHAMBERLIN (*Arch. Int. Med.*, January 15th, 1923, p. 96) investigated the effect of olive oil on gastric function, as measured by fractional analysis, in thirteen patients, seven with normal gastro-intestinal tracts, and six with either pyloric or duodenal ulceration. It was found that one ounce of olive oil given before meals caused a reduction in the average total acidity by about 12 per cent. and a similar lowering of the high point of the curve. There was also delayed evacuation of the test meal in the stomach; the bread of an Ewald meal was delayed forty minutes longer than in the control, the oil remaining at least fifteen minutes longer and being the last portion of the meal to be evacuated. Regurgitation of bile occurred in about 80 per cent. of the cases, being five times as frequent after the administration of oil as without it. The results coincided with those of Cowie and Munson, who attributed them to the oil coating the food and mucous membrane, thus lessening the normal local reflex action of the food; but in view of the biliary regurgitation into the stomach it seemed possible that the reverse peristalsis resulting therefrom might account for the delayed emptying, and alkaline duodenal regurgitation might also lower the acidity to the extent found.

## SURGERY.

## 189. "Rejuvenating" Operations.

W. HAUBENREISSER (*Deut. Zeit. f. Chir.*, November, 1922, p. 31) compares the present interest taken in the subject of "rejuvenating" operations in the medical and lay press with that aroused by Brown-Séquard's work on testicular extract in 1889, and considers the end-result will be much the same—namely, an increase in our knowledge of the various internal secretions, but nothing startling in the way of immediate practical results. Three different methods have been tried extensively in recent years—namely, Steinach's operation of ligating the vas deferens, grafting of testicular substance, and exposure of the testes to x rays in doses calculated to stimulate those organs. Some workers have reported very successful cases, others have experienced many complete failures. The theory that the interstitial cells of the testis provide the all important internal secretion does not find general acceptance; experiments on the lower animals have failed to support it, and many authorities (Aschoff, Meyer, and others) consider that these cells are concerned only in the nutrition of the germ cells, the latter being the source of the internal secretion. The author describes his own series of ten cases operated on during the last two years. In eight of these, thin grafts of healthy testicular substance, taken from patients who were being subjected to epididymectomy for tuberculous disease, were implanted into pro-peritoneal pockets in the abdominal wall. One case was successful—that of a man who had lost both testes from a war injury, and suffered from impotence, mental depression, and general weakness. Potency returned four weeks after operation, and the mental and physical improvement which followed was maintained two years later. One patient committed suicide soon after operation. Of the other cases in which operation was undertaken for a variety of complaints—for example, loss of testes from tuberculosis, eunuchism associated with cryptorchism, homosexual perversion, etc.—none were successful. Two cases in which the vas was ligated (one suffering from impotence and mental depression, the other from premature loss of virility) were not benefited. Four cases treated by x rays were not improved in the slightest degree. The author concludes that the only method of any value is that of testicular grafts, applied in cases where both testes have been lost in adult life, to relieve the symptoms which follow that contingency. He doubts whether the graft functions for any length of time; all the evidence goes to show that it is soon absorbed. It is possible that its absorption stimulates other internal secretions in the body, which may then replace to some extent that normally provided by the germ cells of the testis.

## 190. The Effect of Magnesium Sulphate Injections on Carcinomata.

R. REDING and A.-P. DUSTIN (*C. R. Soc. de Biologie*, February 3rd, 1923, p. 301) have issued a brief preliminary note on the influence exerted by the intramuscular injection of magnesium sulphate on certain tumours. Their observations appear to have been conducted on patients suffering from carcinomatous metastasis after excision of the primary growth. In certain cases they were able to amplify their clinical deductions by actual biopsy during the course of treatment. Their conclusions may be summarized as follows: (1) Intraosseous and intradermal metastasis secondary to cancer of the breast diminish rapidly in volume after intramuscular injections of magnesium sulphate.

(2) Histological examination reveals that, after a preliminary phase, during which atypical division is most in evidence, the cells cease to divide in the metastatic growths, so that the latter progressively diminish in volume. This decrease in size is due partly to the failure of cell division, partly to the shrinking of the tumour cells, and partly to the development of a dense fibrosis around, which progressively strangles the alveolar epithelium. Hitherto no destruction of the cells by phagocytosis has been noticed; even when the nodules are reduced in size, so as to be almost imperceptible, it is still possible to find in them the neoplastic cells. (3) The involution of the metastasis is regularly accompanied by an improvement in the general state of the patient.

## 191. Malignant Disease of the Vermiform Appendix.

H. M. PERRY (*Journ. Roy. Army Med. Corps*, December, 1922, p. 419), in outlining the clinical history and pathology of primary malignant disease of the vermiform appendix, states that with routine histological examination the reported cases of this condition have increased in number. In two recorded cases both patients had suffered from recurrent attacks resembling in nature an ordinary appendicitis, and at the time of operation there was no suspicion of underlying malignant disease; in one case signs of chronic inflammation were present, in the other they were entirely absent. Microscopic examination showed that one case belonged to the group of endotheliomata, the cells being arranged in an alveolar formation. These growths possess a low type of malignancy and growth is slow. The second case appeared to be a spheroidal-celled carcinoma with an excessive overgrowth of fibrous tissue, and it is suggested that it originated from the Lieberkühn's glands in this situation. In this case recurrence of the growth took place later, but the prognosis in spheroidal-celled carcinoma of the appendix is usually not unfavourable; extension is, as a rule, slow and early operative interference usually successful. Primary malignant disease of the appendix is often entirely localized, and when infiltration does occur its extension is not rapid. Dissemination by way of the lymphatics does not appear to be usual. How far the occurrence of chronic inflammatory change acts as an exciting agent in determining the incidence of growths is unknown. The fact that malignant change is not altogether uncommon is an added incentive to removal of the organ when symptoms of chronic inflammation become manifest.

## 192. Spinal Anaesthesia.

E. TYTGAT (*Le Scalpel*, January 27th, 1923, p. 91) reviews in detail the subject of spinal anaesthesia. In his opinion it is the procedure of choice in operations below the level of the diaphragm where a purely local anaesthetic will not suffice. Whilst admitting it is not free from danger, he insists that serious mishaps are not frequent—at any rate not more so than with general anaesthesia. He considers that trouble can be largely avoided by never employing the method in any of the conditions of brain, cord, or spinal column which render it unsuitable—for example, syphilis, tuberculosis, deformities, apoplexy, dementia. A further safeguard is scrupulous attention to details of technique, among which he emphasizes the employment of a fine pliable needle as less likely to cause damage, a slow withdrawal of cerebro-spinal fluid to the amount of 10 c.cm. which is utilized as a diluting medium for the particular substance about to be injected, the precaution of keeping the head of the patient strongly flexed on the chest in all cases, and a strict observance of asepsis. He prefers novocain and its analogous products to cocaine or stovaine, as being less toxic, exercising no paralyzing action on the nervous system, having considerable anaesthetic power, and being very diffusible. Along with it he employs adrenaline (half a milligram to ten centigrams of novocain), and claims that the addition reinforces the anaesthetic and hastens the induction. He notes that by some authorities adrenaline is said to cause trophic disturbances, headaches, and localized gangrene, but this is not his experience. The level of the anaesthesia is influenced by the site of puncture, the position of the patient, and the diffusibility of the drug used. The duration is determined by the amount injected. In his experience neither the pressure of the cerebro-spinal fluid nor the amount withdrawn has any influence on the height or depth of the anaesthesia.

## 193. Treatment of Temporo-sphenoidal Abscess.

F. MUECKE (*Journ. Laryngol. and Otol.*, February, 1923, p. 72) records two apparently almost hopeless cases of temporo-sphenoidal abscess in which recovery took place. One, a woman aged 52, showed every sign of mastoid disease with a direct necrosed tract through the tegmen to the abscess; the other, a child aged 5, presented no evidence of mastoid trouble, the only sign of previous ear mischief

being a healed perforation at the lower anterior quadrant, and healthy tissue was situated between the indolent clot and the abscess, pointing to a probable vascular infection. At operation all disease in the mastoid and middle ear should be eliminated, special attention being paid to the attic and zygomatic cells. For the prevention of cerebral hernia, which not only blocks drainage but so alters relations as to render it increasingly difficult to locate the original abscess, the exposure of the dura mater should be as small as is consistent with the complete removal of diseased bone, and only a small linear incision should be made into it. Not more than three fairly superficial explorations of the brain matter should be made, the first being forwards and upwards, the next directly upwards, and the third backwards and upwards, these being in the order of frequency of the site of a temporo-sphenoidal abscess. The abscess cavity should not be washed out. Drainage is best effected by a stiff rubber tube inserted into the cavity for the same distance as the forceps had to be inserted in order to give free drainage, and long enough to rest on the lower shelf of the chiselled-out mastoid, and prevented from slipping by gauze packing. Since anaesthetics undoubtedly lower resistance in these severe toxic cases the operation should be as speedy as possible, and no anaesthetic should be given for subsequent probings; and since the abscesses are often multiple further explorations may be necessary as symptoms arise.

#### 191. Tumour of the Carotid Gland.

FEDELI (*Arch. Ital. di Chirurg.*, November, 1922, p. 217) records a case of tumour of the carotid gland in a man aged 59 successfully treated by operation. Very full details of the structure of the tumour are given and references with brief details of 90 collected cases (81 observed during life and 9 found at autopsy). Tumours of the carotid gland are often of a mixed character but usually display a mild malignancy. Different authors have classified them in various ways as angiosarcoma, epithelioma, etc., and some of the confusion comes from lack of knowledge as to the significance of the carotid gland. In the author's case the tumour was of mixed origin. Nothing certain can be said as to the etiology, and the symptoms are chiefly due to mechanical pressure. In diagnosis one has to consider the site of the tumour, its horizontal—not vertical—mobility, its ovoid form, with smooth slightly lobulated surface, transmitted, not expansile, pulsation; bruits are rare; sometimes there is myosis of the corresponding pupil; growth is slow. There is no pain. Operative treatment is not free from risk, but much of this risk is due to the fact that owing to slow growth and absence of marked symptoms operation is delayed until the disease is well advanced. The author thinks that it might be well to operate earlier in these cases. Local anaesthesia and preliminary temporary haemostasis of the carotid are useful points in the technique of operation. There is a valuable bibliography of cases collected from various sources and numbering 90 in all.

#### 195. An Unusual Fracture of the Os Calcis.

H. VULLIET (*Rev. Méd. de la Suisse Romande*, December, 1922, p. 815) describes two cases of fracture of a portion of the anterior articular surface of the os calcis. In the first case the patient fell with the foot fixed; there was ecchymosis and pain localized in the instep over the outer part of the medio-tarsal articulation. As the pain persisted a skiagram was taken and showed an incomplete fracture of the anterior part of the os calcis; a semi-diagrammatic drawing (from the skiagram) shows the fragment of bone still attached to the articular cartilage. The patient was unable to work for eight weeks. In the second case the foot had been strongly compressed from before backwards. A few days afterwards ecchymoses appeared on each side of the tendo Achillis, and more especially on the dorsum and outer surface of the foot. A skiagram showed a larger fragment of the os calcis in the same region as described in the first case, but completely separated from the anterior articular surface of the os calcis. The patient was completely incapacitated for fifteen days, and partially incapacitated for a second fortnight. Vulliet discusses the mechanism of the fracture, which appears to be due to a laceration of the ligaments in the region of the calcaneo-cuboid joint; he recommends the routine use of skiagraphy in all cases of obscure injury to the foot.

#### 196. Congenital Malformation of the Intestine.

W. S. QUINLAN (*Boston Med. and Surg. Journ.*, December, 1922, p. 370) suggests that atresia and imperforate anus may be regarded as rare forms of congenital malformation of the intestine due to embryonic arrest in development. The arrest occurs once in about 15,000 infants, and may be found in any portion of the intestine from the duodenum to the rectum. Imperforate anus results from the imperfect union

between the rectum above and the posterior part of the common cloaca below. The deformity exists in varying degrees. The rectum may open into various situations, more commonly into the bladder or urethra, or sometimes into the vagina. Atresia may be due to bands, twists, adhesions, or bends. In the duodenum the lumen becomes divided into compartments by septa in the embryo; later the compartments become confluent and the lumen is re-established. The persistence of these septa may lead to occlusion of the gut. Atresia is due to embryonic arrest of development rather than to mechanical injury, of which it may be the end-result. The majority of cases seem to occur in the duodenum and jejuno-ileum regions. The prognosis is grave on account of complications, particularly in males, in whom the malformation is more frequent. Death occurs in five or six days if the occlusion is high up. The presence of a patent external anus usually furnishes enough proof that the intestine is well formed, but importance must be attached to the first bowel movement of the infant. Surgical intervention is the only treatment. The perineal approach is most frequently adopted, but sometimes an enterostomy is resorted to. The author records twenty-five hitherto unpublished cases, with notes on the condition.

### OBSTETRICS AND GYNAECOLOGY.

#### 167. Pituitary Extract in the Induction of Labour.

B. P. WATSON (*Amer. Journ. of Obstet. and Gynecol.*, December, 1922, p. 603) describes two methods of administering pituitary extract for the induction of labour. His first method is as follows: Castor oil at 6 p.m., quinine hydrochloride gr. x at 7 p.m., enema at 8 p.m., quinine hydrochloride gr. x at 9 p.m., quinine hydrochloride gr. x at midnight. If labour does not begin by 9 a.m. pituitary extract 1/2 c.c.m. is given intramuscularly and is repeated at half-hourly intervals until six doses have been given, no further doses being given should labour start with fewer injections. If labour does not start pituitary extract is given in the same way the next day and the day after. Labour was induced in 90 per cent. of cases by this treatment. The second method is to give the pituitary extract in the dosage mentioned above without having administered castor oil and quinine previously, and by this method labour was induced in 90.7 per cent. of cases; 29.9 per cent. were induced by the castor oil and quinine alone. No untoward effects in the mother or the child were noted in a series of 276 cases except in the case of one mother, who had severe vomiting, which ceased when the pituitary extract was discontinued. The author shows that the above methods can be used in cases of eclampsia and high blood pressure, as the pressure was never raised more than 5 mm. with a single dose of pituitary extract, and the subsequent injections raised the pressure no higher.

#### 193. Cranial Stress in the Foetus.

EARDLEY HOLLAND (*Journ. Obstet. and Gynaecol. of the British Empire*, Winter, 1922, p. 549) describes and illustrates the intracranial septa springing from the dura mater of the foetal skull and points out that certain localized thickenings which they present form strengthening bands arranged along the lines where the chief stress is likely to fall during the moulding of the head in its passage through the pelvis. Post-mortem examination in 167 foetuses dying during the course of labour showed tears of the tentorium cerebelli in 81, associated with tearing of the falx cerebri in 5 cases, and with subdural cerebral haemorrhage in all but 6. The tears were found to occur in the region of the strengthening bands, and varied according to the direction of the stress in different presentations of the head. The subdural haemorrhages did not arise from the tears of the tentorium, and from dissections of formalin preparations it was apparent that the bleeding occurred in a narrow area bounded in front by the transverse fissure, behind by the upper parts of the tentorium, below by the pons Varioli, and laterally by the mesial aspects of the lateral cerebellar lobes. The centre of this area corresponds to the vein of Galen, and although rupture of the vein itself was detected in two instances only it is concluded that the usual source of the haemorrhage is the tributaries of that vein, which, by reason of drawing up of the apex of the tentorium during the moulding of the head, becomes kinked at its entrance into the straight sinus. Together with tentorial tears the vein of Galen was always found greatly engorged and distended. Of the 44 foetuses showing subdural haemorrhage after birth by vertex presentation, 25 had been delivered by forceps, and Holland is inclined to believe that the forceps had been used with excessive force, or applied in the wrong diameter of the head, or both. Tears were found in 35 of the 47 cases of breech delivery in the series, and in

no fewer than 15 of 17 cases of normal breech labour followed by foetal death. The presence of tentorial tears in 71 per cent. of dead foetuses delivered after podalic version was less surprising. With few exceptions the foetuses whose examination forms the basis of the paper were born in hospital practice.

#### 199. Manual Removal of the Uterus after Abortion.

L. RAEMI-BOESCH (*Schweiz. med. Woch.*, January 11th, 1923, p. 41) records the following incident to show how disastrous "furor operativus" may be. A nullipara, aged 38, was four months pregnant when violent uterine haemorrhage began. A practitioner, summoned in the evening, inserted a tampon in the vagina. Returning next morning, he withdrew the tampon with part of the ovum. He then attempted to remove the placenta by hand, working without any instrument and giving no anaesthetic or other drug. After he had removed the placenta with great trouble, he thought he felt a myoma in the uterus, so he proceeded to remove it—again without instruments or drugs. After he had been engaged in this occupation for nearly two hours, he pulled out through the vagina a "tumour" which remained attached to the body only by a few strands of tissue. The patient's relatives forbade further interference, the author was summoned in consultation, and the patient taken to hospital, where the "tumour" proved to be the uterus, attached to the body only by some filaments of peritoneum. These were severed, laparotomy was performed, and the torn structures hastily sutured. The uterus was as large as a fist, but not inverted. It still contained a large piece of the placenta. The patient left hospital twenty-seven days later cured. There were no medico-legal sequels, and the practitioner had, apparently, acted in perfectly good faith.

#### 200. Radium Treatment of Metrorrhagia.

A. SIREDEY (*Paris méd.*, February 3rd, 1923, p. 113) discusses the indications and contraindications for radium in the treatment of metrorrhagia not due to cancer or fibroids. In the first place, he considers radium unnecessary in metrorrhagia due to constitutional causes such as cardiac, renal, or hepatic disease, endocrine disturbance, or changes in the blood cells or plasma. In the great majority of such cases rest, suitable drugs, and the application of ice to the abdomen are all that is required. Secondly, radium therapy is contraindicated in puerperal haemorrhages in which rest, careful observation, and, in case of retained placenta, curettage are needed. On the other hand, radium is specially indicated in cases of haemorrhagic metritis in which the uterine mucosa has undergone ulcerative dystrophy or has become the seat of minute rudimentary myomata, haemorrhage from which is not checked by curetting. Radium is also indicated in cases in which polypi recur after careful curetting, except when there are acute or chronic inflammatory lesions of the adnexa present. It is specially valuable for obstinate cases of metrorrhagia which frequently occur about the menopause, whether the haemorrhage be due to a large subinvolved uterus in multiparae, old inflammatory lesions, or sclerosis of the uterine vessels or parenchyma. In such cases there is no need to be deterred from using radium by the fear of producing an early menopause, which is of much less importance than the persistence of severe haemorrhage.

### PATHOLOGY.

#### 201. The Serum Diagnosis of Tuberculosis.

FURTHER evidence of the value of the complement fixation test in the diagnosis of tuberculosis is brought by E. RENAUX and P. KULLMANN (*Archiv. médicales belges*, January, 1923, p. 1). For one series of serums they used Calmette and Massol's technique with Besredka's antigen; for another series they employed this technique together with Goldenberg's, so as to study the comparative values of the two. In this latter method the same antigen is used, but instead of working with guinea-pig's complement and an anti-goat haemolytic immune body, advantage is taken of the presence of both complement and haemolysin for goat's red cells in the serum of the patient. In the first series of patients examined there were 31 who had tubercle bacilli in their sputum; of these, 30 gave a positive fixation reaction, while the serum of the remaining patient could not be studied, as it had a marked agglutinating effect on the red cells employed. Of 14 subjects clinically and radiographically tuberculous 10 gave a positive reaction, and of 26 patients suspected of tubercle 6 reacted positively. In the second series 109 persons were examined. Of 18 with positive sputum 14 were positive by the former technique, 13 by the latter. Of 40 subjects clinically and radiographically tuberculous 30 gave positive reactions by both methods. Of 45 subjects suspected of tubercle 20 reacted positively by both methods, and in

6 normal persons negative results were obtained in each case. With the single exception of one serum, the two methods corresponded absolutely. Taking the two series together, it is found that 89 per cent. of patients eliminating bacilli in their sputum, 74 per cent. of patients clinically and radiographically tuberculous, and 36 per cent. of suspects give a positive reaction. In these figures all cases giving a positive Wassermann reaction are excluded. The authors obviously consider that a positive complement fixation reaction is highly suggestive of active tuberculosis, and that a negative reaction is to be interpreted as evidence against its existence, though neither result is to be treated too dogmatically.

#### 222. Multiple Types of Bacteriophage?

EVIDENCE is being produced in favour of the proposition that more than one type of (hypothetical) bacteriophage exists. J. TCHANG KOUO-NGEN and J. WAGEMANS (*C. R. Soc. de Biologie*, February 3rd, 1923, p. 303) find, for example, that there is a distinct difference in the sensibility of various strains of bacteriophage to the action of heat. Some are able to withstand a temperature of 80° C., while others are killed by exposure to temperatures lower than this. Further, the effect of heat on successive cultures of any one strain does not appear to be constant; an instance is given of one strain which at first resisted exposure to 80° C., but which in later cultures succumbed to the same degree of heat. J. WAGEMANS (*Ibid.*, p. 304) likewise cites a point of difference between the various bacteriophages—namely, in their capability to excite antibody production in animals. With some antigens it is a simple matter to obtain a serum of a titre of 1 in 1,000, while with others it is difficult to raise the titre above 1 in 2. That this does not depend on the idiosyncrasy of the particular animal employed is shown by the fact that the same results were obtained even when several animals were employed. Another point of interest is that bacteriophages which have become adapted to micro-organisms other than their original one can still, as a rule, be neutralized by their primary antiserum. A. GRATIA and Mlle L. DE KRUIF (*Ibid.*, p. 308), in studies on the titration of the bacteriophage, find that the activity of the latter is dependent, not on its concentration, but upon the actual amount present. Thus, if a quantity  $x$  be placed in a tube containing 1 c.cm. of broth, and the same quantity in a flask containing 1,000 c.cm. of broth, lysis occurs equally well, even though the dilution is very much greater in the second case.

#### 203. The Effect of Naphthalene Emulsion on Experimental Intestinal Tuberculosis.

T. REDMAN (*Journ. Path. and Bact.*, 1922, vol. xxv, p. 433) reports the results of some work designed to ascertain the effect of naphthalene emulsion on intestinal tuberculosis. The animals chosen were guinea-pigs; these were divided into twelve sets, comprising in all 56 animals, of which roughly one-half were used for experimental and one-half for control purposes. With the exception of two sets, they were all infected by feeding with heavily infected sputum mixed with a bran mash, either one, or at most two, feeds being given. In this way a slowly progressive ascending infection of the alimentary tract was produced; the mesenteric glands were involved by about the thirty-sixth day after feeding, the ileo-colic glands and spleen by the fifty-fourth day, the portal, post-sternal, and bronchial glands, together with the liver and lungs, by the seventy-fifth day, and the cervical and submental glands by the eighty-third day. The upward progress of the infection was constant and continuous, no intermediate glands being skipped. The general plan of the work was to allow the infection to proceed unchecked in both control and experimental animals, and then after periods of time varying from 20 to 132 days to treat the latter by means of the naphthalene emulsion, the usual dose of which was 1 drachm by the mouth daily for seven days. The effect of the treatment was observed at the subsequent autopsy of the guinea-pigs, undertaken after suitable intervals, when the lesions in the treated animals were carefully compared with those in the controls, histological examinations being conducted in most cases. Briefly, it may be said that no matter at what stage the naphthalene emulsion was administered, its effect was to retard the progress of the infection. If given 20 days after infection it delayed the appearance of tuberculous lesions for 75 days, at the end of which period only a slight infection of the caecal glands was found, while after 111 days, though the mesenteric glands were enlarged, there was no other evidence of tuberculosis; this was in marked contrast to the control animals, in which extensive invasion of both glands and organs has occurred. Infection of the spleen was prevented for between 54 and 75 days, and of the liver and lungs for 115 days after ingestion of the tuberculous material; and even when not given till severe infection had become established, the effect of treatment was to prolong the life of the animal.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## MEDICINE.

### 202. Psychotherapy in General Practice.

EDWIN BRAMWELL (*Edin. Med. Journ.*, February, 1923, p. 37) urges the importance of psychotherapy in general practice, since it is to the general practitioner that the best opportunities are given for studying the neuroses in their earliest stages. From such a unique experience he should be capable of dealing with all but severe cases by the application of psychotherapeutic methods of suggestion and persuasion, and be responsible for their prevention. For him a study of the disorders of the mind is as important as the study of bodily ailments in the successful treatment of patients by psychotherapeutic measures, and he must be able to recognize the necessity for such treatment and be fully alive to the mental suffering often associated with the neuroses. To tell a patient so afflicted that there is nothing the matter with him constitutes both an act of cruelty and a display of ignorance which must eventually reflect upon the honour of the profession. The clinical teaching of the subject, if it is to be of use to the general practitioner, must remain largely in the hands of the general hospital physician, who has the necessary experience and material at his disposal, and alienists and pure psychologists in their teaching must avoid creating the false impression that psychotherapy is a specialty only to be taught and practised by specialists. Psycho-analysis, requiring as it does much time and patience, ought only to be carried out by specialists able to devote adequate time to the treatment of individual cases, and it must not be confused with psychotherapy, which comes into the domain of the general practitioner, who should keep abreast with advances in this direction in so far as it has a direct application to his daily work.

### 205. Psychic Sequels of Encephalitis Lethargica.

K. WINTHER (*Ugeskrift for Læger*, February 1st, 1923, p. 73) has studied the psychic after-effects of epidemic encephalitis, and has come to the conclusion that there is no relation between the acuteness and the severity of the primary disease and the onset and character of the psychic sequels. As a rule the psychic disturbances follow directly after the acute stage. There were 4 cases in which the encephalitis was followed by lassitude, lack of initiative, apathy, faulty memory, and incapacity for work. There were 4 other cases in which the dominant character of the psychic disturbances was emotional instability. In all these 8 cases there appeared to be a tendency towards recovery, although the duration of the symptoms ranged from six months to three years. Turning from adults to children, the author insists that when the disease attacks children between the age of 5 and puberty, and the mind is affected, the psychic phenomena are amazingly uniform, and are suggestive of a psychopathic degeneration. Owing to such troublesome symptoms as libido praecox, these cases are very difficult to manage at home, and are badly in need of institutional supervision. The prognosis for these cases is, indeed, bad, and most of the changes observed by the author were for the worse. Of a total of 25 cases of epidemic encephalitis observed at one hospital in the period 1918-22, 11 terminated fatally in the acute stage. Two survivors could not be traced, and of the remaining 12 patients not one was well six months after the illness. Two years after the illness 5 were still suffering from severe and 3 from slight psychic disturbances.

### 203. Unusual Results of Encephalitis Lethargica.

K. PETRÉN and L. BRAHNE (*Journ. of Nerv. and Mental Disease*, February, 1923, p. 105) describe two cases of encephalitis lethargica in which hypertonic rigidity of the limbs was so intense that neither active nor passive movements were possible in them. In neither case were there any signs of lesion of the pyramidal tracts. In one case the paralysis was hemiplegic, and syphilis was suspected, but negative blood and cerebro-spinal fluid tests, the hypertonic character of the paralysis, and the rapid restoration of power made the diagnosis of encephalitis lethargica more probable. In the other case immobilization affected the whole body with the exception of the ocular, respiratory, and swallowing movements, which were preserved. The patient lay like a statue, and the limbs were so rigid that passive movement of the joints was impossible. Swellings appeared in the limbs and were followed by irregular ossification of the soft parts round the right elbow- and knee-joints, resembling myositis ossificans. Under treatment by massage and move-

ments these bony formations disappeared, and the activity of the limbs returned to a great extent. Similar ossification of paralysed soft parts has been described by Mme Dejerine-Klumpke and by Ceillier in cases of severe injuries of the cord or cauda equina. As in Petré's case it was always preceded by oedema of the limbs, but its relation to either paralysis or oedema is unknown. In no previously reported case has it been known to disappear.

### 207.

### Neurasthenia.

F. DAUWE (*Arch. méd. belges*, December, 1922, p. 1163) observes that neurasthenia is not a product of modern times. It is common to all countries, and has existed probably in all ages. Hippocrates described it, and it is evident that Galen's "hypocondria" was allied to neurasthenia and melancholia. Richelieu described the neurasthenia of Louis XIII. It is the result of the "struggle for existence," and is therefore most common in the strenuous period of life—from 20 to 50. The male sex comprises two-thirds of the cases. It is rare in infancy, but is frequently hereditary and constitutional. The mental condition is dominant, and it is often described as "psychasthenia," characterized by anxiety, phobias, impulsive obsessions, tics, and most frequently exhaustion is the foundation of true psychasthenia. Janet regards it as an entity, but while true neurasthenia and true psychasthenia demand a special description, in practice it is very difficult to define the hereditary factor, and frequently the conditions are associated. Even in acquired neurasthenia we must accept predisposition. Nervous overwork is always its foundation. Dauwe enumerates the physical symptoms—headache, dyspepsia, etc.—and then describes the mental condition resulting from the physical state of the patient: failure of will power, of concentration, of memory; but the mental state is not that of hysteria. The psychasthenic writes out a long list of his symptoms, and returns, fearing that he has omitted one. It is not an imaginary disease—hysteria is the offspring of imagination, suggestion will cure it; neurasthenia is the product of exhaustion, suggestion cannot control it. Treatment requires all the ingenuity and knowledge of the physician. The cause must be discovered and removed. Almost all these patients love the stress which exhausts them and cannot withdraw from it because it is their means of livelihood. Stimulants or narcotics only increase the exhaustion of the nerve cell. Possibly increase or diminution of the intracranial pressure by hypertonic or hypotonic intravenous saline injections may do good. Prophylaxis may be summed up in a phrase—moderation in all things. Mental work and physical exercise should alternate. The patient should be (in the words of Henri Bordeaux) taught that life has still, for him, some mission to be fulfilled in the world; he must be warned against fruitless introspection. The healthy man is an altruist. Egoism and "ego-centrism" are pathological. The egoist is not cured and cannot be.

### 208.

### Treatment of Pernicious Anaemia.

G. ROSENOW (*Klinische Wochenschrift*, January 1st, 1923, p. 24) reviews the various methods of treatment in pernicious anaemia. He concludes that either combined or separately certain results cannot be expected therefrom. Nevertheless some of them undoubtedly prolong life and accelerate the occurrence of remissions of the disease. For general practice three are specially to be recommended: (1) Arsenical treatment; (2) intramuscular injections of small quantities of blood; and (3) treatment by thorium X water. Since Byrom Bramwell first recommended arsenic no better drug has been found in the treatment of pernicious anaemia. There can be no doubt that since its use remissions in the course of the disease have been observed much more frequently than formerly. It is best given by mouth (10 c.cm. of liquor arsenicalis are mixed with 10 c.cm. of peppermint water in a drop bottle, and 3 drops are given three times a day; the dose is increased up to 30 drops of this mixture three times a day); the drug should be given on a full stomach, and it should be continued for a long period—several weeks or months. The possibility of toxic symptoms, skin pigmentation, and arsenical neuritis should be borne in mind. But in pernicious anaemia the tolerance for arsenic is high. Atoxyl should not be given on account of the risk of optic atrophy. Salvarsan is not superior to inorganic arsenical preparations. The author has treated cases with thorium X and not infrequently obtained results equal to the best obtained by arsenic. Thorium X is of service in some cases when arsenic has failed. It is given in a solution two or three times a week for four to

six weeks. The bottle containing the suitable dose should be used immediately because the activity rapidly diminishes. Not infrequently improvement in the blood condition follows transfusion of normal blood. This can be best performed according to Weber's intramuscular method: 10 to 20 c.cm. of blood are taken by means of a syringe from the arm of a healthy individual (free from syphilis and malaria) and injected directly into the gluteal region of the patient. The injection may be repeated later.

#### 209. Duodenal Ulcer.

ASCOLI (*Rif. Med.*, November 13th, 1922, p. 1092) finds duodenal ulcer more common than gastric ulcer in the proportion of 2.4 to 1, and occurs twice as often in the male as in the female. The first symptoms are usually noted at about 20 years of age. Predisposing causes are heredity, nervous temperament, chronic poisoning by lead, alcohol, infections, oral sepsis, tuberculosis, appendicitis, and cholecystitis. Duodenal ulcer is often secondary to some other chronic gastro-intestinal disease. The ulcer is more often superficial than deep, and the resulting cicatrices differ. Exceptionally the ulcer becomes cancerous. Radioscopy gives valuable aid in diagnosis. Points to look for are hypermobility of the stomach, duodenal shadows six hours after food, circumscribed tenderness, dextro-position of the stomach, hour-glass stomach, and persistent wrinkling of the stomach. Hydrochloric acid may or may not be in excess; if in excess the ulcers are usually recent. Occult blood may be found in the faeces. The character of the pain is very suggestive, if not exactly pathognomonic. Serial radiography is an important aid to diagnosis. Examination of the contents of the stomach has little importance *per se*. In the presence of severe pain and abdominal colic one should suspect peritonitis by propagation or perforation. When an ulcer becomes chronic this depends in the first place on hypersecretion of the gastric juice and disturbed mobility. Spontaneous cure may take place. In treatment, general measures should first be tried, so as to eliminate the cause if possible. Diet should be non-stimulating (few proteins, no spices, no alcohol), indigestible residues should be avoided (few vegetables, food well cooked and well masticated), a sufficiency of calories and adequate diet. Alkalis and mild saline laxatives, atropine injections, papaverine internally, bismuth or barium salts, and rest in bed are the lines of medical treatment. Surgical treatment is, in the author's opinion, usually concerned with deep ulcers, and with complications when they arise.

#### 210. Primary Pfeiffer Bacillus Meningitis in Infants.

LISBONNE and LEENHARDT (*Paris méd.*, January 13th, 1923, p. 47), who record a fatal case in a male infant aged 2 years, remark that while numerous cases of meningitis due to the Pfeiffer bacillus have been recorded as occurring at the terminal stage of an attack of severe or complicated influenza, comparatively little attention has been paid to primary Pfeiffer bacillus meningitis in infants. The authors' case shows that Pfeiffer bacillus meningitis may commence like any other acute primary meningitis, apart from any epidemic or source of contagion or previous symptoms of influenza. At most a septicaemic stage ranging from twenty-four to forty-eight hours may precede the meningeal localization. The onset is sudden, like that of meningococcal meningitis, and the disease rapidly proves fatal without treatment having any effect. The diagnosis is only possible by lumbar puncture, which enables the bacillus to be identified. Although too few cases have been recorded to enable the frequency of this condition to be estimated, the authors think it probable that a large number of cases of purulent meningitis in which the organism remains unknown are really due to the Pfeiffer bacillus. They are strengthened in this belief by the technical difficulties in identifying the bacillus and the variable character of its morphological appearances in the cerebro-spinal fluid.

#### 211. Hereditary Osteitis.

CAMURATI (*La Chir. degli Organi di Movimento*, November, 1922, p. 662) reports (with radiographs) a rare case of chronic osteitis of the lower limbs in a boy aged 7 years. The history was that he had suffered from birth with pains in the lower third of the thigh and upper third of the leg—worse on movement and at night. Ten males in the family (going back three generations) had suffered in a similar fashion. In other respects the health was good; the Wassermann reaction was negative in father and son. After 20 years of age the legs gave no trouble. In both father and son the affected parts were much enlarged. The appearances were like those of osteitis deformans.

## SURGERY.

212.

#### The Etiology of Femoral Hernia.

J. ALLISON PANTON (*Journ. of Anatomy*, January, 1923, p. 106) discusses the etiology of femoral hernia, which he has investigated on the cadaver and from hospital records of the condition, as well as from careful pelvic measurements carried out on patients. He reasons that man is peculiarly exposed to this form of hernia as a result of his erect posture, and in particular of his plantigrade mode of progression. The erect attitude has resulted in an increase of abdominal pressure against the crural ring; it demands a widened pelvis in order to balance the trunk properly, which would otherwise be top-heavy, and widening postulates weakening. Furthermore, plantigrade action has led to alteration in muscle structure and insertion, involving a widening and weakening of the femoral ring as compared to that of anthropoids, who are erect but not plantigrade. He refutes the commonly expressed view of textbooks that the greater incidence of femoral hernia in the female is due among other factors to the wider pelvis, and states that the false pelvis in the female is either narrower than in the male or equal to it. He also draws attention to the fact that the female Poupart's ligament is the shorter, and the pelvo-crural interval, therefore, the more narrow. He is of opinion that the greater incidence in females is due to the less developed ilio-psoas, which permits the femoral vessels to diverge more than in the male, thus producing a wider crural ring, to which contributes also a greater tendency of Poupart's ligament to sag. Women, too, are more deficient in muscular tone and development, and subject to greater variations in abdominal pressure. In either sex defective or poor development of Gimbernat's ligament may be a contributing factor, but in the female this ligament is actually the larger. The small number of cases in children is attributed to the narrowness of the pelvis, the efficient muscular tone, the small pelvo-crural interval, and the absence of exposure to sudden strain. The actual occurrence of femoral hernia depends on the existence of a preformed sac. This appears to be remarkably common even where the subject had never shown any symptoms of hernia. It is probable that the diverticulum is brought down by abnormal gubernacular muscle bundles. Such sacs are said to be equally common in both sexes.

213.

#### Appendicitis and Oxyuris vermicularis.

THE relation between appendicitis and *Oxyuris vermicularis* has been studied by E. H. EASTWOOD (*Journ. of Path. and Bact.*, January, 1923, p. 69), who found that oxyuris occurred in the appendix with equal frequency in cases of appendicitis and in normal appendices from the post-mortem room, so that no evidence was found to support the theory that oxyuris is frequently a cause of appendicitis. Oxyuris when present in the appendix does not cause a local eosinophilia, but eosinophils are present in the mucosa of the appendix in much greater numbers in appendicitis than in normal appendices, their numbers showing a definite relation to the stage of inflammation. Twenty-four hours after the onset of the attack they rise to above normal and they reach their maximum in the second week, after which the numbers gradually subside. The local increase of eosinophils in the appendix is not accompanied by a general eosinophilia. The author has observed also that the lymphoid tissue of the normal appendix shows an increase in amount up to the tenth year, and thereafter gradually retrogresses with age. The muscular coat of the normal appendix increases gradually in thickness up to the age of 60 years, and pigmentation of the appendix is as frequent in normal as in diseased appendices.

214.

#### Pyloric Stenosis in Infants.

HEILE, Professor B. (*Zentralbl. f. Chir.*, February 3rd, 1923, p. 162), considers Rammstedt's operation of dividing the tumour longitudinally down to the submucous layer to be the best procedure for this condition, with certain modifications which he has found useful. In some cases the tumour projects into the duodenum, so that a fold of mucosa lies superficially to the mass at its right extremity. This may be wounded, causing perforation, sometimes concealed. To avoid this the incision is begun in the middle, and carefully extended laterally in either direction. Sometimes the incision does not open out sufficiently to relieve the stenosis, owing to the presence of a larger quantity of connective tissue in the tumour. To overcome this difficulty the author uses blunt force, by means of artery forceps, to split the mass well open, instead of using the simple incision alone. If this is done rapid improvement follows the operation immediately, provided the case is a fairly early one. In later cases, where

the stomach has become markedly dilated and hypertrophied, operation is less successful than in earlier cases. The author has operated on 27 cases with one death, but he considers that the usual mortality is in the region of 10 per cent., and advises that the operation should not be undertaken without weighing the risks and alternative methods of treatment. Diagnosis is made by x rays, the opaque meal being introduced by means of the stomach tube. In organic pyloric stenosis very little of the meal has passed the pylorus in two hours. A case is quoted where a child with symptoms of organic stenosis gave almost normal x-ray appearance. Operation was not performed, and the child died later from malnutrition, when autopsy revealed an anatomically normal stomach.

#### 215. Fistula in Lung Abscess.

W. MEYER (*New York Med. Journ. and Med. Record*, January 3rd, 1923, p. 7) advocates the establishment of a temporary, or permanent, pulmonary lip fistula in the conservative treatment of advanced bronchiectatic lung abscess, by which means the cavity is emptied, drained, and ventilated, and the pus loses its foul odour. The result is usually so satisfactory that the patients generally refuse the second stage of operation for closing the canal or opening, and in two cases spontaneous closure of the fistula took place, resulting in complete cure. Unless closure occurs such patients cannot take a bath, nor must they fall into water, as death would be instantaneous through flooding of the lung, and though it might be possible to render the fistula airtight by a rubber stopper the slightest leak when immersed in water might cause drowning. While extirpation of the affected lobe or lobes is the ideal procedure to effect a complete cure, this is not always advisable or possible, and this pulmonary lip fistula operation affords a less severe method in such cases. Since aspiration of foreign substances is the most frequent agent in setting up the trouble the importance of prophylaxis in operations about the nose and throat is emphasized; in the early stages of such disaster surgical intervention is contraindicated, and thorough aspiration by a trained bronchoscopist should be carried out.

#### 216. Exploratory Puncture of the Peritoneum.

SAVARIAD (*Bull. et Mém. Soc. Chir. de Paris*, November 21st, 1922, p. 1174), in discussing the value of exploratory puncture of the peritoneum to ascertain whether a blood-stained effusion is present, points out that this procedure has a certain clinical value but is not devoid of risk. He records the results of eight cases—three negative and five positive punctures. In one case failure was due to the patient being very fat, and he did not dare to push the needle in sufficiently far; in a second case of ruptured ectopic gestation the puncture was made too oblique and pushed the peritoneum aside without piercing it. In a case of this nature he suggests that vaginal puncture might be preferable. Though allowing the value of this method in diagnosis, the author points out that if clinical signs indicate the advisability of operation a negative puncture must be ignored. On the other hand, if the needle withdraws a profuse amount of blood, it is not necessary to conclude that the visceral lesion is beyond the resources of nature in effecting a cure. In two cases where the liver was ruptured and the puncture gave a positive result, spontaneous recovery followed without operation. The side of the injury is of considerable importance, and in a rupture of the spleen operation should be carried out. Exploratory puncture is of value in doubtful cases when used in conjunction with other signs. Though rather more difficult to carry out than lumbar puncture, it has certain advantages which warrant its use in traumatic lesions of the abdomen.

#### 217. Cartilage Implants after Eye Excision.

W. B. DOHERTY (*Amer. Journ. Ophthalmol.*, January, 1923, p. 19) points out the advantages over other materials of formalized beef cartilage implants following enucleation of the eye. Costal cartilage grafts, when cut into spheres ranging from 16 to 22 mm. in diameter, the anterior surface being slightly flattened, are placed in a 2 per cent. formalin solution for a fortnight, and, after being thoroughly washed in sterile normal salt solution on successive days for a week, they can be preserved indefinitely in sterile water. In enucleation it is important to hug the sclera so that Tenon's capsule can be preserved and closed vertically over the implant with interrupted catgut sutures, over which the muscles are sutured and the conjunctiva closed horizontally with silk sutures. Similar grafts are suggested to fill in the depressions following radical frontal and mastoid operations. The advantages claimed for such implants are that they are cheap, easily obtainable in any size and shape, and that they can be kept indefinitely and are well tolerated by the tissues.

## OBSTETRICS AND GYNAECOLOGY.

#### 218. Early Diagnosis of Pregnancy by Induction of Glycosuria.

L. LEWIN (*Dent. med. Week.*, January 26th, 1923, p. 117) has carried out in 100 cases Kamnitzer's test for early pregnancy. It depends on the induction of glycosuria by the intramuscular injection of phloridzin. In early pregnancy, but not under other conditions, the injection of as small a quantity as 2 mg. of phloridzin gives rise to glycosuria. After briefly describing the technique of the test the author analyses the 100 cases, which included several non-pregnant controls. There were 24 cases of pregnancy, 6 of which were threatened by abortion. The reaction was invariably positive in the 17 cases in which pregnancy had lasted one to three months. But among the 7 cases in which the pregnancy had lasted four to six months there was only one in which the reaction was positive. It would thus seem that the test is valuable up to the end of the third month, but not later. Very instructive were the findings in 16 cases of abortion within the first three months. In 50 per cent. of these cases the reaction was still positive on the day after the uterus had been evacuated. In 6 out of 7 cases of incomplete abortion the reaction was positive. The test was of great practical value in the 7 cases in which it was doubtful whether abortion had been completed or not. There was a history of haemorrhage for some days and of absence of normal menstruation for a month or two. The uterus in these cases was of the size of a two or three months' pregnancy, the cervix was soft, the external os closed, and there was a blood-stained discharge. The clinical evidence suggested threatened abortion, but the phloridzin test was negative. This test therefore suggested that pregnancy did not exist. Ultimately it was proved that all these were cases of endometritis or parametritis following abortion which was not threatening at the time but had occurred at an earlier date. The test is useful in distinguishing between extrauterine pregnancy and inflammatory swellings of the uterine appendages, and among the 50 control cases in which pregnancy was absent there were only 4 which reacted with glycosuria to the injection.

#### 219. A Rare Cause of Foetal Death.

P. A. DE WILDE (*Nederl. Tijdschr. v. Geneesk.*, November 25th, 1922, p. 2386) states that syphilis is generally regarded as the chief cause of foetal death. Renal disease in the mother is also an important factor. Treub in his textbook states that general debility is another cause. De Wilde, however, has met with three cases in which excessive length of the umbilical cord caused foetal death. In two cases in which a dead foetus was born in the seventh month the cord was found coiled twice round the neck and once round the upper arm. The changes in the epidermis showed that death had taken place fourteen days previously. In these cases death was obviously due to compression of the vessels in the cord. In the third case the mother was a primipara who gave birth to a foetus by breech presentation. Foetal movements had ceased to be felt about a fortnight before birth. The umbilical cord, which passed between the legs, over the back, and round the neck, was no thicker in size than a piece of string, so that circulation in it was obviously impossible. De Wilde concludes that when a practitioner is called in to see a pregnant woman who complains of not having felt foetal movements for some time the possibility of an exceptionally long umbilical cord should be considered, if syphilis and renal disease can be excluded.

#### 220. Scope and End-results of Myomectomy.

A. E. GILES (*Journ. Obstet. and Gynaecol. of the British Empire*, Winter, 1922, p. 608), who holds the view that for the majority of myomata requiring surgical treatment hysterectomy is a more suitable and more satisfactory operation than myomectomy, discusses the range of applicability of the latter as shown by the late results in 93 cases, and reaches the general conclusion that the advantages of myomectomy outweigh its disadvantages in a restricted class of cases numbering roughly 15 per cent. The most important indication for myomectomy is the fact that the patient is of child-bearing age; in general, except in the case of single women over 30, myomectomy is the operation of choice in patients who have not passed the fourth decade. Of 50 of the author's patients who had the opportunity of conceiving after myomectomy, 14 became pregnant. The complication of myomata with prolapse or procidentia is an indication for myomectomy if possible; after removal of the myoma the uterus may be made to play an important part in the operation for displacement. When a myoma is solitary and pedunculated, and not associated with excessive bleeding, a myomectomy may properly be done, whatever the patient's

age and expectation of pregnancy may be. In the following conditions myomectomy should not as a rule be performed: (1) After the age of 40 to 45; (2) when there is associated bilateral tubal disease or bilateral ovarian tumour formation; (3) when myomectomy, in consequence of the position or number of the tumours, would leave a battered and useless organ (thus most cervical myomata call for hysterectomy); (4) in cases accompanied by excessive haemorrhage. In the after-history of Giles's patients, the uterus was found to be of normal size, without recurrence of myoma in 90 per cent., and menstruation was normal in 80 per cent. In association with pregnancy myomata that are causing no symptoms should be treated expectantly. Myomectomy during pregnancy is indicated (1) if the tumour or tumours appear to be increasing rapidly in size; (2) if the patient suffers from pain, pressure symptoms, or indications of septic or degenerative changes in the tumour; (3) if the position of a myoma makes it probable that labour will be obstructed. The outlook both for mother and foetus is good.

## PATHOLOGY.

### 221. Vitamins and Infection.

In a study of the relation of vitamin C to bacterial infection, G. M. FINDLAY (*Journ. of Path. and Bact.*, January, 1923, p. 1) worked with guinea-pigs suffering from chronic scurvy, showing no actual symptoms of disease except that they were less active than usual and failed to increase in weight. The bone marrow of such animals showed areas of gelatinous degeneration, consisting of a homogeneous interstitial ground substance in which were found a few fibrous tissue elements together with a certain amount of blood pigment. Experiments were carried out on such animals with the following organisms: *Pneumococcus*, *Staphylococcus aureus*, *Streptococcus haemolyticus*, and *B. coli*, special attention being directed to determine the number of organisms and the time required to produce a fatal result, and the cellular reaction to infection as shown by changes in the blood and haemopoietic organs. The results of these experiments showed that guinea-pigs fed on a diet deficient in vitamin C succumb to a smaller infecting dose of bacteria than animals fed on a complete diet. The symptoms of toxæmia are manifested more rapidly in scorbutic than in control guinea-pigs because the tissues, especially the heart, are more susceptible to the action of bacterial toxin, or because in scorbutic animals there is more toxin formed by the bacteria as a result of some rupture in the defence mechanism of the body. Since it has been established that degeneration in the haemopoietic bone marrow is associated with a reduced resistance to bacterial infection, it is probable that the lesion in the bone marrow which occurs in chronic scurvy is one of the factors in the reduction of the resistance to bacterial infection exhibited by animals with chronic scurvy.

### 222. Blood Phosphate in Infants.

A. F. HESS and M. A. LUNDAGEN (*Journ. Amer. Med. Assoc.*, December 30th, 1922, p. 2210) record investigations showing that in infants the inorganic phosphate of the blood can be raised to the normal level by frequent exposure to the sun's rays, or by irradiation with the carbon arc lamp, the ultra-violet rather than the visible rays being most probably responsible for this biologic action, since when these former are filtered out from the spectrum the rays lose this power. Seeing that in the temperate zone the sun's rays are richer in ultra-violet rays during the spring and summer than during the winter, investigations were conducted to ascertain whether the transitions of the seasons led to periodic chemical alterations. In infants from 6 to 18 months old the seasonal tide of blood phosphate was marked, beginning to rise in April and attaining an almost normal level during June, but in older children on a mixed diet the variations were less obvious but still definite. The ultra-violet rays vary much with the season, and their curve resembles closely that of the inorganic phosphate content of the blood, which points to their being the main cause of such seasonal variation, though possibly other climatic conditions operate to a minor degree. Chemical alterations of the tissues induced by seasonal meteorological variations may possibly influence nutrition and infection, and such alterations of the blood may bear some relationship to the incidence of epidemic diseases, and should be considered in studying epidemiologic problems.

### 223. Cultivation of *B. diphtheriae*.

S. R. DOUGLAS (*Brit. Journ. of Exper. Pathol.*, December, 1922, p. 19) describes a new medium for the isolation of *B. diphtheriae* on which the colonies of this organism have a characteristic appearance. Working on the supposition that

the neutralization of the antitryptic power of blood increases the value of serum as a medium for the growth of bacteria, Douglas adds 5 to 8 c.cm. of trypsin solution to 100 c.cm. of horse serum, and filters it through a porcelain filter. The basis of the medium is nutrient agar 2 per cent., made by digesting meat broth, and to each 100 c.cm. of this is added 4 c.cm. of 1 per cent. potassium tellurite solution and 15 c.cm. of sterile trypticized serum. The resulting medium is clear, and when inoculated with material containing diphtheria bacilli this organism produces colonies about 1 mm. in diameter, granular, and with regular outline, of a dusky grey black colour, while the peripheral part is opalescent greyish-white. Hoffmann's bacillus produces similar colonies, but streptococci and staphylococci have each a distinctly different appearance. After forty-eight hours' growth the colonies of diphtheria bacilli are likened to "flattened drops of partially dried black paint." To test the utility of this new medium 29 throat swabs from a fever hospital were examined, using this and the commonly employed Loeffler's serum medium for comparison: 19 positive results were obtained with the new medium, and 16 positive results with Loeffler's medium.

### 224. Staphylococcal Vaccines.

F. ARLOING and L. LANGERON (*C. R. Soc. de Biologie*, 1923, No. 3, p. 220) have studied the effect the age of the culture used for the preparation of a staphylococcal vaccine has on the protective properties of the vaccine by the following technique: Rabbits were given five doses of staphylococcal vaccines which had either been prepared from a twenty-four hour culture or from cultures which had been grown for as long as five days. One series received the injections subcutaneously, another intravenously. Three weeks after the last injection each rabbit was given a lethal dose of living virulent staphylococci, such a dose as was found by experiment to kill rabbits with certainty which had not received preliminary vaccine treatment. Complete immunity was only obtained in the case of the rabbits which had received vaccines made from cultures twenty-four hours old; all the other rabbits died presenting symptoms of subacute staphylococcal infections. Thus the authors conclude that only a vaccine prepared from a twenty-four hour agar culture should be used for making up protective staphylococcal vaccines.

### 225. Experimental Production of Paraffin Oil Tumours in Monkeys.

F. D. WEIDMAN and M. S. JEFFERIES (*Arch. of Derm. and Syph.*, February, 1923, p. 209) draw attention to the frequency with which hard swellings follow injections of paraffin oil or wax, either for cosmetic purposes or as a vehicle for camphor, mercury, or arsenical preparations. In order to prove that the paraffin and not the drugs contained in it was the cause of the tumours they injected two monkeys subcutaneously in various places with olive oil, cottonseed oil, paraffin, and camphor in paraffin. Forty-eight injections were made in all, and nine tumours developed within eleven months, and some more at the end of seventeen months. All but two of the tumours were at the site of the paraffin injections, and there was no difference between the camphorated and the plain paraffin oil. There was no tendency for the tumours to disappear. The tumours were adherent to skin and muscle; they were very hard, and on naked-eye section showed no evidence of the oil. Microscopically they were similar to those described in human cases. They were granulomatous rather than neoplastic in nature, and were formed of fibrous tissue with droplets of paraffin oil surrounded by endothelial cells and foreign body giant cells. The lymphatic glands also contained paraffin oil but showed no fibrosis, and no such reaction to the presence of the oil as was seen in the subcutaneous tumours. It seems possible that some irritating impurity in the oil had been removed in the subcutaneous tissues and the oil passed on to the lymph nodes in a purer condition.

### 226. The Diagnostic Value of the Rate of Sedimentation of the Blood Cells.

MORAL (*Deut. med. Woch.*, January 19th, 1923, p. 74) has investigated the sedimentation reaction (S.R.) in about 400 persons, some of whom were healthy. He concludes that the reaction is of value in distinguishing between functional and organic disease only when it is abnormally rapid. But a normal reaction does not exclude organic disease. A normal sedimentation reaction does not exclude active pulmonary tuberculosis any more than a negative skiagram. But the more abnormally rapid the reaction the worse is the prognosis in pulmonary tuberculosis. The reaction is of no value in distinguishing between tumours and inflammatory swellings, but in spite of these and other limitations it has, he believes, a definite sphere of usefulness.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## MEDICINE.

### 227. Ocular Disturbances in Respiratory Disease.

F. TERRIEN (*Paris méd.*, January 27th, 1923, p. 81) states that ocular disturbances in affections of the respiratory system may be of three kinds—reflex, infective, or mechanical. In the last case venous stasis due to obstruction in the lesser circulation gave rise to haemorrhage. (1) Reflex ocular disturbance. Inspiration is accompanied or followed by a slight degree of dilatation of the pupil even in the normal state, whereas expiration gives rise to a slight contraction of the pupil. In dyspnoea the pupil is dilated, as the inadequate supply of oxygen in the blood irritates the centre for the pupil in the medulla. In Cheyne-Stokes breathing the pupils are contracted during the period of apnoea and do not react to light, but become dilated again on return of respiratory movements, and the reaction to light reappears. (2) Mechanical ocular disturbance. Haemorrhages in the conjunctiva or even in the retina may occur after violent attacks of coughing or in a child during spasms of pertussis. Terrien has seen a case of paralysis of the external rectus and of the facial nerve complicated by hemianopsia in a child, probably as the result of pontine haemorrhage. Similar cases have occurred in glass-blowers, especially in elderly persons and in tabetic subjects. All these manifestations are the result of venous stasis. They are most pronounced in cases of hanging, in which haemorrhages are found in different parts of the eyeball, such as the conjunctiva, eyelids, retina, and canal of Schlemm. (3) Infective disturbances. Pulmonary infections, especially pneumonia, are often complicated by herpes of the cornea or dendritic keratitis. The affection is chiefly found in the adult, especially in men, often at the same time as herpes on the nostrils or lips and pain in the back, the latter suggesting a meningeal reaction. Changes in the pupil in pneumonia or chronic apical disease, consisting in dilatation on the affected side followed by contraction, are the result of irritation and later paralysis of the sympathetic. Paralysis of the extrinsic and intrinsic muscles of the eye may occur during pneumonia or a few weeks later, as in diphtheria. Blood infection fairly often gives rise to a metastatic ophthalmia, and more rarely to a neuro-retinitis. The irido-choroiditis frequently ends in panophthalmia, and when this is bilateral the prognosis is usually fatal. Profuse haemoptysis, like all other haemorrhages, may be complicated by amaurosis, but this is relatively rare. In a lesser degree, the author suggests, the eye reacts upon the lung. Vigorous pressure on the upper lid retards expiration, and the same is true of irritation of the conjunctiva or cornea. Malignant tumours of the eyeball have sometimes given rise to metastases in the lung. Thus in 46 cases of sarcoma of the uveal tract complicated by metastases the lung was involved three times and the epiglottis once.

### 228. Underfeeding in Diabetes.

S. ISAAC (*Klinische Wochenschrift*, January 29th, 1923, p. 212) criticizes the treatment of diabetes mellitus by prolonged fasting and underfeeding, which has been advocated strongly in America, and disputes many theories on which it is based. The value of single fast days introduced by Cantani and Naunyn, and especially recommended by von Noorden, has long been recognized. If fasting for twenty-four hours does not check the glycosuria the prognosis is generally unfavourable. A fast day diminishes the acetone in the urine, and is the best treatment for acidosis. But the author considers that, even in severe cases, the fasting should never be extended beyond thirty-six hours, and he is not convinced that the prolonged fasting treatment gives better results than treatment with short fast periods. He admits that it is possible, even in severe cases of diabetes, to check the glycosuria and hyperglycaemia by the American treatment whilst underfeeding is continued. But he insists on the difficulty in carrying out the treatment; he thinks the great reduction in weight, which can hardly ever be recovered, is of doubtful value, and states that a permanent increase of the tolerance is not obtained thereby. The underfeeding treatment is not suitable for a continued diet, on account of its deficiency in fat. The maintenance of strength and nutrition is only possible when the diet contains sufficient fat. In severe diabetes especially we should be content with a moderate controlled sugar excretion and a diet which is suitable to the taste and permits a certain amount of enjoyment of life and

the ability to perform a little work, instead of the ideal permanently sugar-free urine: the latter (in severe cases) can only be maintained by most rigid treatment, which still further reduces the already greatly diminished vitality of the patient. The vegetable and fat diet of Petré is also not suitable permanently, though it can check the glycosuria and acetone excretion. It contains so much fat that it is difficult to digest, and is disagreeable to the patient. But the results of this treatment show that the danger of fats, as regards increase of acidosis, need not be considered.

### 229. Queckenstedt's Sign of Compression of the Cord.

E. SAHLGREN (*Hygiea*, January 31st, 1923, p. 53) is greatly impressed by the diagnostic value of Queckenstedt's sign, first described in 1916 (*Deut. Zeit. f. Nervenheilk.*, Bd. 55). When the veins in the neck are compressed on one or both sides there is a rapid rise in the pressure of the cerebro-spinal fluid of healthy persons, and this rise quickly disappears when pressure is taken off the neck. But when there is a block in the vertebral canal the pressure of the cerebro-spinal fluid is little, or not at all, affected by this manoeuvre, and if there is a rise in the pressure it is very gradual. Queckenstedt assumed that when the veins in the neck are obstructed the veins of the central nervous system become distended, and thus diminish the space in which the cerebro-spinal fluid is accommodated. Hence its rise of pressure. This rise can only be rapidly conducted to the lower part of the vertebral canal if there is no obstruction above the point at which the pressure of the cerebro-spinal fluid is being gauged. Sahlgren records six cases in which he found this sign positive and in which there was compression of the spinal cord by tuberculous caries or growths. He refers to a case in which the other clinical signs pointed to compression of the cord, while Queckenstedt's sign was negative. The necropsy showed that there was no block in the vertebral canal.

### 230. Auto-Serotherapy in Tuberculous Pleural Effusions.

V. PETERSEN (*Ugeskrift for Læger*, January 11th, 1923, p. 25) has practised auto-serotherapy in several cases of tuberculous pleurisy, and recommends this treatment when a pleural effusion has persisted for a month or more and has proved refractory to rest in bed and other methods. The treatment is harmless, and in some cases acts like a specific. The author records in detail the case of a woman, aged 39, suffering from pulmonary tuberculosis. The left lung was collapsed by a pleural effusion, and the removal of 1,200 c.cm. of straw-coloured fluid was rapidly followed by a reaccumulation. Another 1,200 c.cm. were therefore withdrawn. Cultural tests in bouillon and on agar yielded no growths. Phenol was added so that the serum should contain 0.25 per cent. Cultural tests having again proved negative after the serum had been kept on ice for several days, 1 c.cm. was given by intramuscular injection. The injection was repeated daily for thirteen days. Rapid improvement followed, and the patient gained steadily in weight in spite of the absorption of the pleural effusion. She was discharged feeling much better and without tubercle bacilli in the sputum. On re-examination, more than half a year later, recovery was found to be maintained.

### 231. The Tone of the Voluntary Muscles in Tuberculosis.

F. FLARER (*Arch. di patol. e clin. med.*, December, 1922, p. 596) employed Mosso's myotonometer for estimating the degree of muscular tone in pulmonary tuberculosis. All forms of the disease were represented, one or both lungs being affected, and some of the patients being cachectic and others in a good state of nutrition. Flarer found that there was no relation between the muscular tone and the size of the muscle. Tracings characteristic of hypertonic muscles were obtained in individuals with small muscles, in whom the general musculature was not well developed, and atonic tracings were found in men and women with well developed muscles and in a good general state of nutrition, indicating the importance of the nervous system in the production of muscular tone. Flarer maintains that the statement made by many writers that tuberculous patients have atonic muscles is not correct, though it is true that muscular atony is present in some very advanced cases; it is due to anatomical changes in the muscle fibres. On the other hand, it is not found in cases of tuberculosis in which, either because the morbid process is of recent onset, or because it has not a destructive tendency, no muscular atrophy or degeneration

has occurred. The myotonometric curve taken in the morning always differed from the evening curve, which invariably showed an increase of tone. An immediate response was obtained in a tuberculous muscle to a stimulus which was of too slight a character and too short duration to provoke a response in a normal muscle, but the increased excitability was accompanied by a rapid exhaustion of the muscular tone. It is obvious that this condition differs essentially from true atony, inasmuch as in the latter reaction to a stimulus is absent or delayed, whereas in tuberculous the reaction is most prompt though easily exhausted even with minimal stimuli. The explanation of this condition is to be found in the chemical changes caused by the tuberculous toxin either in the nerve elements or in the muscle fibre itself.

### 232. The Comparative Value of Medicinal-Dietetic and Light Treatment in Rickets.

I. JUNDELL (*Acta Paediatrica*, December 16th, 1922, p. 113) points out that in 1919 two new methods for treating rickets were introduced. One of them, advocated by himself, consisted of reducing the dietary and, in severe cases, giving phosphorus and cod-liver oil. The other, advocated by Huldshinsky, consisted of exposure to ultra-violet light from a quartz lamp. To test the comparative merits of these two methods, the author has treated twenty-one cases at his hospital, partly by one method or the other, and partly by a combination of the two. The six patients put upon a reduced dietary, phosphorus, cod-liver oil, and calcium phosphate, responded remarkably well. The response of the six patients given only quartz lamp treatment was, however, equally good. The patients given the benefit of both methods did well, but no better than those given one or other treatment, and it would therefore appear that each method singly is so effective that little or nothing can be gained by combining them. Each method has its own sphere of usefulness: for obviously overfed children, the dietetic restrictions and medicinal treatment advocated by the author may be the best; but when a child is debilitated, dietetic restrictions may be undesirable, and ultra-violet light preferable. The medicinal-dietetic treatment possesses the great advantage of not being dependent on institutional equipment.

### 233. Heredity in Dupuytren's Contraction.

T. LÖWY (*Zentralbl. f. inn. Med.*, January 27th, 1923, p. 51) remarks that the etiology of Dupuytren's contraction is still obscure, and that attempts have been made to associate it with a great variety of diseases, such as disorders of metabolism, diseases of the central and peripheral nervous systems, tuberculosis, and especially chronic joint diseases. The oldest view which still prevails is that of the action of chronic trauma on the palmar aponeurosis. The disease is commonest in certain occupations—for example, in cabmen who use a whip, sailors who handle ropes, sealers of letters, barrel borers, etc. Löwy remarks that important as trauma is in the pathogenesis of the disease, attention should also be paid to heredity as a factor. He describes a family in which Dupuytren's contraction was present for four generations. In the first three generations the condition developed at or after the age of 40. In 15 members of the third generation who had not reached this age it was uncertain whether the disease would occur or not. Of the 5 affected persons in the third generation, 3 were peasants, 1 was a printer, and 1 a joiner. In the fourth generation, on the other hand, one member was affected at the age of 24, while her sister, aged 17, was not affected. Other examples of the inheritance of Dupuytren's contraction have been reported by Largillière, Adams, Goyrand, Vizioli, Kocher, Caspari, Stephensen, Friedrichs, and Durel.

### 234. Antimony in the Treatment of Leprosy.

VERSARI (*Rif. Med.*, January 15th, 1923, p. 53) reports two cases of leprosy treated with intravenous injections of tartar emetic. The solution used was a 1 per cent. watery solution, and in the first case fifteen injections of 7 c.cm. each were given—that is, 90 cg. of antimony. Some retching and troublesome cough were the chief unpleasant effects, but the results on the disease were very favourable. The ulcers were completely healed after the fifth injection. In the second case the drug was better tolerated, and twenty-two injections were given, making a total of 1.84 grams of tartar emetic in all. The ulcers in this case were completely cicatrized after the seventh injection, and the tubercles were then beginning to dissolve. The Wassermann reaction was strongly positive in both cases, and Hansen's bacillus was present all the time. Although the ulcers healed, the bacillus was still present at the end of treatment.

## SURGERY.

### 235. Synovectomy in Chronic Infectious Arthritis.

P. P. SWETT (*Journ. of Bone and Joint Surgery*, January, 1923, p. 110) describes the operation of synovectomy in chronic infectious arthritis. The operation consisted in opening the joint at the site of greatest thickening and effusion, and then with scissors and forceps dissecting out all the diseased inner layers of the synovial membrane down to what appeared to be healthy tissue. The joints were closed without drainage or fixation. All the cases treated were of long standing, with marked thickening and joint effusion. There should be no ulceration of the joint cartilages—in one case where this was present the operation was a failure. Mechanical improvement was promptly manifested by a restoration of painless function in every case; in two cases which relapsed re-operation led to complete ultimate recovery. No disastrous complications have followed the operation, and there has been little post-operative reaction. This operation warrants further consideration in cases of chronic infectious arthritis, but should not be attempted if extensive cartilaginous damage has already occurred. The operation is most likely to succeed if it is done in the type of case or at the stage of the disease where the damage is entirely synovial, the effusion extensive, and the cartilages not ulcerated. A record is given of the histories of a number of cases in which the patients have gained in weight and strength and recovered from their anaemic condition.

### 236. Arterial Decortication.

G. L. CALLANDER (*Annals of Surgery*, January, 1923, p. 15), in discussing arterial decortication, points out that it has been shown that sympathetic nerve plexuses lie in the intima sheath of large arteries and in the adventitia of these vessels. Certain definite results follow the excision of these structures in the treatment of different syndromes. Jaboulay performed this operation with beneficial results on the femoral artery in certain perforating ulcers of the foot, and to a less successful degree on the coeliac trunks in certain visceral disturbances. In the operation the main arterial trunk is exposed and the external fibrous coat incised for 8 or 10 cm., and the artery with its inner sheath is then exposed. The inner sheath is incised and freed from the artery. Certain reactions follow this procedure—a diminution in the calibre of the artery takes place, whilst an increase in surface temperature in the parts distal occurs. These conditions are thought to be the result of trauma to the sympathetic fibres. The operation has been successful in a number of cases of unassociated clinical pictures of a rather vague description where a disturbed vasomotor balance is present. In traumatic lesions, causalgia, and spontaneous ulcers in amputation stumps improvement has been noted. The author reports a number of cases, and considers that improvement in otherwise hopeless conditions has resulted from this procedure, even though the mechanism of the production of the diseases and that of their cure is unknown.

### 237. Influenzal Coxitis with Spontaneous Dislocation.

K. OCHSENIUS (*Deut. med. Woch.*, December 29th, 1922, p. 1726) points out that acute infectious diseases like scarlatina, measles, pneumonia, and typhoid fever may give rise to acute or subacute coxitis. As a rule, the serous or sero-fibrinous effusion into the joint is small, and the disease runs a favourable course without complications. Occasionally, however, in typhoid fever, suppuration ensues, the capsule of the joint becomes greatly distended, and spontaneous dislocation occurs backwards. Hitherto apparently, no such accident in the course of influenza has been recorded. The author reports such a case. During an epidemic of influenza a 10-months-old child developed this disease with typical manifestations—high fever, naso-pharyngitis, and bronchitis. A little later bilateral purulent otitis media set in, with coli-pyelo-cystitis and spasmophilic fits. The right hip became tender, and the limb was held flexed. Four days after the tenderness of the hip was first detected an x-ray examination showed that the head of the femur was dislocated upwards and backwards. As there was no history of trauma, the dislocation was evidently spontaneous. It was reduced, and the limb secured in plaster. Complete recovery followed.

### 238. The Operation for Subphrenic Abscess.

J. SOMMER (*Zentralbl. f. Chir.*, February 10th, 1923, p. 215) describes a method of deciding by x rays whether a subphrenic abscess is operable by the subcostal route or whether it will be necessary to cross the pleural cavity. The subcostal route is preferable, provided the abscess cavity extends downwards sufficiently to allow of drainage without opening the general peritoneal cavity. This point is determined by

laying the patient on the sound side, with the pelvis slightly raised, and screening antero-posteriorly. In the case of a gas-containing abscess the gas will rise to the highest part of the cavity—that is, towards the ribs and costal margin—and the extent of the cavity in that direction can be mapped out, assisted by slight alterations in the position of the patient. In the case of an abscess not containing gas, it is a simple matter to inject a little air with an exploring syringe, after withdrawing a corresponding amount of the fluid contents. In the case of a gas-free subphrenic abscess associated with a large pleural effusion the problem of diagnosis is difficult. If the exploring syringe strikes different fluids at different levels, subphrenic abscess may be presumed with fair certainty. If this fails, however, a quantity of the pleural effusion may be withdrawn and replaced by air; with the patient in the lateral position the remainder of the pleural fluid will then fall away from the diaphragm, and the position and mobility of the latter may be observed. If any doubt still remains, an exploratory puncture may then be made, under the guidance of the x-ray screen.

#### 239. Treatment of Carcinoma of the Oesophagus.

E. B. FREEMAN (*Boston Med. and Surg. Journ.*, November 23rd, 1922, p. 727), in a preliminary report upon the treatment of carcinoma of the oesophagus with colloidal selenium injected intravenously, considers that the method may be useful in certain cases. An initial dose of 3 c.cm. is followed on the second day by 5 c.cm., and this, in the absence of reaction, is continued three times a week for about six weeks. Improvement followed in the cases under observation, as evidenced by relief of pain, lessened dysphagia, control in loss of weight and in one case a very marked gain, and distinct psychic improvement. During the treatment oesophagoscopic and x-ray examinations are made from time to time in order to ascertain whether there is any resulting hyperaemia, sloughing, or increase in flexibility and patency in the oesophagus, or changes in the size and contour of the growth. Dilatation is also carried out by bougies passed over a guiding silk thread in order to prevent any injury. In most cases slight anaphylactic shock follows the injections with possibly temporary increased difficulty in swallowing, and six or eight hours later there may be some general reaction lasting for ten to twelve hours. For the present the treatment must be regarded as palliative only, though further observations may, the author believes, establish its therapeutic value. Where technical difficulties can be overcome surgical treatment is preferable to all other methods, and with earlier diagnosis patients may be referred to the surgeon in time for operative treatment; but these observations suggest that in certain hopeless cases colloidal selenium may offer a palliative treatment.

#### 240. Myositis Ossificans Treated by X Rays.

L. BAZY (*Bull. et Mém. Soc. Chir. de Paris*, November 28th, 1922, p. 1219) reports the case of a patient, 15 years of age, who as the result of a fall sustained a posterior dislocation of the elbow-joint. The following day the dislocation was reduced under anaesthesia without difficulty. The subsequent treatment consisted of hot baths and passive movement which did not cause pain; massage was not practised. Eleven days later x-ray examination showed two areas of new bone formation in the region of the brachialis anticus—one, the size of a large pea, fixed to the bone, the other, free from the bone, the size of a large almond. X-ray treatment was immediately started, and the result was very satisfactory. However, the newly formed bone had not completely disappeared, but showed an increased opacity to the rays, when examined at a later date. In spite of the presence of a nodule of bone in the brachialis anticus the functional result was excellent, all the movements being complete except extension, which was slightly limited. The points of special interest are the rapid appearance of the new bone eleven days after the accident, the formation of the bone in spite of the absence of forcible treatment or massage of the injured area, and the satisfactory result obtained although new bone formation remained present in the substance of the brachialis anticus.

#### 241. Lipoma of the Mammary Region.

TORRACI (*Rif. Med.*, December 4th, 1922, p. 1157) reports a case of lipoma in the mammary region in a man aged 73. Lipomata in this area seem to be rare, and the author has only been able to collect references to 42 other cases. The patient first noted the swelling, above the nipple, about eleven years ago. It was elastic, movable, painless, and covered with normal skin. Five years later it had grown as big as a goose's egg, and was then treated by twenty injections of some unknown substance, but without any good effect. When admitted into hospital the tumour was as big as an

adult head, the skin covering it was normal, except for some small veins. The growth was found to be under the great pectoral muscle, and when removed weighed 1,600 kg., and proved a typical lipoma.

## OBSTETRICS AND GYNAECOLOGY.

#### 232. Rectal Examination in Labour.

J. H. VAN BLOMMESTEIN (*Nederl. Tijdschr. v. Geneesk.*, January 20th, 1923, p. 259) quotes the following statistics from Catherine van Tassenbroek's work on aseptic midwifery in Holland. In the Amsterdam Obstetric Clinic the percentage of deaths from puerperal infection for the decennium 1891-1900 was 1.6. In the city of Amsterdam the mortality from puerperal infection for the year 1895 was 2.2 per cent., and for 1900 1.8 per cent. In twelve smaller towns it was 1.3 per cent. in 1895 and 1.8 per cent. in 1900. In New York 1 in every 250 puerperal women (or 0.4 per cent.) dies from infection (Polak). The mortality, therefore, is not much lower in clinics than in private houses in the town or country, such favourable circumstances as good feeding and careful nursing being probably outweighed to a great extent by the repeated examinations required for teaching purposes. Bukva, in Chrobak's Clinic at Vienna, found that the mortality from puerperal infection among 2,155 women who had not been examined was *nil* as compared with a mortality of 0.07 per cent. among 8,631 women examined in the clinic only, and a mortality of 0.43 per cent. among 1,843 examined outside the clinic. For many years van Blommestein has employed rectal examination during labour, as it enabled him to determine the following points: (1) The stage of labour; (2) the state of the membranes, whether ruptured or not; (3) the position of the presenting part in relation to the pelvis; (4) the nature of the presenting part; (5) prolapse of the cord; (6) prolapse of a limb; (7) placenta praevia. In addition to the advantage of avoiding contact with the internal sexual organs, this method permits of numerous examinations without any danger to the patient. According to Heimann a temperature of 100.4° F. was found in 7.3 per cent. of women who had had no examination, in 6.8 per cent. after rectal examination only, and in 20.6 per cent. after vaginal examination. Van Blommestein thinks it desirable that medical students and midwives should be taught that in many labours external examination alone is sufficient; that when this does not yield adequate information rectal examination should be employed; and, lastly, if that is not sufficient, a vaginal examination should be carried out, especially if there is any prospect of an operation.

#### 243. Vulvo-vaginitis in Children.

ACCORDING to I. F. STEIN (*Surg., Gynecol., and Obstet.*, January, 1923, p. 43), different observers have reported from 63 to 80 per cent. of cases of vulvo-vaginitis in children as being of gonorrhoeal origin. Stein, among 49 cases coming to a children's clinic, records that 23 showed the presence of the gonococcus in smears taken from the vulvo-vaginal region. Cultures proved positive in only 50 per cent. of cases in which the smear showed gonococci, and are therefore of little diagnostic significance. Vulvo vaginitis, although purulent, is non-gonorrhoeal in a large number of instances. Indirect infection, as by common sleeping quarters, towels, linen, or baths, is responsible for the majority of cases, and is favoured by imperfect personal cleanliness. The epidemic vulvo-vaginitis of children's institutions is usually gonorrhoeal. Especially in the chronic forms, treatment must be carried on for some weeks, and recurrences are to be expected in many instances. Stein suggests as the criterion of cure the disappearance of clinical evidence of the infection, negative findings in three smears taken at weekly intervals after suspension of treatment, and an observation period equal to the duration of the treatment. Wacho and Mazer obtained 40 per cent. of cures in three months by daily instillation into the vagina of 1 per cent. Dakin's oil from a medicine dropper, the child being placed in the Trendelenburg position. Gellhorn recommends daily vaginal injections of 1 per cent. silver nitrate in an ointment of equal parts of lanolin and white vaseline. Daily hot baths (42-44° C.) have been of use in some cases, but are not without danger in children. Using Gellhorn's method, with the substitution of mercurochrome for silver nitrate, Stein found that gonorrhoeal cases could be cured in an average of ten weeks, suspicious cases in six weeks, and non-gonorrhoeal cases in five weeks. In two of the gonorrhoeal cases recurrence was noted after an attack of contagious disease. Stein believes that a daily tub bath is an aid to local treatment, and in mild non-gonorrhoeal cases is all that is required for cure.

244. **Fibroma of the Ovary.**

M. R. HOON (*Surg., Gyn., and Obstet.*, February, 1923, p. 24) analyses 55 cases of ovarian fibroma, not associated with other morbid conditions, coming to operation and afterwards to microscopic examination during ten years' work at the Mayo Clinic. Of the 55 cases, 26 had not reached and 26 had passed the menopause, 7 had not reached the thirtieth year. In general, menstruation appeared to be little influenced, and in four patients only was it increased. Of the 55 patients 9 were single and 30 had borne children. Subjective symptoms were comparatively few; in the absence of torsion of the pedicle pain was dragging rather than severe, and in very small or very large tumours was usually absent. Objectively the tumour, although occasionally fixed by adhesions, was as a rule movable. Ascites was present in 14 cases (25 per cent.); 2 patients had in addition bilateral hydrothorax, which disappeared after operation. In the absence of demonstrable metastasis, ovarian tumour associated with serous effusions is therefore not necessarily due to malignant disease. In only 2 cases were both ovaries the site of fibroma. The diameter of the tumours varied from 0.5 to 30 cm.; the surface was usually nodular and irregular, and the consistency varied according as the tumour was or was not complicated by calcareous degeneration on the one hand or myxomatous change on the other. According to Hoon, treatment must be surgical; operation should be advised as soon as the diagnosis of ovarian tumour is made, for malignant degeneration may occur, or torsion of the pedicle may lead to gangrene and peritonitis. Inquiry into the after-history of the patients of the series showed that good prognosis is justified and that normal pregnancy may occur when the adnexa of one side only have been removed.

245. **Icterus Neonatorum.**

G. LINZENMEIER and LILIENTHAL (*Zentralbl. f. Gynäk.*, November 25th, 1922, p. 1873) record observations which support the view that icterus neonatorum is a physiological condition of hepatogenous nature. Accepting Vidal's view that haemoclastic leucopenia following ingestion of protein in the fasting state is a sign of hepatic inadequacy, they made blood counts in 30 infants before and after suckling. Those showing leucocytosis were invariably non-icteric; those showing jaundice gave leucopenia; and in infants with post-prandial leucopenia it was possible accurately to predict the onset of jaundice within two or three days *post partum*. These observations confirm the views of Hirsch and of Yllpö, who demonstrated in the newborn a bilirubinaemia which they regarded as due to persistence of an increased permeability for bilirubin characteristic of the foetal liver. The same observers noted parallelism between the intensity of the bilirubinaemia and that of icterus in the newborn.

## PATHOLOGY.

246. **Neurotropic Ectodermosis: Studies on the Vaccine Virus.**

C. LEVADITI and S. NICOLAU (*Ann. de l'Inst. Pasteur*, January, 1923, p. 1) occupy a complete number of the *Annales* with a description of the properties of the vaccine virus. Of these properties only a brief summary can be given here. In the first place a neuro-vaccine was prepared from the common dermo-vaccine by passing it through the brains of rabbits; after two hundred passages its virulence had become practically fixed, so that it killed the animal within four to five days in the majority of cases. Comparison of this neuro-vaccine with the original dermo-vaccine showed that there were certain differences between them; the former had a greater elective affinity for nervous tissue and a slighter affinity for the skin; it was more susceptible to the action of heat and of ox bile, and its action on certain animals had become less or, as in the case of the fowl, had disappeared altogether. In man it gave rise to a good vaccinal eruption on the skin, simulating closely in its extent and evolution that caused by the usual vaccine. Inoculation experiments performed on rabbits showed that the neuro-vaccine had a special affinity for the tissues derived from the embryonic ectoderm, such as the skin, cornea, central nervous system, and testicle, while it failed to affect those organs which were of mesoblastic origin. Inoculation into these ectodermal tissues was followed by generalization of the virus throughout the body, followed by its subsequent localization in those organs which possessed a special affinity for it. With the exception of the reproductive glands, however, it was necessary before this localization occurred for the organ in question to be irritated, so as to put its cells into a state of regenerative proliferation. Thus, the hair of the

skin could be plucked out, or the cornea scarified, or the brain irritated aseptically. Once this localization had occurred, the organ in question acquired an immunity to further inoculation—direct or indirect—with the virus. Experiments were made to show that this immunity was essentially of a local nature; the humoral element, which could be substantiated on some occasions, appeared to be of an entirely subsidiary nature. In course of time, however, the refractory state of the organ gradually wears off, and it seems probable that the loss of this immunity runs *pari passu* with the reproduction of the cells. The faster the cells of the tissue reproduce, the quicker does the organ regain its susceptibility. As the cells of various tissues reproduce at different rates, it is plain that the degree of immunity evinced by each of these tissues must be different. It is suggested that the general immunity of the organism can be decomposed into a number of partial local immunities. This very interesting hypothesis is supported by work done on the association existing between the vaccine virus and the ultra-virus of contagious avian epithelioma. When the latter is inoculated on to an ectodermal tissue having either a natural or an acquired immunity towards the vaccine virus, it causes so much proliferation of the cells that these gradually lose their immunity and become susceptible to the vaccinal germ. This destruction by one virus of the resistance to another virus may possibly explain the frequent association noticed between herpes zoster and chicken-pox.

247. **Retroperitoneal Cysts.**

CAUCCI (*Arch. Ital. di Chirurg.*, December, 1922, p. 481) classifies these cysts as (1) epithelial, (2) lymphatic, (3) pseudo-cysts, and (4) parasitic. In Class I are included dermoids, Wolffian cysts derived from the embryonic uro-genital apparatus, cysts derived from accessory suprarenals, and endodermic cysts. The author gives details as to these various types. The lymphatic group may contain serous or chylous fluid, and may be simple or neoplastic. Many hypotheses have been put forward to explain their origin, but not one is wholly satisfactory. They are perhaps more often found in the mesentery than in the retroperitoneal space. Pseudo-cysts include perirenal haematomata, collections of urine, inflammatory cysts, and cystic degeneration of neoplasms. Echinococcus cysts are rare in the retroperitoneal space. The author discusses the anatomical relations and symptoms of these cysts, and points out that the key to diagnosis is given by the relations of the cyst to the intestine, and radiology gives help in this respect. The course of these cysts is usually slow and unnoticed for some years; pseudo-cysts (haematomata) differ in their sudden onset. As regards treatment, puncture followed by antiparasitic injections is generally useless, and may be dangerous; laparotomy and complete or partial incision give the best results.

248. **The Mechanism of Variations in the Leucocyte Count.**

PIERRE MAURIAC and M. MOUREAU (*Journ. de Méd. de Bordeaux et de la Région du Sud-Ouest*, January 25th, 1923, p. 39) state that little progress in the knowledge of the phenomena of leucopenia and leucocytosis has been made since the discoveries of Nicati and Tarchanoff in 1875. More recent observers agree that fluctuations in the leucocyte count are the result of an unequal and variable division at the centre or at the periphery, and that the passage of leucocytes driven from the peripheral circulation towards the viscera by a form of chemiotaxis produced leucopenia; on the contrary, leucocytosis marked the return of the migratory cells towards the periphery. Mironesco's experiments confirm this view: simultaneously blood was withdrawn from the ear and from the median basilic vein; a marked difference in the leucocyte count was found. Certain contradictory results led Mironesco to conclude that the leucocytosis observed clinically was no actual index of the total number of leucocytes existing in the mass of the circulating blood. Other authors consider that leucopenia may be due to dilution of the mass of the blood and leucocytosis to its concentration. Thus, the vasodilatation resulting from anaphylactic shock drains the viscera in order to refill the dilated vessels and to restore the blood pressure; as plasma is poured out the dilution reduces the proportion of cells. The authors discuss at length the arguments supporting the theory of leucolysis, and they give charts showing leucocyte destruction due to anaphylactic shock, disappearing before a rapidly increasing leucocytosis. In one experiment they quote Abrami's observation in malaria, that the onset of a rigor, which is a good example of shock, is not accompanied by an increase of leucocyte destruction, but rather by a decrease. The authors conclude that neither of the foregoing theories covers the whole ground, and that the question is more complex.

consist in a marked and progressive diminution in size of the tonsils, and a change in their colour from bright red to a pale pink, while the surface, which was previously granular, becomes smooth. The functional symptoms also diminish in intensity; the respiration improves, snoring in sleep ceases, phonation becomes more distinct, pain in swallowing disappears, and the general health improves. In Nogier's cases this improvement was maintained for several years. The advantages of x-ray treatment over other methods, according to the author, are that it is simple and painless and does not expose the patient to the risks of haemorrhage or infection. F. H. WILLIAMS (*Paris méd.*, February 3rd, 1923, p. 110) states that the rationale of radium treatment consists in the fact that the lymphoid tissue of which the tonsils are composed is particularly susceptible to the action of radium, and that diseased tonsillar tissue is even less resistant than the same tissue in the normal state. Radium, however, cannot be expected to have any action on fibrous tissue or suppuration. Williams has treated 101 cases, aged from 5 to 60 years, which he classifies as follows: enlarged tonsils without inflammation, 44 cases; tonsillitis (2 acute, 31 chronic), 33 cases; enlarged tonsils with various complications, such as rheumatism, cardiac disease, and nephritis, 14 cases. In all but three of the cases of simple enlargement, and in all but two of the tonsillitis cases, the tonsils were considerably reduced in size as the result of treatment. The use of radium is not without danger, and should only be carried out by an expert. Radium is stated to be more suitable than x rays for enlarged tonsils because it is easier to determine the exact dose, and because the radiations are applied to the tonsils by the mouth and are almost entirely absorbed by the tonsils themselves, whereas x rays, which are applied externally, are in great part absorbed by the intervening tissue, especially the parotid.

#### 259. Involvement of the Auditory Nerve in Early Syphilis.

M. BAB (*Deut. med. Woch.*, February 16th, 1923, p. 218) has carried out investigations with a view to checking the claims of Alexander, Kobrak, and others, according to whom the auditory nerve is often implicated before the appearance of secondary signs of syphilis. The author examined 26 cases of primary syphilis in which the diagnosis was confirmed by microscopic examination. On the same day on which this examination was made the patients were sent to a specialist in aural diseases for him to say whether they had symptoms of ear disease or not. On the same day or on the following day abortive treatment with neo-salvarsan was instituted. The report of the aural specialist showed that in about 75 per cent. the auditory nerve was already involved, and this was as often the case when the Wassermann reaction was negative as when it was positive. In most cases with signs of disease of the auditory nerve there were no subjective symptoms, but the signs were so characteristic that they may possibly prove of considerable value in the clinical diagnosis of doubtful cases of syphilis—for example, cases of mixed infection in which it is impossible to demonstrate the *Spirochaeta pallida*. In 70 per cent. the abortive treatment of these 26 cases was successful; six to eighteen months later there was no clinical or serological evidence of syphilis. In those cases in which there were no signs of involvement of the auditory nerve when the abortive treatment was instituted, it was invariably successful. It would seem that the injury to the auditory nerves caused by syphilis takes long to repair, and it may be demonstrable after the patient appears to have recovered in other respects from syphilis.

#### 250. The Value of Perirenal Inflation.

M. CHEVASSU (*Bull. et Mém. Chir. de Paris*, February 6th, 1923, p. 189) gives the results of over a year's experience of perirenal inflation. The technique of the operation is simple, but the results are often unsatisfactory, as there are a number of spaces round the kidney which may become injected instead of the perirenal tissue. These include the peritoneum, pleura, or mediastinum, which may rarely be injected, or more commonly the muscular planes, of the psoas muscle in particular; where this muscle is thick the point of the needle may be arrested in its sheath and the gas be injected among the muscle fibres, or sometimes it may result in the injection entering the central ligament of the diaphragm and thence passing to the chest or downwards into the abdomen. The author's procedure differs from that of Carelli in that he makes the injection at the point where the kidney approaches nearest to the skin; this point lies at the upper point of the line which divides the muscles of the back from those of the abdomen over the apex of Petit's triangle. He employs the trocar used to produce artificial pneumothorax; even so it is impossible to be sure the injection will proceed satisfactorily, and it may

merely enter in the pararenal layer. When successful the kidney can be shown surrounded by the gas and separated from neighbouring structures. When the injection does not spread equally around the kidney it may be due to perinephritis or to the gas collecting in pockets, and this leads to mistakes in diagnosis. The author concludes that at present no technique so far designed will give constant results. The image obtained by this method is often difficult of interpretation and no better than an ordinary radiogram; it may sometimes be used with advantage in cases of tumours of the loin where the diagnosis is obscure and other methods have been tried without success.

#### 261. Cystography in Prostatism.

PIRONDINI (*Riv. Osped.*, January 15th, 1923, p. 1) directs attention to the diagnostic value of cystography in prostatic cases. The bladder is filled with a 2 to 5 per cent. solution of potassium iodide or 5 to 15 per cent. solution of sodium bromide and the x-ray tube directed strictly vertically. Three points are to be noted: (1) the generic form of the vesical shadow; (2) the small irregularities of the margin of the shadow; (3) the lower edge of the shadow is above the pubic symphysis line. Of these three facts the third is the most important. Whenever this lower line is above the pubic line it is safe to say that prostatic adenoma exists. The cause of the elevation is the raising of the floor of the bladder. Some prostatic adenomata of periurethral localization do not raise the base of the bladder, and in such cases this clear interstice is not present, and other means of diagnosis may be necessary—for example, cystoscopy. Cystography is particularly useful when the passing of an endoscope is difficult or dangerous, and when there is great vesical irritability or severe haematuria. Several cystograms are given, which illustrate the author's statements.

### OBSTETRICS AND GYNAECOLOGY.

#### 262. Treatment of Ruptured Ectopic Pregnancy.

E. M. HAWKS (*Surg., Gyn., and Obstet.*, February, 1923, p. 232) discusses the question of whether immediate or delayed operation should be employed in cases of collapse following a ruptured ectopic pregnancy. He presents the clinical evidence afforded by 824 cases of ectopic pregnancy, of which 187 were in various degrees of collapse; three of the latter cases, through errors in diagnosis, did not receive palliative treatment, and of the remaining 184, 113 were operated on immediately, and 71 were treated expectantly. He suggests that there would be no question as to the time of operation if all the cases improved under palliative measures, but, unfortunately, a considerable percentage of these cases die when left to themselves, or when treated expectantly. This last statement has been denied by other authorities, but the author supports his opinion by statistics. The mortality in 133 consecutive cases of collapse due to this condition operated upon immediately in three hospitals was 8.8 per cent., while the mortality in 71 consecutive cases of collapse in two institutions, treated expectantly and in which operation was deferred, was 17 per cent.; in a more recent series of 21 consecutive cases of collapse in one institution, operated upon immediately, there was one death. The author suggests that the vital thing needed by such cases collapsed from haemorrhage is the addition intravenously of a warm circulating medium such as saline, gum glucose solution, or blood. Fluids cannot be given, however, unless operation is planned to follow soon or is done coincidentally. Infusion and transfusion give the immediate operation a great advantage. A small amount of fluid will often revive almost immediately a patient in *extremis* and make an operation possible. If an immediate operation has not been planned, fluids must not be added to the circulation and the slower method of the patient taking up her own serum must be relied upon. The type of case that dies in the wards within an hour or so would seem to have a better chance if the patient were infused and operated upon immediately, and transfused later, if necessary.

#### 263. Skin Diseases at the Menopause and their Treatment.

BAUER (*Zentralbl. f. Gynäk.*, February 3rd, 1923, p. 188) states that the two commonest skin troubles occurring at the menopause are pruritus and eczema. Pruritus, which may affect the labia, the genital crural clefts, the mons veneris, or may become diffuse, is especially distressing as it causes intense itching day and night and nearly drives the patient mad. Eczema is found on the external genital organs, the insides of the thighs, the elbows, neck, and face. The local and dietetic treatment which used to be given in such cases should, in the author's opinion, be omitted, as it is now

recognized that disturbances of the endocrine system are responsible, it having been shown by Luthlen that owing to these disturbances the skin is specially susceptible to inflammation at this time, and he has succeeded in reducing this susceptibility by reducing the permeability of the capillaries by colloidal therapy and blood-letting. With this treatment combined with organotherapy he has achieved good results. The author has had the opportunity to treat numerous women, either at the menopause or just before it, suffering from widespread pruritus and eczema on all parts of the body, and he has always improved and generally cured the condition by giving an ovarian extract 1 c.cm. subcutaneously every second day. If the treatment is begun in the early stages the disease is cured very rapidly, and even in old-standing cases not more than sixteen injections are usually required. He records two interesting cases in which the treatment, which he regards as quite harmless, was apparently successful.

#### 264. Treatment of Uterine Myomata.

J. RÉCAMIER (*La Gynécologie*, December, 1922, p. 714) surveys the treatment of uterine myomata during the last fifty years, and discusses the present-day indications for surgical, x-ray, and radium treatment. Radium or x-ray therapy in expert hands is without danger and usually efficacious in cases of uncomplicated myoma, but has the drawbacks that (1) the curative action is obtained as the result, and at the price, of a sterilization of the ovaries; (2) not all myomata can be diagnosed in the unopened abdomen, and to irradiate a supposed myoma, which is in reality an ovarian cystoma or an inflammatory adnexal condition, may cause grave and even fatal complications. Surgical treatment, which permits of exact diagnosis and of carefully planned conservative measures with regard to the genital functions, is nevertheless fraught with a mortality of approximately 6 per cent. (hysterectomy) or 8 per cent. (myomectomy). In assigning the various classes of myomata to radiological or to operative treatment, Récamier lays down the following general rules: Radiotherapy is called for, provided the diagnosis be not doubtful, in small or medium-sized tumours, in the diffusely fibromatous bleeding uteri of the menopause, and in patients whose general condition of health contraindicates surgical operation. Myomata unsuitable for radiotherapeutic measures are those which are large, high and subperitoneal, low and intraligamentary, degenerated, suppurating, submucous, and enucleable per vaginam; also those requiring intervention during pregnancy. According to the author, about one-third of myomata require operation; two-thirds may be left to x-ray or radium treatment. He believes that subtotal hysterectomy (the mucosa of the cervical stump being excised) is the operation of choice in the majority of women over 40 years of age having subperitoneal or interstitial myomata. Myomectomy is most suitable for women who are not yet 35, having myomata which are few and subserous, and possessing healthy adnexa; even in a young woman, however, it is better to do subtotal hysterectomy than to leave a "loque utérine" after multiple myomectomy.

### PATHOLOGY.

#### 265. The Blood Count in Erythema Nodosum.

W. HOYER (*Acta Medica Scandinavica*, February 22nd, 1923, p. 587) has examined the blood in twenty cases of erythema nodosum, and has found little change in the erythrocytes apart from a slight reduction in their number in about two-thirds of his cases. The anaemia was, as a rule, proportional to the severity of the disease. In most cases the total number of the leucocytes was above normal at the time of the eruption, and as this faded the number of the leucocytes returned to normal. Early in the disease there were neutrophilia, eosinophilia, monocytosis, and lymphocytosis. As the eruption faded, numerous neutrophils with rod-shaped nuclei appeared and persisted for a considerable time. Discussing this blood picture, the author points out that it does not tally with that of acute rheumatism. It is more like that of anaphylaxis, and erythema nodosum may be an anaphylactic phenomenon provoked by certain protein poisons, for one of which the tubercle bacillus may be responsible. Indeed, the late changes observed in the leucocytes after an attack of erythema nodosum resembled those seen after a primary infection with tuberculosis. In all but two of the author's cases v. Pirquet's reaction was positive, and in most it was violent. Yet there was a family history of tuberculosis in only three cases, and none of the twenty showed the habitus phthisicus. Some of the patients were nurses who had come as probationers to the hospital from the country and had nursed tuberculous persons during their first year of service.

#### 266. Skin Cancer following Exposure to Radium.

W. J. MACNEIL and G. W. WILKIS (*Journ. Amer. Med. Assoc.*, February 17th, 1923, p. 466) report an interesting case of skin cancer following exposure to radium which occurred in a medical practitioner aged 46. This patient worked with x rays in his practice from 1905 to 1917, but not since; he was fully cognizant of the danger of x-ray burns and precautions for self-protection were carefully employed. From 1912 to June, 1920, however, he handled radium without any precautions for self-protection; he used it in small amounts up to 1915, but in quite large amounts from 1915 to 1920, 200 to 365 mg. in individual tubes being taken between the right thumb and forefinger almost every day. Various changes, which might be ascribed to the exposure to radium, began to be observed late in 1918, and since early in 1920 the skin changes required constant care. In September, 1922, a fissure on the ball of the right thumb underwent a peculiar and extremely painful alteration in character, and did not improve under various treatments. The central portion of the lesion was excised and on microscopical examination was found to be a disintegrating squamous-celled carcinoma, extending beyond the limits of the specimen examined. Immediate amputation of the thumb was advised, and this was carried out on the following day. The condition was then found, on further examination, to be a squamous-celled carcinoma of the distal phalanx of the right thumb, extending to the base of the phalanx; there were hyperkeratosis and parakeratosis of the cutaneous epithelium. The authors admit that the earlier work of the patient with x rays throws some little doubt on the causal relation of the radium. On the evidence, however, they are strongly inclined to the opinion that radium may, when exposure has been sufficient, give rise to changes in the skin predisposing to development of malignant new growth, and that the radium had precisely this effect in the case reported.

#### 267. Destruction of Diphtheria Bacilli by the Pneumobacillus.

LESBRE (*C. R. Soc. de Biologie*, January, 1923, No. 3, p. 227) has succeeded in eradicating the diphtheria bacillus from the throats of carriers by inoculating their throats with the pneumobacillus. It has been known for some time that certain harmless organisms play an important part in inhibiting the growth of the Klebs-Loeffler bacillus in the throat and the existence of an antagonism has been established between the pneumobacillus and the diphtheria germ. Lesbre inoculated living pneumobacilli on to the tonsils of four diphtheria carriers and found that in each case the number of diphtheria bacilli diminished rapidly and they disappeared completely in seven to twelve days. The same treatment was then applied to a convalescent case suffering from pharyngitis, with the result that the diphtheria bacillus could not be found after seven days. An early case of diphtheria was also treated successfully. All the recipients of these inoculations were examined again after a period of two months and were found to be free from infection: they had not suffered from any symptoms as the result of the implantation with pneumobacilli. Such a method of treatment may therefore be of value in destroying diphtheria bacilli in the throat and diminishing the period of isolation of carriers.

#### 268. Can Tuberculosis Give a Positive Wassermann Reaction?

H. BOAS and C. WITH (*Hospitalstidende*, January 31st, 1923, p. 69) review the extensive literature according to which tuberculosis, notably of the skin, frequently is responsible for a positive Wassermann reaction. Their review shows that with one possible exception these publications do not bear scrutiny. Their own observations show that the chance of a tuberculous person (without clinical evidence of syphilis) giving a positive Wassermann reaction is only 0.1 per cent. (thrice in 2,308 cases). At the Finsen Institute in Copenhagen it has been the practice since 1910 to test every patient with Wassermann's reaction, and in addition to the material obtained at this institute the authors have added some cases from other hospitals. Altogether 1,174 cases of tuberculosis of the skin, or of cutaneous diseases which might have a tuberculous origin, were examined by Wassermann's reaction and only in 3 was it positive, although there was no evidence of syphilis. In 758 cases of surgical tuberculosis and in 376 cases of pulmonary tuberculosis the reaction was tested; it was not once positive in the latter class, and among the cases of surgical tuberculosis there were only 17 with a positive Wassermann reaction, and in all these 17 cases syphilis was found to coexist with tuberculosis. It is therefore a myth that this disease can *per se* give rise to a positive Wassermann reaction.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## MEDICINE.

269.

### The Biological Test of Paternity.

LATTES (*Rif. Med.*, February 19th, 1923, p. 169) discusses recent views on heredity in relation to paternity. Mere resemblance of child to parent, whether gauged by ordinary observers or by artists, is not a safe guide from the medico-legal point of view. We are getting a little nearer a test when we study the question in the light of Mendelian laws. The dominance or recessivity of certain characteristics, corresponding to the Mendelian hypotheses, should be borne in mind. Sex linkage—as, for instance, in the case of haemophilia—may come in as a disturbing factor. The shape of the skull, of the hands, the disposition of the venous arches, the whorls of the finger-tips, and the distribution of pigmentation have all been used as tests. As regards the colour of the iris, blue is said to be recessive to grey, and grey to brown. Brown or black hair is dominant in regard to red or blond, and the section of the hair is also a factor—for example, smooth round hairs are recessive in regard to oval sectional hair. Again, a good deal of work has been done in relation to blood characteristics, especially as regards the red corpuscles, details of which are given, but so far the author would not be prepared to judge a case of disputed filiation solely on the blood findings. The upshot of the discussion is to suggest that by a proper use of Mendelian doctrines in relation to heredity we possess a clue which might help, if not certainly settle, cases of disputed paternity.

270.

### The Etiology of Erythema Nodosum.

A. WIBORG (*Norsk Mag. f. Lægevidenskaben*, February, 1923, p. 135) has observed an epidemic of erythema nodosum in a country district in Norway, and has come to the conclusion that the disease is of rheumatic rather than tuberculous origin. Between November, 1921, and August, 1922, he saw as many as 30 definite cases, 18 of which occurred in December. In each of the other months there occurred only 4 cases or fewer. The epidemic was practically confined to a district where only 816 persons lived; here 26 of the 30 cases occurred. The age of 26 of the patients was between 8 and 15—most of them were girls; the remaining 4 patients were women between the ages of 16 and 25. Only in two homes were there as many as two cases in each, yet in many families where a single case occurred there were several children. Most of the patients suffered from protracted anaemia after the illness, and 3 developed fatal tuberculous meningitis. The 8 cases of pleurisy occurring in conjunction with the erythema terminated in recovery. In the same period there were 19 other cases of pleurisy, all with effusion, and 14 cases of acute rheumatism. There were also numerous cases of muscular rheumatism. In support of his view that erythema nodosum is a rheumatic disease, the author remarks that in many of his cases the erythema nodosum was associated with erythema multiforme and pains in the joints; most of the cases reacted promptly to salicyl. Another point in favour of his view was the great frequency with which many cases of undoubted rheumatic disease occurred in the same period, and it is conceivable that the very wet Norwegian summer of 1921, with almost incessant rain from May till Christmas, favoured the development of rheumatic diseases.

271.

### Orthostatic Albuminuria.

J. W. RUSSELL (*Quart. Journ. of Med.*, January, 1923, p. 73) reports a study of orthostatic albuminuria by means of graphic records. He describes a method for the rapid estimation of albuminuria of small degree, and gives charts indicating the amount of albumin in the urine, at different times of the day, in cases of apparent orthostatic albuminuria. He compares the results with those obtained in certain mild cases of nephritis. In the cases of mild nephritis studied during and immediately after a subacute attack, the reactions of the albuminuria to the upright position are identical with those of the orthostatic group. He is inclined to think that many of the cases diagnosed as orthostatic albuminuria are not really "functional" in nature, but have a "renal pathology." The author concludes that there appears to be a group of mild kidney lesions which reveal themselves chiefly by the inability of the kidney to bear, without leakage of albumin, the circulatory disturbance brought about by the upright position; and he believes that the orthostatic albuminurias belong to the same group, though at its mildest extremity. In none of the cases examined has the

"bed urine" been always completely free from albumin. There is a close association between the quantity of urine secreted and the amount of albumin contained. Generally the two curves are inverse in direction. When the urine is persistently and abnormally scanty, the two curves cease to show any relation to one another. In the more obviously nephritic cases, the albumin response to the upright position is not immediate, except during a subacute exacerbation. In the more definitely orthostatic cases standing at once and invariably gives rise to albuminuria, except during a period of diuresis.

### 272. Posture in the Treatment of Bronchial Diseases.

H. SCHAEFER (*Klinische Wochenschrift*, February 5th, 1923, p. 252) records his experience of the sloping posture in the treatment of bronchial diseases. The patient is placed in a posture suitable for the draining away of bronchial secretion by gravitation. After part of the bronchial secretion which has accumulated during the night has been expectorated by coughing in the morning, the patient rests flat on the bed for two hours, so that the rest of the bronchial secretion can flow more easily into the large bronchi. After a few days the foot of the bed is raised 30 cm., and the patient rests on his healthy side. Not only is the foot of the bed raised, but the bed is tilted obliquely. The gluteal region is raised by a wedge-shaped cushion, and finally the head and shoulders are placed on a chair close by the bed; thus an oblique hanging posture is obtained. The treatment is at first for half an hour daily, and then the time is rapidly increased to two hours daily. Patients with cardiac disease or high blood pressure are obviously unsuitable for this treatment. Of 8 cases of bronchiectasis treated by this method, 5 recovered and 1 improved considerably. By this treatment the sputum was definitely diminished, and the general condition improved. The treatment by posture does not cure bronchiectasis, but it often causes distinct improvement. In a case of abscess in the lower part of the right lung, and in another case of fetid bronchitis, recovery followed the postural treatment. Apparently the treatment is chiefly of service in bronchiectasis or abscess, but only when the lower part of the lung is affected; in diffuse bronchitis it is useless.

273.

### Malarial Splenomegaly.

O. CIGNOZZI (*Il Policlinico*, Sez. Chir., February 15th, 1923, p. 57) records his observations on enlargement of the spleen in malaria and the complications arising therefrom, based on the study of several hundred cases during twelve years' surgical experience at the Grosseto Hospital. He maintains that the treatment of all enlarged malarial spleens should be medical as long as they are situated in their normal position. Operation, however, is required in the following complications:—(1) Violent lesions: (a) spontaneous rupture, (b) rupture of spleen from abdominal contusions, (c) rupture of spleen from penetrating wounds of the abdomen and thorax. (2) Acute inflammatory processes: (a) Splenic abscesses, (b) perisplenic and subphrenic abscesses. (3) Parasitic cysts, especially echinococci. (4) Ectopia of a chronically enlarged malarial spleen. (5) Ectopia of a chronically enlarged spleen due to latent malaria. (6) Splenic infarction and blood cysts in an ectopic malarial spleen. (7) Necrosis of an ectopic spleen with acute torsion of the pedicle. (8) Ectopic spleen with subacute or chronic torsion of the pedicle. In 15 out of 17 cases which presented the complications described Cignozzi performed splenectomy, with only one death. The results of the operation were as follows: (1) Improvement in the general condition, due partly to removal of a mechanical interference with the gastro-intestinal functions and partly to removal of a large quantity of toxic material. (2) Improvement not only in the number of the red corpuscles and haemoglobin value but also in the white cell count, the typical leucopenia being gradually replaced by a normal formula. (3) Resistance to various infections, especially septic infections, was diminished. (4) Relapses, though liable to occur, were more likely to develop a long time after splenectomy than directly after the operation.

### 274. Hospital Epidemic of Pemphigus Traced to a Laundrymaid.

H. SCHULTHEISS (*Schweiz. med. Woch.*, February 15th, 1923, p. 171) gives an account of an outbreak of pemphigus among infants in a maternity hospital in Basle. The outbreak, which included 21 cases, began with two which occurred simultaneously in different wards, served by different members of

infantile death, from enteritis and pneumonia on the fifth day. The other children were absolutely normal except for a slight increased sleepiness for the first two days. The authors attribute the success of the rectal ether to the gradual, regular, and constant absorption, to the fact that no alkaloids were used and that the effect can be stopped at once by washing out the rectum, and to the ease with which the technique can be learnt. The disadvantages are the impossibility of a regular dosage to be followed in all cases, owing to the non-retention of the whole dose and also to the differing susceptibility to the drug in different women. It is also not suitable for administration in a private house. It compares very favourably with the statistics of hyoscine-morphine narcosis taken from the statistics of eight different authorities, a table comparing the two being appended:

	Hyoscine-morphine (1,076 cases).	Rectal ether (100 cases).
Full amnesia ...	81.2%	88%
Partial amnesia ...	16.3%	8%
Failures ...	2.5%	4%
Children healthy ...	70.0%	84%
Children apnoeic, oligopnoeic, or asphyxiated ...	27.5%	16%
Children, total mortality ...	3.0%	2%
Frequency of forceps ...	9.2%	3%

#### 284. Treatment of Early Malignant Disease of the Genital Tract.

ACCORDING to R. T. FRANK (*Amer. Journ. of Surg.*, February, 1923), the extreme malignancy of carcinoma of the vulva affords an urgent indication for prophylactic removal of irritating, especially pigmented warts, and the excision of intractable kraurotic or leucoplakic areas. Even the smallest cancer in this region requires complete vulvectomy with excision of the inguinal and possibly of the iliac glands; vulvar cancer, however, seldom reaches the surgeon in an operable stage and is rarely susceptible of permanent cure. Carcinoma of the vagina takes, as a rule, a still more rapid course, and the author has found hysterectomy and colpectomy to be fraught with such high mortality and tendency to recurrence that he prefers to substitute radium treatment. Early carcinoma of the cervix uteri not infrequently escapes medical recognition, and, on the other hand, innocent eversion, erosions, and even chancres have been mistaken for cancer and have caused removal of the normal uterus. In every case therefore, whether only "suspicious" or practically certain, it is imperative to secure microscopic examination of an excised fragment by an experienced pathologist. For a small tumour or ulcer localized on one lip Frank advocates a radical so-called Wertheim operation without systematic extirpation of unenlarged pelvic glands; for the more frequently encountered "border-line" case, in which the pericervical tissues are probably or certainly affected to a slight extent, he prefers preliminary radium treatment, followed eight to ten days later by complete hysterectomy (not the Wertheim technique).

#### 285. Partial Symphysectomy for Pelvic Contraction.

ACCORDING to P. CASTAGNA (*Rivista d'Ostetricia e Ginecologia Pratica*, January, 1923), partial symphysectomy as described by Costa constitutes the most valuable means of treatment of contraction of the pelvic inlet with the true conjugate measurement reduced below 75 mm. It is followed by a permanent enlargement of the pelvis, as has been shown by radioscopic and other examinations of patients made after an interval of some months after operation. The operation, which does not present great technical difficulty and is accompanied by little haemorrhage, consists in shaving off from the upper and posterior portion of the symphysis pubis a crescentic area 2 cm. broad, 1 cm. deep, and 1 cm. thick, including bone, periosteum, and ligamentous attachments; the part excised is roughly that lying between the two pubic spines. Two cases are related by the author in which the operation performed during labour was followed by issue of a living healthy child; the true conjugate measurements were respectively 78 and 80 mm., and in both cases previous labours had been protracted and resulted in stillbirth after application of forceps.

### PATHOLOGY.

#### 286. Rupture of the Aorta.

W. M. DE VRIES (*Nederl. Tijdschr. v. Geneesk.*, December 16th, 1922, p. 2713), who records 24 cases which occurred among about 6,500 autopsies, classifies the varieties of rupture of the aorta into traumatic and spontaneous. In the traumatic form, of which he relates four examples, the rupture is often localized in the region of the ligamentum Botalli and just above the valves. Longitudinal ruptures are less frequent

than transverse. In spontaneous rupture, of which de Vries reports 20 cases, two forms may occur: (a) A form in which local diseases of the aorta may give rise to rupture by causing weakness of the vascular wall; and (b) a form in which the rupture occurs with little or no change in the aorta. Sometimes the aorta possesses only two valves or there is a stenosis of the aortic isthmus. In this form a more or less violent bodily effort may be the exciting cause of the rupture, or there may be cardiac hypertrophy or chronic nephritis. Weakening of the aortic wall is most frequently caused by aortic aneurysm, of which 8 cases occurred in this series, other causes being purulent infection of the aortic wall—caused by pyogenic emboli in one of the vasa vasorum of the aorta (aortitis mycetica), tuberculosis of an adjacent lymphatic gland, or a caseous abscess involving the aorta, ulcerative endaortitis complicating ulcerative endocarditis, and carcinoma of the oesophagus. Five examples of the last named cause occurred among 136 cases of carcinoma of the oesophagus, but none of the other three causes were represented in the present series.

#### 287. Rapid Test for Albumin and other Urinary Proteins.

A TEST has been devised by W. G. EXTON (*Journ. Amer. Med. Assoc.*, February 24th, 1923, p. 529) for both qualitative and quantitative estimation of albumin in urine, with a reagent consisting of a 5 per cent. solution of sulphosalicylic acid and 20 per cent. sodium sulphate. The test is reported to be so trustworthy that confirmation by other tests is rarely if ever necessary. The reagent is highly acid, approximately equivalent to one-tenth normal hydrochloric acid, and so thoroughly loaded with salt that, when added to an equal volume of urine, a mixture is obtained that is quite uniform in specific gravity, hydrogen ion concentration, and salt content, irrespective of the physico-chemical constants peculiar to the particular urine tested. A litre of the reagent is made by dissolving 200 grams of sodium sulphate (crystals) in from 700 to 800 c.cm. of distilled water. After cooling down to about 35° C., 50 grams of sulphosalicylic acid are dissolved by stirring and without further heating, and enough water is then added to make 1 litre. The reagent is not sensitive to light, and keeps indefinitely. The test is performed by mixing equal parts of urine and reagent, and warming. Even the warmth of a match suffices. Boiling does not spoil the test, but is unnecessary. Albumin-free urines so treated give a perfectly clear, transparent mixture; albuminous urines are rendered cloudy, the degree of turbidity being directly proportionate to the concentration of albumin.

#### 288. Vitamin B and the Sexual Glands.

THOUGH several workers have noted the fact that deprivation of vitamin B leads to degeneration or atrophy of the germinal tissue of the sexual glands, their experiments have often been open to criticism on the ground that the basal dietaries employed have been insufficient to avoid a certain element of starvation—and it is known how sensitive these glands are to inanition. To avoid this objection H. GOTTA (*C. R. Soc. de Biologie*, February 10th, 1923, p. 373) adopted Simonnet's vitamin B free diet—one which, besides containing several varied constituents, includes a quantity of meat residue—and gave it in such amount as to exclude any possibility of starvation. Working with pigeons, he divided them into three groups. To the first group of 9 he gave the basal dietary; to the second group of 7 the basal dietary with the daily addition per bird of 2.5 grams of fresh beer yeast to ensure an ample supply of vitamin B; while the third group, acting as controls, were allowed a full diet of maize. In eighteen to thirty days after the commencement of the experiment the pigeons of the first group showed symptoms of polyneuritis; those of the second group appeared perfectly healthy. All three groups were killed. At autopsy it was found that those birds which had been deprived of the B constituent had lost considerably in weight, while the size of their testicles was only about one-tenth that of the controls. Those of the second group, which had received the B factor, had actually gained slightly in weight, but their testicles, when compared with those of the controls, were seen to be diminished in size by about one-half. Histological study of the sexual glands of the first group showed a marked retrogression of the germinal tissue; the canaliculi were narrow, lined by only one or two layers of cells, and showed no spermatozooids. These facts can be explained on three hypotheses: (1) that the yeast supplied sufficient of the B factor to avoid the symptoms of polyneuritis, but not sufficient to prevent the sexual atrophy—in which case the testicle may be taken as a delicate reacting agent to the presence or absence of vitamin B; (2) that in the basal diet employed there was some necessary, but unknown, factor missing; or (3) that the meat residue had a deleterious effect on the testicle.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## MEDICINE.

### 789. Tuberculosis of the Lymphatic System.

SIR R. PHILIP (*Edin. Med. Journ.*, March, 1923, p. 85) emphasizes the importance of the lymphatic system in the early spread of tuberculosis. Following invasion, whether by local soro or not, a secondary incubation occurs, as shown by the enlargement of the lymphatic glands in the vicinity, with extension to others more distant. It is suggested that in children the lymphatic system should be periodically reviewed, and in cases of delicate health all those groups of glands readily accessible should be carefully investigated by detailed palpation. Following inoculation of the tonsillar region, in addition to the obviously enlarged glands at the angle of the jaw, multiple enlargement of lymph nodes may progressively extend in fan-like fashion into the submaxillary and supraclavicular regions, the affected glands becoming infiltrated and indurated; when gross enlargement of glands occurs a thoroughgoing search should be made for obvious infiltration extending to adjacent glands, and frequently over wide areas to other groups. Prolonged tuberculin treatment at this early lymphatic stage has a marked effect alike on the obvious glandular enlargements, on those groups less obviously affected in other areas, and on the general intoxication. Under such continued use of tuberculin, either subcutaneously or percutaneously (inunction giving excellent results), the gross enlargement becomes sensibly reduced as it resolves into discrete glands which eventually become smaller, fibrous, and possibly calcified, while the glands at a distance are influenced, and the relief of intoxication is evidenced by improved appearance, gain in weight, and recovery of muscular tone. Operative treatment should be limited to emergencies, such as removal of deformity or the evacuation of a softened gland, and such treatment should avoid extensive incision, and must never be regarded as in any way radical.

### 290. Silicosis and Tuberculosis.

C. L. SUTHERLAND and W. C. RIVERS (*Tubercle*, March, 1923, p. 255) publish details concerning the relation of silicosis to tuberculosis in the West Riding of Yorkshire. In 1858 the first ganister brickworks in the country were opened at Oughtibridge. The mineral in question, when the quality is good, contains 87 to 96 per cent. of silica. Dust is disengaged in all the processes, the brick ceasing to be dangerous only after baking. The relative danger of the different processes is indicated by the following numbers, which represent percentage frequencies of silicosis or silicosis plus tuberculosis: Setters, 13.95; miners, 13.33; breakermen, 9.21; quarrymen, 2.43; labourers in sheds, 2.21. Taking the industry collectively, it was found that 64 of the 1,254 employees examined (about 5 per cent.) suffered from silicosis or tuberculosis. By the deduction of the 128 employees engaged in the least dangerous part of the work, the incidence of silicosis or tuberculosis was raised to 8.3 per cent. Even this ratio was too low, for about a third of the persons examined were birds of passage. It was found that in established disease the skiagram gives much more detailed, precise, and extensive evidence than do the ordinary physical signs.

### 291. Treatment of Pulmonary Oedema following Thoracentesis.

S. H. LINDBLOM (*Hygiea*, January 31st, 1923, p. 36) raises the question: What is the best treatment for severe pulmonary oedema, provoked by the too sudden removal of a large quantity of pleural effusion? He suggests that the best course may be for the physician to retrace his steps and to compress the lung again by introducing gas into the pleural cavity. He insists, however, that the best treatment of all is prophylactic, and that, particularly when there are signs of cardio-vascular disease, the physician should be very careful not to remove much pleural fluid at a time. He should also restore the intrapleural pressure to its original height, which is probably in excess of the atmospheric pressure. The case from which he deduces these principles was that of a man, aged 22, who had suffered from a pericardial effusion at an earlier date. The author withdrew nearly 2 litres from his right pleural cavity. Soon afterwards he began to cough and choke, bringing up several litres of frothy, rose-coloured sputum. Death seemed imminent, and it was as a desperate resort that the author plunged a needle into the chest, inducing a pneumothorax under a positive pressure by blocking

the needle whenever the patient coughed, and thus preventing escape of air from the chest. Camphor and morphine were injected subcutaneously. The patient's recovery from the most alarming symptoms was prompt, but convalescence was delayed by a subfebrile temperature which lasted for months.

### 292. Active Immunization against Diphtheria.

C. DE LANGE and J. C. SCHIPPERS (*Nederl. Tijdschr. v. Geneesk.*, January 13th, 1923, p. 145), inspired by the good results obtained by Park, Zingher, and other American observers in the active immunization of children against diphtheria, performed Schick's reaction on 90 children in the Emma Children's Hospital at Amsterdam as a preliminary measure, and obtained a positive result in 51 cases, or 55.6 per cent., and a negative result in 39 cases. Like Park, Zingher, and Serota, the Dutch physicians found that there was a tendency for all the children of one family to give a similar reaction, whether positive or negative; 32 of the 51 positive cases were immunized by the injection of toxin-antitoxin. In 24 of the 32 cases a Schick reaction was performed again at the end of six months: the remaining 8 could not be traced. The results were as follows: 6 were still decidedly positive, 6 were feebly positive, and 12 were negative. No bad effects were observed as the result of the Schick reaction. The local and general effects of injection of toxin-antitoxin in infants were very slight; in older children there was occasionally a rise of temperature and slight constitutional disturbance, which disappeared the next day. The injection sometimes produced a slightly tender swelling of the axillary glands, which soon subsided. The authors conclude that it is improbable that active immunization against diphtheria will be carried out in Holland on so large a scale as in America, but they are firmly convinced that the method will be of great value in holiday colonies, orphanages, and other institutions, and will serve to render bacillus carriers a negligible quantity.

### 293. Treatment of Herpes Zoster.

POIROT-DELPECH (*Bull. Soc. de Thér.*, January 10th, 1923, p. 25) has recently treated 8 cases of intercostal or abdominal herpes zoster by the following method, which was advocated by Deboue: 5 grams of picric acid were dissolved in 50 grams each of absolute alcohol and sulphuric ether, and the solution was applied every two days to the lesions, which were allowed to dry and covered with cotton-wool. Internal treatment consisted in administration of 1 or 2 grams of antipyrin according to the severity of the pain. As a rule the pain diminished after the first application of the solution, and the vesicles began to dry up. In six moderate cases a cure was obtained in three to six days, and in two severe cases in nine and twelve days respectively. It was never necessary to use more than five applications. As soon as the vesicles had desiccated and the pain had disappeared an inert powder such as talc or bismuth subnitrate was substituted for the picric acid solution. No relapses occurred. It is important to keep the solution far away from a flame, and not to throw the soiled dressings into the fire.

### 294. Treatment of Anthrax.

J. R. DE SILOS (*Arch. de méd., cir. y esp.*, February 10th, 1923, p. 275) states that, though salvarsan is undoubtedly an excellent drug for the treatment of anthrax, especially the bacteriaemic forms owing to its bactericidal action, other methods should not be neglected, especially the cautery. In the course of 1922 he treated more than half a dozen cases of malignant pustule with success, although he was unable to obtain any salvarsan. All were treated with the thermo-cautery and some with specific serum as well. As the serum was always used at the same time as the cautery, it was difficult to determine exactly how far it was responsible for the good result. De Silos accepts the view that if no specific serum is available any other serum may be used, including normal horse serum. Protein therapy in the form of commercial preparations, or even milk, may also be tried.

### 295. Etiology of Cirrhosis of the Liver.

PROFESSOR KLIENEBERGER (*Zentralbl. f. inn. Medizin*, February 24th, 1923, p. 123) considers that the severe infective diseases of the intestine, particularly enteric and dysentery, play a more important part in the causation of liver cirrhosis than has hitherto been recognized. Cirrhotic liver is strikingly prevalent in Macedonia, Asia Minor, and India—regions where typhoid fever and dysentery are very common

diseases. In Macedonia Krause has found that cases of cirrhotic liver almost always give a history of diarrhoeal disease. In these regions, on the other hand, the commonly assigned causes of liver cirrhosis—namely, alcoholism, syphilis, etc.—are not particularly in evidence, although malaria is common, and may be a factor. Moreover, jaundice is common during convalescence from enteric and paratyphoid; and the bacilli of enteric and dysentery are known to remain for long periods in the gall bladder in many cases. The author has noted many cases of enteric in which the liver was slightly enlarged. In a fatal case of liver cirrhosis in a young man, *post-mortem* examination revealed a healed ulcer in the ascending colon and marked pigmentation of the mucous membrane of the colon—evidence of a previous attack of enteric fever.

#### 296. The Function of the Spleen.

M. H. KAHN (*Amer. Journ. Med. Sci.*, February, 1923, p. 214) reviews the literature relating to the functional activity of the spleen, pointing out that, since the spleen has no external and no known internal secretion, its action cannot be studied directly. Although essentially a lymphatic structure and part of the lymphatic system, its functions are also related to the blood and blood-forming organs and to the liver, to immunity and infection, to the metabolism of iron, and to special blood diseases. Studies of the white blood cell content of the venous blood of the spleen prove that the organ is concerned in blood formation, while one of its normal functions is the capacity for selecting those red blood cells which are to undergo destruction and those which are to continue in circulation. In iron metabolism it acts as a storehouse for the iron liberated from the decomposition of the blood tissues, while the liver is in the main the storehouse of the iron ingested. The spleen exerts a stimulating influence on blood-producing organs, since anaemia due to bleeding or haemolytic poisons recovers much more slowly in splenectomized than in normal dogs. Its exact rôle in digestion is not known, though there is evidence of a pepsinogenic function, and it appears to possess a cholesterolinogenic function. That the spleen produces an internal secretion has been surmised, but is not proved, though, while it probably produces certain enzymes important to its function, such function is shared by other lymphoid structures which continue the function after splenectomy. The general metabolic processes appear to be unaffected by its removal, its function becoming fully compensated for within five or six weeks. In physical diagnosis palpation gives the only definite information as to the size of the organ, though its outline can be fairly well determined by *x* rays; splenic puncture is dangerous, and even in localized infections is to be condemned as a diagnostic method.

## SURGERY.

#### 297. Chronic Empyema.

AS C. EGGERS (*Annals of Surgery*, February, 1923, p. 142) points out, there is probably no suppurative inflammation of any part of the body, except that of bone, which leads to chronicity as often as inflammation of the pleura, the reason being that, in addition to infection, mechanical factors are present, such as negative air pressure, a rigid thoracic wall, and the development of an open pneumothorax. In acute empyema, drainage at the most dependent point usually leads to a cure without any difficulty; certain cases, however, have a tendency from the beginning to become chronic. Some patients may go for months with an accumulation of pus in the pleural cavity unrecognized, and this leads to chronic invalidism; such cases are really avoidable; they should be treated by incision and drainage. There is a class of case which does not heal in the usual time—that is, within one to three months—whilst a number of patients appear to heal well, but this is followed by spontaneous opening of the old empyema wound. The usual causes for these conditions may be found in epithelialization of the drainage canal, or healing may be prevented by the presence of infected granulations along the canal. Osteomyelitis of a rib is sometimes found, and, a sequestrum being formed, keeps up the discharge, or chronic infection of the resected ends of the rib cartilages keeps up the discharge. Treatment of the conditions by curettage of the tract often leads to a cure; when this fails more radical methods may be necessary. Often the drainage opening is found to be contracted or placed at a too high level; in such cases fresh drainage must be established. Many cases which refused to heal rapidly improved when adequate drainage was provided and regular Carrel-Dakin treatment started. In chronic empyema Carrel-Dakin treatment is of

real value; the author records a number of cases where this was adopted with extremely satisfactory results. When cultures from the wound became negative healing rapidly followed. In cases which showed no tendency to heal more radical treatment had to be adopted.

#### 298.

#### Surgery of the Bile Ducts.

GOSSETT (*Bull. et Mém. Soc. Chir. de Paris*, January 30th, 1923, p. 118), in discussing accidental wounds of the bile ducts when carrying out cholecystectomy, advises that the gall bladder should be removed from behind forwards. When removing the gall bladder it is always advisable, before dividing the cystic duct, to identify the cystic duct itself, the hepatic duct, and the common bile duct. If this is done wounds of the common duct will be avoided. The author advises that the cystic duct should be divided first and the gall bladder then separated from neck to fundus. In an earlier case before he adopted this technique, where he wounded the bile ducts, it was necessary to make an end-to-end anastomosis between the hepatic and the common bile duct; the result of this has been completely satisfactory, however. In removing the gall bladder from behind forwards it is easier to find the proper plane of separation from the liver, and this reduces the amount of oozing. After dividing, between two pairs of forceps, the cystic duct near its junction with the common duct, the arteries can be put on the stretch and identified as they reach the gall bladder along the peritoneal fold. They can then be easily tied and perfect haemostasis secured with a single ligature. If the bile ducts are thus carefully isolated and identified complete safety is assured even in cases where an abnormality of the ducts is present. It is also possible to conserve the peritoneum and at the end of the operation place a drain under the sutured edges of the peritoneum. Savariaud advises that accidents may be avoided by slitting up the gall bladder and cystic duct until one reaches the junction of the duct with the common bile duct. If the cystic duct is dilated owing to the presence of a calculus damage to the hepatic or bile duct is avoided by this procedure.

#### 299.

#### Non-parasitic Cysts of the Liver.

O. MARGARUCCI (*Il Policlinico*, Sez. Chir., December 15th, 1922, p. 649, and January 15th, 1923, p. 16) has collected 50 cases of non-parasitic cysts of the liver on which an operation was performed, including two of his own in women aged 58 and 67, as well as six others in which the condition was not found until the autopsy. He adopts Thöle's classification of non-parasitic cysts of the liver into (a) blood and lymph cysts; (b) neoplastic cysts (cysto-adenoma). Blood cysts arise (1) as the result of trauma; (2) from softening of morbid tissue (sarcoma, carcinoma, adenoma, and haemangioma). Lymph cysts originating in dilatation of pre-existing lymphatic vessels contain a transparent yellowish fluid, rich in albumin and chlorides, without bile or mucus, and are invested with epithelium. Neoplastic cysts form the great majority of non-parasitic cysts, and possess the greatest clinical interest. All modern investigations lend support to the view that the so-called cystic degeneration of the liver (plurilocular or polycystic cysto-adenoma) or the solitary epithelial cyst of the liver (unilocular adeno-cystoma) should be regarded as a genuine new growth (cysto-adenoma) derived from proliferation of the epithelium of the bile ducts. Any part of the liver may be the site of formation for the cyst, but the sites of predilection are the inferior surface and the margins. The right lobe is more often affected than the left. The contents of the cysts may be transparent, thin, viscid, or pultaceous, or contain bile, blood, or pus. The diagnosis is based on the history, the long course, and the subjective symptoms (local pain and colic), but chiefly on the results of physical examination, performed if necessary under an anaesthetic. In the great majority of cases the diagnosis is not made until the operation. The prognosis is generally favourable. Blood and lymph cysts are not progressive. As regards the prognosis of neoplastic cysts, multiple cysts, especially when they are associated with similar processes in the kidneys or other organs, have a progressive tendency, and sooner or later prove fatal; whereas the prognosis of solitary cysts is favourable, as their progress is usually slow, and a complete cure can be effected by operation. The following methods of treatment have been employed: (1) evacuant puncture, single or repeated; (2) incision of the cyst wall and evacuation of its contents after laparotomy; (3) total excision of the cyst either by enucleation from the hepatic tissue or by simultaneous removal of the portion of liver substance in which the cyst is embedded. The last method should always be employed in preference to the others when there are no contraindications.

### 300. Inflammatory Tumour of Intestine Associated with *Ascaris lumbricoides*.

K. ANDRASSY and K. HIMMELREICHER (*Zentralbl. f. Chir.*, February 24th, 1923, p. 302) describe three cases of inflammatory ileo-caecal tumour which have recently come under their observation. *Ascarides* were present in the intestine in each case. (1) A male, aged 29; had suffered from vomiting and colicky pains for seven weeks. He had been treated for round worms shortly before admission to hospital. A smooth, slightly movable tumour about the size of a child's head was felt below the umbilicus. At operation, the caecum and lower third of the ascending colon were found to be enormously enlarged, the wall being thick, soft, and oedematous, the surface reddish-yellow and covered with flakes of lymph, with some recent adhesions. The nature of the tumour was not recognized, and resection of caecum and ascending colon was performed, with end-to-side anastomosis. Histological examination showed inflammatory infiltration, especially around the vessels, the cells being chiefly leucocytes with many eosinophiles. A superficial ulcer was present on the mucous aspect of the caecum, about the size of half a crown. The patient made a good recovery. (2) A male, aged 22; severe pain in the right side of the abdomen for thirty-six hours; tenderness and slight rigidity in the right iliac fossa. Appendicitis was diagnosed, but at operation an ileo-caecal tumour the size of a fist was found, with recent adhesions; the caecal wall was stiff, thick, and brawny, and yellowish-red on the surface. Numerous round-worms were felt in the small intestine. The tumour was not removed, and treatment was subsequently directed to the worms. The tumour disappeared completely within a month, and the patient had had no further trouble a year later. (3) A male, aged 22; severe pains in abdomen and vomiting; tenderness at ileo-caecal region. At operation an ileo-caecal tumour was found the size of a fist, displaced upwards and lying under the stomach and transverse colon. The caecum was thickened, yellowish-red, with recent adhesions, and the last few inches of the ileum were intussuscepted into it. The intussusception was reduced and the caecum infolded with a few serous stitches to prevent recurrence; the abdomen was then closed. *Ol. chenopodii* was administered, and in due course seven round worms were passed. The tumour disappeared within a few weeks. In no case did the tumour present the naked-eye appearances characteristic of tuberculosis, actinomycosis, syphilis, or new growth. The authors conclude that the condition was secondary to lesions of the mucous membrane caused by *Ascaris lumbricoides*, that parasite being present in each case.

### 301. Pyelography.

E. PAPIX (*Journ. de Méd. et de Chir.*, December 10th, 1922, p. 848) says that in pyelography substances opaque to x rays are more generally useful than substances transparent to x rays. Collargol in 5 per cent. solution was originally employed, but this was of insufficient strength and the author used a 20 per cent. solution. Iodide of silver has been used, and bismuth subnitrate and bismuth bicarbonate. During the last two years he has used sodium bromide with success. The use of translucent gases such as oxygen or air is useful in cases of renal calculus, and shows up the shadow well. In practising pyelography a small opaque ureteral bougie is passed, whilst two bougies may be used in each ureter at the same time. The injection may be made with a syringe or simply by atmospheric pressure. The latter method is the best, and a pressure of 50 c.cm. of water gives an excellent filling of the ureter and pelvis. The procedure is not more painful than simple catheterization of the ureter when properly performed. In cases of gall stones and appendicitis pyelography allows one to eliminate such conditions as hydronephrosis and other renal conditions. In cases of mobile kidney pyelography is essential to establish the indications for operation; in pyelitis and pyonephrosis it enables a diagnosis to be made of an infected hydronephrosis or a true pyonephrosis. In cystic kidney and in other cysts of the kidney it is indispensable for making a correct diagnosis. In renal calculus the author considers pyelography of great value and an important addition to exploration of the kidney. The paper, which is illustrated with numerous radiograms, emphasizes the great value of this method of diagnosis.

### 302. Intracardiac Injection of Adrenaline in Acute Heart Failure.

E. BAUMANN (*Schweiz. med. Woch.*, February 22nd, 1923, p. 198) has achieved two dramatic successes with intracardiac injections of adrenaline several minutes after the heart had stopped beating. The first patient was an infant, aged 6 months, who was given chloroform for a hernia operation. During the operation the heart beat and respira-

tion ceased (the so-called "white heart-death") and artificial respiration failed. Four minutes after heart beat and respiration had ceased an intracardiac injection of 0.75 c.cm. of a 1 in 1,000 solution of adrenaline was given, and seven seconds later a single heart beat occurred, being followed in two and a half seconds by another, the skin flushing a bright scarlet, and the patient ultimately recovering completely. The second patient was a child, aged 2½ years, whose heart beat and respiration stopped after an attack of coughing (whooping-cough). The intracardiac injection (1 c.cm. of a 1 in 1,000 solution) was given three and a quarter minutes after the heart beat and respiration had stopped. Complete recovery followed after the same bright red flush had appeared as in the previous case.

## OBSTETRICS AND GYNAECOLOGY.

### 303. Interstitial Pregnancy.

ACCORDING to E. VALLI (*Annali di Ostetricia e Ginecologia*, January, 1923, p. 56), the interstitial portion of the Fallopian tube, which in normal conditions has a length of 1 cm. and a lumen 1 mm. in diameter, is the site of the gestation sac in 1 to 2 per cent. of cases of tubal pregnancy. Etiological factors to which importance has been ascribed are congenital or post-inflammatory diverticula of this portion of the tube, nodular salpingitis, and tubal polypi. In about one half of the recorded cases, as in one reported by the author, the local findings have been without etiological significance. Decidual formation in the tube is lacking, according to most authors; but in interstitial as in other forms of ectopic pregnancy there is well marked decidual transformation of the endometrium, which may be expelled as a cast. The sign regarded by Simon and Ruge as indicative of interstitial gestation—namely, a special asymmetrical enlargement of the uterus due to a sessile hemispherical protuberance directed upwards and backwards from one of the angles—is not invariably present and probably disappears after the fourth month. It is probably incorrect to regard the disposition of the round ligament, with respect to the swelling at the angle of the uterus, as constituting a constant or characteristic sign of interstitial pregnancy. There is no recent and well authenticated case of persistence of interstitial pregnancy to term, but in several instances rupture has been followed by persistence for some months of secondary abdominal pregnancy. Rupture, as compared with abortion, is a more frequent sequel of interstitial pregnancy, and takes place usually on the posterior surface of the sac. Diagnosis is comparatively easy when there is acute and profuse intraperitoneal haemorrhage; but cases in which limited haemorrhage after rupture forms a pelvic haematocele are easily confused with inflammatory adnexal disease, or with myoma, situated in the uterus near the tubal attachment. Treatment, which is always operative, should be as conservative as possible; if the pregnancy has not passed the first months, excision of a wedge from the fundal and angular regions of the uterus may be practicable, and has in some instances been followed eventually by normal pregnancy with healthy issue at term.

### 304. Premature Birth Statistics and Congenital Syphilis.

FROM statistics taken from the Dresden Maternity Clinic for the years 1914-22, E. KEHRER (*Zentralbl. f. Gynäk.*, February 10th, 1923, p. 226) finds that there were 1,541 premature births. The Wassermann reaction of the mother was taken in 71.3 per cent. of the cases and was only found to be positive in 11.5 per cent. This figure is considerably less than the figures quoted by other authors—for example, Ruge states that 83 per cent. of premature births are due to syphilis, Seitz 91.6 per cent., Heynemann 60 per cent. Of the premature children, 74 per cent. left the clinic healthy, and 6 per cent. died; in these cases the mother had a positive Wassermann in only 17 per cent. In 21 per cent. of the stillbirths the mothers gave a positive Wassermann reaction, and 20 per cent. of the premature children who died in the clinic were also syphilitic. In the 125 premature deliveries where the mothers showed a positive reaction, 37 per cent. of the infants left the clinic healthy, 15 per cent. were macerated, 33.5 per cent. stillborn, and 14.5 per cent. died shortly after birth. It was also found that the syphilitic premature children were more liable to die shortly after birth than the non-syphilitic—namely, 14.5 to 6 per cent. Among the macerated foetuses expelled during the period investigated 41.3 per cent. were syphilitic, which again is a much lower percentage than is generally estimated, Seitz putting the percentage at 80. On the strength of his statistics the author considers that syphilis does not play a great part as a cause of premature delivery, at any rate not the important rôle that has usually been attributed to it. On the other hand, he regards the prognosis for the child of a syphilitic mother to be bad, as intrauterine death is likely to

occur, and if born alive the child is more liable to die during the first few days of life than are the children of a healthy mother.

### 305. Induction of Abortion.

J. A. VAN DONGEN (*Nederl. Tijdschr. v. Geneesk.*, February 10th, 1923, p. 538), who recently dealt with the subject of criminal abortion (see EPITOME, February 24th, 1923, No. 175), now discusses the legitimate indications for the interruption of pregnancy. As a general rule abortion is only indicated when a sick woman becomes pregnant or a pregnant woman falls sick and the risk to life can only be removed by interruption of pregnancy. Simple as this formula appears, the decision in individual cases is usually difficult. It is hard to draw up a list of indications for abortion, as in some diseases in which it is hardly ever required circumstances may arise which call for the interruption of pregnancy. Hyperemesis gravidarum is regarded by most writers as so serious a condition that induction of abortion is the only remedy. Van Dongen, on the other hand, maintains that almost all cases of pernicious vomiting in pregnancy can be cured by medical treatment—such as diet, drugs, suggestion, rest, change of environment, and in severe cases rectal or hypodermic injections—and he has personally never had to induce abortion for this reason. In pulmonary tuberculosis interruption of pregnancy is justified only in rapidly progressive cases in the first half of pregnancy. In latent tuberculosis abortion is not indicated. In renal disease abortion is indicated only in the presence of albuminuric retinitis or threatening anaemia or cardiac failure. Van Dongen has seen several women with chronic nephritis and severe albuminuria go to term and be delivered of a normal child after treatment by special diet and rest. In only one case of pyelitis gravidarum was he compelled to induce abortion. Patients with heart affections, both myocarditis and valvular disease, generally stand pregnancy and delivery well, but abortion may be indicated when failure of compensation takes place and cannot be remedied in any other way. A severe degree of acute hydramnios may also be an indication for induction of abortion. As regards the method to be employed, in the first half of pregnancy the cervix should be dilated with a laminaria tent and the uterus emptied with or without an anaesthetic, preferably without one in cases of severe heart and lung disease. In the second half of pregnancy abortion should be induced by puncture of the membranes, with or without insertion of a laminaria tent. If the placenta does not come away by itself, Crèdè's method of external expression should be tried.

## PATHOLOGY.

### 306. Achondroplasia.

E. A. D. CLARKE and E. C. KOENIG (*Bull. Buffalo General Hospital*, January, 1923, p. 5) report a case of labour in an achondroplastic dwarf with delivery by Caesarean section of an achondroplastic child, and illustrate their paper with interesting photographs and radiographs of mother and child. The mother was born in America of Polish parents, who were apparently of normal size, and her three brothers and two sisters were alive and of normal structure. Obscure as the cause of achondroplasia still is, its pathology is now fairly well understood. Kaufmann found that the cause of the shortness of the extremities lay in a defective growth of the cartilage and premature cessation of endochondral ossification. The diaphyses remain short, but often become sclerotic as a result of relatively increased periosteal bone formation. In accordance with this conception of the deformity, which amounts to a nutritional disturbance of the cartilage, Kaufmann chose the name "chondrodystrophy" in preference to "achondroplasia," which infers an absence of cartilage formation. Dandy has pointed out that the enlargement of the head in chondrodystrophy is not merely relative to the size of the body but absolute, and that this enlargement is due presumably to hydrocephalus, which tends to cease spontaneously.

### 307. Etiology of Paralysis of the Recurrent Laryngeal Nerve.

V. GUTTMANN (*Arch. Intern. de Laryngol., d'Otol. et de Rhinol.*, January, 1923, p. 13) says that paralysis of this nerve is usually a sign of some grave disease, and it is important to be able to identify the latter. Such conditions as aneurysm of the aorta or right subclavian artery, mediastinal, peritracheal, and peribronchial glands are well known. The author cites a number of cases in which the paralysis was said to be caused by hypertrophy of the left auricle, but shows that the

pulmonary artery always intervenes, and considers that the paralysis was probably caused by glands. Kahler has, however, shown that the left bronchus may be displaced by the enlarged auricle and press on the nerve. The central nervous system may be at fault as in bulbar paralysis, amyotrophic lateral sclerosis, and other lesions of the mid and hind brain. Removal of the cerebral hemispheres in animals does not cause paralysis so long as the quadrigeminal bodies are left. The nerve itself may be affected by lead or arsenic or any of the exanthemata and often by influenza. Goitre, cervical adenitis, and, more important, carcinoma of the oesophagus, may cause paralysis by pressure or infiltration. A certain number of cases of gout have been complicated by affection of the crico-arytenoid joint and consequent immobility of the cord. Such cases simulate recurrent nerve paralysis.

### 308. The Nature of Local Immunity.

It has been suggested that the acquired local immunity of certain tissues results not from the presence of antibodies, but from some special property of the cells—a cellular immunity, in fact. To discover whether this is the case, R. TURRÓ and P. DOMINGO (*C. R. Soc. de Biologie*, February 17th, 1923, p. 410) injected 6 guinea-pigs intratracheally with a killed emulsion of typhoid bacilli containing about 8,000 million organisms. While controls injected with simple saline showed a light hyperaemia, disappearing in six hours, the experimental animals developed severe congestion of the bronchial mucosa, together with bronchopneumonic foci in the lungs. Examination of the bronchial exudate showed that the bacilli underwent a process of degeneration and agglutination between the first and second days, which disappeared completely shortly afterwards. By extracting the bronchial mucosa with acetone, drying the extract *in vacuo*, and suspending the powder in saline, a fluid was obtained which had marked bacteriolytic and agglutinating properties. Similarly with an extract of the lung tissue. Titration of the agglutinin content of these two extracts revealed a titre of about 1 in 1,000 for the former on the sixth day, and 1 in 400 for the latter on the seventh day. At this time the agglutinin titre of the serum was only 1 in 10; this, however, began to rise subsequently, and reached a maximum of 1 in 2,500 on the fifteenth day. Another set of guinea-pigs was treated in the same way, but received a second dose of bacilli on the ninth day. The resulting congestion of the broncho-pulmonary tissues was less marked after the second injection, and the extracts obtained six days later showed a bacteriolytic activity twice as great as that of the extracts made after the first injection. In another four days the titre declined in the tissue extracts, while it increased progressively in the serum. From these facts the authors conclude that local immunity is due not to phagocytosis, but to the action of ferments—agglutinins and bacteriolytins—which are produced locally in the cells of the tissues affected.

### 309. Effect of Antiseptics on the Bacterial Flora of the Upper Air Passages.

A. L. BLOOMFIELD (*Johns Hopkins Hosp. Bull.*, February, 1923, p. 65) has studied the effects on the normal bacterial flora of the upper air passages of the antiseptics commonly employed in rhinological practice, and found that, though it is possible in some cases to modify the bacterial flora by intensive treatment, no essential or permanent alteration can be produced. This failure is partly due to the fact that the organisms found in the mouth have established a vital alliance with the mucous membrane of the host, involving a close relationship both functionally and anatomically, for such organisms grow, not only on the mucous membrane, but in the superficial layers as well—probably in crevices between the epithelial cells and in the orifices of the small mucous glands. Under other conditions organisms may become established in a focus of diseased tissue, such as tonsil, adenoid, or sinus, in a somewhat analogous fashion. The bacteria are very firmly lodged in the tissues, and therefore chemicals applied to the mucous surfaces cannot effect sterilization without destroying the superficial layers of epithelium at the same time. Even when drugs were used which caused a distinct red colour in the treated membrane after twenty-four hours the flora remained essentially unaffected. In attempting to reconcile these findings with the clinical impressions of experienced laryngologists, to the effect that the application of antiseptics is of value in the treatment of acute and chronic inflammations of the nose and throat, two considerations must be kept in mind. In the first place, it is possible that inflammatory processes due to some unknown type of virus may be affected by antiseptics in a manner different from those due to known bacteria; or, on the other hand, it may be that a beneficial effect indirectly follows irritation, hyperaemia, or ischaemia produced by the drug.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## MEDICINE.

### 310. Infection of Convalescent Blood in Pertussis.

In view of the beneficial results claimed by some workers who have treated cases of whooping-cough with injections of the blood of patients convalescing from the disease, M. LESSÉ and ALLO PETOT (*Bull. et Mém. Soc. Méd. des Hôpitaux de Paris*, March 8th, 1923, p. 323) considered it worth while to report their own findings on the subject. Children were chosen who had suffered from pertussis for at least a month, who experienced not more than one or two spasms of cough a day, who showed no clinical evidence of syphilis, and who had a negative Wassermann reaction. From these blood was taken by venous puncture and injected in 10 to 20 c.cm. doses intramuscularly every day or every other day into patients with the fully developed disease. No beneficial effect whatever was noticed on the cough, even after ten or twelve injections; though the general health of the children seemed to improve considerably, as shown by increase in weight and by the general appearance. With patients suffering from bronchopneumonia the injections, on the contrary, were given with excellent result. Three children showing disseminated foci of bronchopneumonia, with dyspnoea, cyanosis, and high fever, rapidly improved after three injections of 10 c.cm. of convalescent blood; the lung disease cleared up, leaving the pertussis to continue its normal course. The blood of normal children, injected under similar conditions, proved valueless.

311. H. MERY and LUCIEN GIRARD (*Bull. et Mém. Soc. Méd. des Hôpitaux de Paris*, February 22nd, 1923, p. 243) refer to the progress of specific human serotherapy in the treatment of the exanthemata—rubeola, scarlatina, small-pox, and poliomyelitis. The authors have injected the blood of a patient, convalescent from whooping-cough, into a child dangerously ill from the same disease. The results were remarkable. A female infant, aged 8 weeks, contracted pertussis from her mother, who had had a paroxysmal cough three or four times a day for three weeks. At first the child's illness ran a mild course—it persisted for nearly two months without signs of bronchopneumonia; the temperature oscillated between 39° and 40° C., and she became emaciated, with frequent paroxysmal cough. The authors took 20 c.cm. of the mother's blood, diluted it with 1 c.cm. of a 10 per cent. sodium citrate solution, and injected 5 c.cm. of this citrated blood subcutaneously into the child's thigh. At night the temperature fell to 36.6° C., and the child was slightly collapsed; there was no local reaction; she slept through the night with no cough. Next day the temperature was normal and the attacks of cough were reduced to ten. On the following day an injection of 10 c.cm. of the citrated blood (which had been kept in an ice-chest) was well borne. Four days later there was no fever and the attacks of cough were reduced to one or two per diem. The child gained weight and was definitely cured. The authors consider that this case shows that the facts observed in the serotherapy of rubeola and scarlatina may apply equally to whooping-cough.

### 312. Prophylactic Injections in Measles.

DEBRE and RAVINA (*Bull. Soc. Méd.*, Paris, February 15th, 1923, p. 226) give their experiences in the use of a serum taken from measles convalescents, as a prophylactic. The serum is tested by the Wassermann reaction before use. From 2½ to 3 c.cm. of the serum are injected intramuscularly. Children who have been exposed to measles but showed no signs themselves were vaccinated with the serum, and weakly children who were in danger of being exposed were also vaccinated, and attention was paid to certain crèches. The vaccination was particularly successful in preventing outbreaks of measles in the hospital. If a child suffering from measles was admitted by mistake, all the other children were immediately vaccinated, and by this means the authors say they have been able to escape outbreaks of measles. It does not appear that the immunity secured by this vaccination lasts long. In some cases after vaccination a modified benign form of measles occurred, characterized by very slight catarrhal symptoms, no Koplik spots, slight fever, and moderate rash. To bring about this modified measles the authors recommend injecting infected children (that is, children incubating for measles) about the seventh to the tenth day of the incubation period.

### 313. Control of Cerebro-spinal Meningitis.

F. WIRING (*Ugeskrift for Læger*, March 8th, 1923, p. 161) gives an account of how he limited to a certain district in Greenland an epidemic of cerebro-spinal meningitis. It began in the autumn of 1920, when a whaler reached Greenland and disregarded the port regulations, allowing sailors to go ashore on August 28th to 30th. The epidemic began as a comparatively mild disease, but after successive passages through susceptible persons it became more and more violent. A cordon was drawn around the infected area, and effective isolation was maintained for ten months in spite of threats and riots. The quarantine regulations were suspended in August, 1921, the last case having occurred on June 19th. The disease did not spread farther, and it would thus appear that if effective isolation of an infected area is maintained long enough the disease dies out for want of suitable susceptible material. In 51 cases (89 per cent. of the total) the onset of the disease was sudden; in the remainder it was insidious. The two most effective remedies proved to be hexamethylenetetramine (4 to 5 grams daily for adults) and lumbar puncture. This was repeated at intervals of one to three days, and whenever convulsions or headache became severe. Its action was remarkably prompt, and it almost invariably gave relief.

### 314. Infection of Dysentery and Tuberculosis in Mental Hospitals.

B. H. SHAW (*Journ. of Mental Science*, January, 1923, p. 24) discusses the paving of yards and treatment of floors in mental hospitals in relation to the incidence of asylum dysentery and tuberculosis. An epidemic of dysentery was traced to a bed-ridden patient of tidy habits, from whom Flexner's bacillus must have been carried by flies. Further infection appeared to have been spread by the dust in the rooms or yards used by uncleanly patients. Experiments showed that dysentery bacilli can remain alive for a long time in dust if not exposed to direct sunlight. Shaw therefore recommends that all parts of the exercise yards which are not exposed to direct sunlight, as under north walls, should be concreted, and special attention should be paid to the cleansing of the floors of rooms. He found that fewer cases of diarrhoea and dysentery had occurred in wards the floors of which were scrubbed with carbolic soap three times a week than in those with polished floors. The high mortality from tuberculosis in asylums he considers to be also chiefly due to dust contamination. Experiments showed that the dust in the air of a ward fifteen minutes after sweeping, either with or without damp sawdust and tea-leaves, contained far more micro-organisms than after the use of a vacuum cleaner. He therefore recommends the general adoption in asylums of a central exhaust system of vacuum cleaning; if this is impossible the floors should be polished or swept only after the patients have left the rooms. He insists on rigid attention to every detail of ward hygiene.

### 315. Treatment of Amoebic Dysentery.

A. W. SELLARDS and L. LEIVA (*Philippine Journ. of Science*, January, 1923, p. 1), from experimental amoebic dysentery produced in cats with a moderately virulent strain of *Entamoeba histolytica*, found treatment successful with emetine and with quinine, but papaverine was inefficacious. Large doses of quinine were necessary, but, unlike emetine, repetitions could be tolerated for several days. Investigations with plants belonging to the family Simarubaceae, popular with the natives in the tropics as remedies against dysentery, showed that *Castela nicholsoni* possesses a toxic principle well borne by patients in therapeutic doses. In five cases prompt relief of symptoms with disappearance of the amoebae followed its administration, and, after several months, re-examination in four of the cases showed one relapse, two remaining well, but with cysts of *Entamoeba histolytica* in the stool of one; the fourth had no symptoms and the stool was negative microscopically on two examinations. *Castela nicholsoni* compares very favourably with emetine both in its immediate and final therapeutic effects, and its administration, being by mouth, is simple, but neither it nor emetine as used at present is an ideal agent for the eradication of *Entamoeba histolytica* infections in man. In the absence of standardization of dosage concentrated extracts of the plant were used in which the fatal dose for rabbits had been previously estimated as a guide for commencing administration in man.

316. *Impetigo Contagiosa.*

F. C. KNOWLES and H. G. MUNSON (*Arch. Derm. and Syph.*, March, 1923, p. 376) call attention to the seriousness of institutional epidemics of bullous impetigo contagiosa—in infants. Recorded outbreaks in institutions having the care of infants show the rapidity of their spread, with a mortality rate as high as 50 per cent. In one outbreak bleb formations occurred on the bodies of three babies less than a week old, and within twenty-four to forty-eight hours nine other babies, three nurses, and two nursing mothers became affected; the nurses on the fingers, ears, and face, and the mothers on the nipples and buttocks. The adults' lesions were mild and yielded to treatment, but in the babies the constitutional symptoms were severe, although not fatal; other epidemics are recorded with a mortality rate of from 30 to 50 per cent. within ten days. The lesions are usually located on the face and trunk and may be extensive; when developing on the lips with extension to the mucous membrane, death may result from inability to take nourishment, while in other cases the fatal issue appears to be due to toxic absorption from the large areas involved. While the streptococcus is the causative organism in the commoner types, the *Staphylococcus pyogenes aureus* is responsible for the bullous type, pure cultures being obtained from unruptured blebs, and probably the different types of lesions are caused by different strains or varieties of cocci. Immediate isolation of all cases is essential, with the exercise of special care by nurses and attendants to avoid further spread.

317. *The Prognostic Value of the Wassermann Reaction in Syphilis of the Aorta.*

T. E. HESS THAYSEN (*Acta medica Scandinavica*, February 22nd, 1923, p. 543) has investigated 60 cases of aortic disease with a view to finding answers to the questions: (1) Do cases with a consistently positive Wassermann reaction fare worse than those with a consistently negative Wassermann reaction? (2) Does the conversion of a positive to a negative Wassermann reaction improve the prognosis? Of the 49 patients with a positive Wassermann reaction 19 showed no symptoms, the disease being detected in the course of routine examinations. Of the 11 patients with a negative Wassermann reaction 3 showed no symptoms. As far as these figures are concerned, there would seem to be little relation between the behaviour of the Wassermann reaction and the frequency with which the aortic disease gave rise to symptoms. A comparison of the fate of the Wassermann positive and negative patients has led the author to conclude that this reaction is of practically no prognostic value. Even when a positive was converted to a negative reaction by specific treatment the prognosis did not seem to be improved.

## SURGERY.

318. *Neuro-Otological Examination of Cases of Brain Tumour.*

D. E. S. WISHART (*Journ. of Laryngol. and Otol.*, March, 1923, p. 109) has made an elaborate investigation of eleven cases of brain tumour from an otological standpoint. The results of the tests have all been verified at operation, autopsy, or both. The cochlea was tested in the ordinary way, using a fork of 128 d.v. and the investigator's ear as a control. The vestibular organ was tested after Bárány's method. Spontaneous nystagmus, past-pointing, co-ordination, and falling were noted. Caloric tests were performed with water at 68° F. with each ear 30 degrees forward and 60 degrees backward for the vertical and horizontal canals respectively. Rotation tests were performed on those patients who were in a condition to undergo them. In either case particular attention was paid to nystagmus and past-pointing. Careful ophthalmic, neurological, and x-ray examinations were carried out and exploratory puncture of the lateral ventricle was resorted to, in some cases followed by pneumo-ventriculography. Very full notes are given of eight of the cases, and by careful reasoning a very accurate estimate was arrived at in all of the cases except those in which the tumour was located in the frontal lobe. There were five cases of subtentorial intracerebellar tumour. In these the cochlear portion of the eighth nerve was not affected, but in each case there was some interruption of the vestibulo-cerebellar-oculomotor tract leading from either the horizontal or vertical series of canals of both sides, but not from both the vertical and horizontal series, thus showing that the lesion was not one affecting the end organ. In one case impulses from all canals of both sides were blocked—this was a case of tumour of the pons and medulla. There were three cases of subtentorial extracerebellar tumour, in which both cochlear and vestibular nerves, and to a varying extent other

cerebral nerves of one side, were affected, but the nerves of the opposite side escaped. These were all cases of tumour of the cerebello-pontine angle. The three cases of tumour of the frontal lobe gave no vestibular or cochlear abnormalities and could only be diagnosed as "tumour, not subtentorial." It is important to note that none of these cases was complicated by old-standing middle-ear disease, which makes the otological investigation of such cases a matter of much greater difficulty.

319. *Cysts of the External Semilunar Cartilage of the Knee.*

D. B. PHEMISTER (*Journ. Amer. Med. Assoc.*, March 3rd, 1923, p. 593) reports what are apparently the first two cases of this condition to be recorded in the United States. Cyst formation in the external semilunar cartilage is evidently a somewhat rare condition. It was first described in 1904 by A. Ebner (*Münch. med. Woch.*, vol. 51, 1904, p. 1737), and of 12 cases described subsequently 8 were also in Germany and 4 were recorded in England by R. Ollerenshaw (*Brit. Journ. Surg.*, April, 1921, p. 409). The pathological findings in these cases are identical with those of colloidal cystic swellings which develop in various connective tissues, especially on the back of the wrist, and are commonly called ganglions. Trauma seems to have played a part in some cases, but it is of less importance than in ganglions of other locations, particularly those about the wrist. The pathological change is essentially a degenerative one, and most of the phenomena of inflammation are absent, which is strongly against a bacterial cause of the disease. The cysts seem to attain their maximum size within a few weeks, after which they remain stationary and continue to produce pain and a variable amount of interference with motion in the joint until they are removed. There is no recorded instance of spontaneous disappearance, either of the symptoms or of the swelling. The treatment consists in operative removal of both the cyst and the external semilunar cartilage. In four instances the cyst alone was removed, and in two of these cases symptoms returned shortly afterwards, necessitating a second operation. Excision of both cyst and cartilage has resulted in a complete cure in all cases in which it has been practised.

320. *Hernia of the Bladder in Children.*

OLIVA (*Arch. Ital. di Chirurg.*, January, 1923, p. 534) records two cases of this rather rare condition operated upon, and reports briefly the sixteen cases he has been able to find in medical literature. One of his two cases was a boy aged 8 years, and the other a girl aged 10; both of these were crural herniae, which is a rarer situation than in the inguinal site—11 per cent. against 89 per cent. Males are more affected than females (94.5 per cent.), and mostly on the right side (89 per cent.). These herniae are paraperitoneal or extra-peritoneal, never intraperitoneal. They may be due to a congenital weakness of the hernial rings or to the position of the bladder, or they may be acquired as a sequel of inflammatory adhesions. The symptoms are indefinite and all the cases have been diagnosed during operation and not clinically. Points suggesting vesical hernia are the presence of a pre-vesical lipoma, the reddish-grey colour of the suspected body, the direction of the peduncle towards the middle line and pubes, the increase in size when fluid is introduced into the bladder, and the existence of vermicular contractions. Strangulation and calculi are the only complications hitherto recorded. Treatment consists in reduction of the herniated bladder, resection of the sac and prevesical lipoma.

321. *Treatment of Anaemia in Children by Blood Transfusion.*

H. OPITZ (*Klinische Wochenschrift*, February 26th, 1923, p. 400) draws attention to the value of blood transfusion in hastening recovery from the anaemia of alimentary origin in children. Such anaemia under usual treatment often persists for weeks or months, and renders the child specially liable to infectious diseases during this period. To limit this anaemic period as much as possible, blood transfusion has been employed in Stolte's clinic. In the child the blood-forming organs have a greater work to perform than in the adult. These organs have not only to keep the blood condition up to the normal level, but they have also to increase the volume of blood along with the growth of the child. Hence deficiency in blood formation is very liable to occur. Relief is possible either by diminishing the degeneration of blood elements, or by the addition of red corpuscles from another individual to neutralize the defect. The first method is often impossible owing to our ignorance of the exact pathology; but transfusion of citrated blood has been carried out in 22 cases (70 transfusions) in Stolte's clinic, with surprisingly good results. There can be no doubt, according to the author, that the red corpuscles of the transfused blood remain active. The haemoglobin and red corpuscles of the

patient's blood increase immediately; slight remissions occur, but if the blood condition is once raised to the normal level this is maintained. Severe cases only of anaemia were treated by transfusion (cases in which the red corpuscles were under one million). By transfusion the blood condition was rapidly brought to the normal level. Longer than three weeks was never required to do this, often only eight to ten days, once only five days. The transfusion not only appears to check the anaemia but to lead to a real recovery.

### 322. The Incision for Gall-stone Operations.

H. SIMON (*Zentralbl. f. Chir.*, March 3rd, 1923, p. 345) uses the middle-line incision for operations on the gall bladder and biliary passages, in preference to the more usual lateral incisions, in which the rectus muscle is split, divided, or retracted. He has used it in his last twenty cases where cholecystectomy was required, and always with success. There is a considerable saving of time as compared with the use of muscle-splitting incisions, particularly in closing the abdominal wall; and as the biliary passages lie practically in the middle line a median approach gives, if anything, better access to these than a lateral. If it is found that the gall bladder is somewhat difficult to get at, the middle line incision can be supplemented by a transverse incision at any time; but the author has always managed to avoid this, preferring to lengthen the incision downwards below the umbilicus in such cases.

### 323. The Frequency and Diagnosis of Paraneuritic Abscess.

F. FRANKE (*Deut. med. Woch.*, February 16th, 1923, p. 214) comments on the fact that paraneuritic abscess is very common and yet is seldom thought of when it occurs. In none of the 5 cases recently seen by the author had the correct diagnosis been made by the patient's medical attendant. This state of affairs is the more deplorable as recovery depends largely on early operative treatment. With regard to the frequency of this disease, one surgeon alone has recorded 26 cases, another has seen 20 within a few years, and a third 12 within three years. The disease is usually secondary to some trifling septic focus, such as a boil or a whitlow, or even a slighter condition; but as the primary focus has often healed before the paraneuritic abscess is diagnosed, the former is frequently overlooked. In most cases the onset or the disease is sudden, with fever, rigors, and severe pain. There may be no local signs, and the symptoms may be those of obscure septicaemia or typhoid fever. Little help is given by examination of the urine, which may be practically normal. There are two important helps to diagnosis: the one is exploratory puncture, repeated frequently if necessary; the other is watching the movements of the diaphragm on the screen. A further point is always to bear in mind the possibility of this condition. In the past it has unfortunately been discussed almost exclusively in the special surgical publications.

### 324. Optic Neuritis of Dental Origin.

H. VILLARD (*Bull. Soc. des Sci. Méd. et Biol. de Montpellier*, January, 1923, p. 126) observes that the connexion between dental and ophthalmic pathology has been closely studied of late, and some ophthalmic surgeons think that dental disease is the cause of a large number of eye diseases—for example, iritis, retinal haemorrhages, optic neuritis, and even of detachment of the retina and glaucoma. Villard describes the case of a woman, aged 34, whose general health was very good, but who complained of rapid deterioration of vision in the right eye; examination showed a typical retrobulbar neuritis. The left fundus was normal. Villard could find no probable cause for the neuritis, except the unhealthy state of the teeth, especially in the right upper jaw. The patient was sent to a dentist, who extracted all the septic or suspected teeth and roots. In two days the vision became almost normal, and in three weeks the right visual acuity was greater than that of the left eye. Villard concludes that in certain exceptional cases dental infection is the direct cause of retrobulbar neuritis, and that extraction of the diseased teeth produces a rapid improvement and ultimate cure of the optic neuritis. Carrère, commenting on this case, related that of a woman, aged 50, whose visual acuity (left) was seriously impaired, with a central scotoma for white and colours. No cause for the acute retrobulbar neuritis could be found, except that the patient wore a denture over a number of very carious roots, and before this optic neuritis occurred the patient had had dental neuralgia, and had had the most severely infected roots extracted. This did not relieve the pain nor improve the vision. However, in eight days there was marked improvement, and ultimately the vision in the left eye was completely restored. Carrère considers that no other explanation of these cases is possible than that they are of dental origin.

## OBSTETRICS AND GYNAECOLOGY.

### 325. Ovarian Transplantation.

M. J. G. DE LA SERRANA and F. H. GARCIA (*Clin. y Lab.*, March, 1923, p. 225), who report three illustrative cases, suggest that the ovary may be transplanted in the same patient (auto-transplantation), from another woman (homo-transplantation), or from an animal (hetero-transplantation). Auto-transplantation has, they state, been successful in more than 80 per cent. of Blair Bell's cases. The site in which the graft is made varies with different operators. Manclaitz selects the vesico-uterine peritoneal fold; Pankow the broad ligament; Schickele, Morris, and others the subcutaneous cellular tissue; Tuffier, Scheurer, Brayne, and others the abdominal rectus. Some surgeons, such as Pankow, Sauvé, Scheurer, Tuffier and Vignes, Zahner and Rouville, use the whole ovary but Unterberger prefers fragments only, provided their size be not less than one-third of the whole gland. When the corpus luteum is transplanted, a monthly enlargement of the graft occurs in 20 per cent., when the medullary portion is transplanted enlargement occurs in 33 per cent., and in transplantation of the cortical portion in 70 per cent. In the authors' first cases auto-transplantation of portions of each ovary was performed into the rectus abdominis and subcutaneous tissue in a woman aged 24, for scanty and painful menstruation. Amenorrhoea without other signs of castration lasted until five months after the operation, when menstruation reappeared. In the second case subcutaneous injection of two fragments of ovary removed from a patient with chronic adnexitis was made into a woman suffering from amenorrhoea and severe ovarian pain. The operation was so far successful in that the pain disappeared, although menstruation did not return. In the third case, in which a portion of an ovary was transplanted from a woman with a fibroid uterus into a girl aged 15 suffering from amenorrhoea, the menses were re-established and considerable improvement in the psychical condition occurred.

### 326. Carcinoma of the Cervical Stump.

L. DAVIS (*Boston Med. and Surg. Journ.*, March 8th, 1923, p. 304) investigates the evidence against the routine operation of supravaginal hysterectomy for fibroid tumours on account of the alleged subsequent inflammatory changes and liability to carcinoma arising in the cervical stump. Of 123 cases of cancer of the cervix eight (6.5 per cent.) occurred in the stump after supravaginal hysterectomy for fibroids at periods varying from five to twenty-four years in three cases, two years in three cases, and less than one year in two cases after operation, and the previous reports of the prevalence of its incidence after such operation are confirmed by the experience at the Massachusetts General Hospital during the last five years. Such incidence may be regarded as from 2 to 3 per cent. or more, in accordance with the accuracy with which coexistent carcinoma was detected at the operation and the length of time the cases were kept under observation. Theoretically total removal of the uterus is the ideal operation provided it can be performed without raising the mortality rate above the level of the incidence of the disease itself, but such routine complete hysterectomy in the hands of the average surgeon would probably result in a rate above that level. Every case should be previously carefully investigated, the cervix inspected, and the uterine cavity curetted, and any suspicious tissue examined under the microscope, a total hysterectomy being undertaken if cancer is present. If, however, there is no evidence of cancer, a supravaginal hysterectomy may be performed unless the clinical appearance of the cervix is suspicious. Every case of incomplete hysterectomy should be carefully watched and any early recurrence in the stump treated either by radical abdominal excision, or by radium, which offers the best chance in the great majority of cases.

### 327. Acute Inversion of the Uterus.

G. ALBANO (*Annali di Ostetricia e Ginecologia*, February 28th, 1923, p. 94) finds that in the three obstetric clinics in Rome 7 cases of acute puerperal inversion of the uterus have been recorded among 51,000 labours during the past fourteen years. Five patients were primiparae, and all were aged less than 30. In three cases the inversion was complete, and two of these patients died shortly after reposition had been accomplished. In four cases persistent adherence of the placenta was noted, and in two instances traction on the umbilical cord had been made. The author is inclined to regard the ultimate cause of uterine atony and inversion as lying in a hypofunction of the sympathetico-tonic endocrine glands. He quotes Mansfeld as having found marked hypoplasia of the suprarenal medulla of both sides at autopsy in a primipara aged 21, dead after uterine inversion, and describes

stigmata of hypopituitarism found in one of the cases related by himself. In the correction of the inversion pressure on the angular zones of the uterus is sometimes found to be more effective than on the central region of the fundus. H. KÜSTNER (*Arch. f. Gynäk.*, March 17th, 1923, p. 203) describes two cases of partial uterine inversion occurring in primiparae aged respectively 21 and 41. In both a portion of placenta was firmly adherent to the posterior uterine wall; in one reposition was accomplished without an anaesthetic, but in the other chloroform was given and it was not found possible to detach the placenta until the inversion had been corrected.

### 328. Symptomatology of Intraperitoneal Bleeding.

SCHMID (*Zentralbl. f. Gynäk.*, February 10th, 1923, p. 234) draws attention to an important sign of intraperitoneal bleeding, which was first noted by Hofstatter in 1909, and later by Cullen in 1919, who definitely recognized it as a sign of a ruptured extrauterine gestation. The sign alluded to is a bluish-green discoloration round the umbilicus, which is associated with an umbilical hernia. The author quotes a case in which the clinical signs were very doubtful, but which was diagnosed as a ruptured extrauterine gestation chiefly on account of an umbilical hernia the size of a cherry, which had a blue-green glimmer, there being no history of sudden rupture, but on operation the diagnosis was substantiated. He gives the sign the name of "haematomphalos," and concludes by saying that if one looks for it it is present in many cases of intraperitoneal haemorrhage, and if it is found it is certain that internal bleeding has occurred.

### 329. Twin Pregnancy in the Fallopian Tube.

L. B. AREY (*Surg., Gyn., and Obstet.*, March, 1923, p. 407) publishes abstracts of the essential anatomical facts from all the cases of tubal twin pregnancy hitherto recorded, forty in number. The commonest plural pregnancy of this sort involves one tube and the uterus. Two new specimens of unilateral tubal twins aged about six weeks are described by the author. In the first the embryos were enveloped in a single amnion, and arising from a common yolk sac two stalks entered the respective umbilical cords—a conclusive demonstration of the origin of homologous human twins from the same ovum. In the other pair of twins, each of which possessed its own amnion, it was proved by examination of serial sections of the umbilical cord that one embryo possessed no yolk sac. The conclusion is drawn that the yolk sac is a vestige unessential to growth or to vascular differentiation. Arey points out that single-ovum twins arise at a later stage than is commonly supposed; the invariable existence of a common chorion proves that this takes place at a date subsequent to the differentiation into an inner cell mass and an outer shell of trophoctoderm.

## PATHOLOGY.

### 330. The Development of Tar Cancer.

P. MENETRIER, A. PEYRON, and J. SURMONT (*Bull. du Cancer*, January, 1923, p. 10) record experimental work on the ears of rabbits and skin of mice relating to the stages observed in the development of tar cancer. Their observations point to the existence of true pre-cancerous stages and negative the importance of the part played by inflammatory reaction in the artificial production of cancer. First there is a rapid falling out of the hair, atrophy of the sebaceous glands, thickening of the epidermis, and increase of the inter-papillary prolongations analogous to that seen in buccal leucoplakia. Development then proceeds in two different directions—hyperplasia of the follicular type and of the simple papillomatous type. A section of the ear of a rabbit five weeks after the first application of tar shows a loss of the characteristic elements in the hair follicle, the sebaceous cells appearing to be completely surrounded by a thickened and proliferation layer. Alongside the follicle are noted thin elongated and often broken papillary buds. Cornification in the centre of the papillary prolongations is normal. In the case of an early papilloma the differentiation between gland and follicles has disappeared. The epithelial covering is somewhat thickened, the proliferating layer has a faintly wavy outline, and the melanoplastic zone shows a regular hypertrophy. The papilloma, at first flat, later shows a tendency to the formation of papilliform vegetations and of a great number of chromatophores, which invade even the true skin. There is no notable inflammatory reaction in the connective tissue of the skin. In the transitional stages, when malignancy is developing, the appearances vary according as the origin is follicular or papillary. In the first case the basal membrane ceases to be distinct, and buds are thrown out from the proliferating

layer into the connective tissue—a point of importance which is against the theory of inflammatory origin. Only beneath an ulcerated surface is there a superficial infiltration of polymorph and lymphocyte cells. In the case of papillary formations there is the same penetration of the basal layer into the connective tissue. At this stage the chromatophores disappear, while the formation of cornified "balls" continues. On the periphery and at the extremity of these papillary prolongations is observed a curious network giving an appearance of continuity between the epithelial and connective tissue elements. In fully developed malignant tissues the neoplasm is clearly defined on the two sides from healthy tissues; below, there is an irregular penetration. Malignant nodules develop at points distant from the seat of irritation in positions connected with the latter only by vascular communications. In conclusion, the authors point out that these stages correspond to those observed in human cancers and go far to prove the existence of a pre-cancerous state.

### 331. The Tuberculosis Mortality in Relation to Influenza Epidemics.

How does influenza affect the progress of the disease in patients suffering from pulmonary tuberculosis? To answer this question G. ICHOK (*Rev. d'Hygiène*, February, 1923, p. 123) prefers to trust to statistical rather than to clinical evidence. Studying the figures furnished in regard to the city of Paris, he finds that between 1900 and 1920 there were seven epidemics of influenza, the shortest lasting seven weeks and the longest—that of 1918-19—thirty-one weeks. The actual number of weekly deaths from influenza and from pulmonary tuberculosis are worked out for the three-monthly period preceding the epidemic and for the epidemic itself. In every case it is seen that the tuberculosis mortality rises considerably during the prevalence of the influenzal outbreak. Taking the mean of the weekly deaths during the epidemic and comparing it with the mean of the weekly deaths for the three-monthly period prior to the epidemic, it is found that there is an increase varying from 12.2 in 1900 to 45.7 in 1907. No relation could be established between the tuberculosis mortality and the length of the epidemic. If the number of deaths from pulmonary tuberculosis be followed for the three-monthly period after the outbreak, it is noticed that there is generally a definite fall, but in two cases—those of the 1905 and 1911 epidemics—a slight rise is observable. In the subsequent three months there is a still greater fall in the mortality from phthisis, so marked as to render it lower than that seen in the three months preceding the epidemic. Since, then, there is a very distinct rise in the tuberculous mortality accompanying the influenzal outbreak, remaining elevated for some time subsequent to the outbreak, and finally dropping to a level lower than that which prevailed beforehand, the author concludes that the curve of pulmonary tuberculosis mortality is influenced by epidemics of influenza.

### 332. Tuberculosis of the Suprarenals.

F. SCHWARZ (*Zeit. f. Tuberk.*, December, 1922, p. 169, and January, 1923, p. 271) carried out the following investigations on tuberculosis of the suprarenals: (1) A naked-eye and microscopical examination of the suprarenals in 20 cases of tuberculosis; (2) a study of 65 cases of tuberculosis of the suprarenals which had been found among 19,061 autopsies performed in the German Pathological Institute at Prague during the last eighteen years (January 1st, 1904, to May 30th, 1922). Fourteen of the 20 cases were children aged from 3 months to 6 years, and 6 were adults aged from 18 to 64; 17 of the 20 cases were examples of general military tuberculosis, among whom 14, or 83 per cent., showed military tuberculosis in the suprarenals. A microscopical examination was made in each case; in only one was it possible to detect tubercles in the suprarenals with the naked eye. In 3 of the 20 cases—2 being chronic pulmonary tuberculosis in adults and 1 acute pulmonary and intestinal tuberculosis in an infant—no tubercles were found in the suprarenals. In both series of cases the right suprarenal was more frequently affected than the left. Military tubercles were found both in the cortex and medulla without any special predilection being shown for either site. Military tuberculosis in the suprarenals showed two forms, one of which was characterized by uniform caseation, while the other represented the type of giant-cell tubercles. Transitional forms were also found. As a general rule the older the individual the more abundant were the giant cells. Tubercle bacilli were present in large quantities in the caseous foci. The changes in the suprarenals always corresponded histologically to similar changes in the other organs, such as the spleen, liver, kidneys, and lungs. Chronic tuberculosis of the suprarenals, which was less frequently found than military tubercles, was always haematogenous and secondary to a primary aerogenous tuberculosis.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## MEDICINE.

### 333. Ether Injections for Whooping-cough.

P. G. BERGUA (*Clin. y Lab.*, March, 1923, p. 233) suggests that since Audrain introduced the treatment of pertussis by injections of ether in 1914, and still more since the method was rendered popular by the articles of Cheinisse, Weil, and Dufour, the prospects of the successful management of pertussis have become much brighter. In the initial stage a single injection may be sufficient to cut short the disease. As a rule, however, the patients do not come under treatment until the paroxysmal stage, when a series of injections (as a rule four to five, and never more than ten) is required. The best results are obtained in children who are free from coryza, adenoiditis, or chronic bronchitis. Pure ether should be used, and the injections should be given intramuscularly and always in the same region, as subsequent injections are rendered less painful thereby. In children under 10 months of age Bergua used a dose of 1 c.cm. daily, and in older children 2 c.cm. He obtained the best results by combining ether injections with vaccine treatment.

### 334. Treatment of Epidemic Encephalitis.

P. CARNOT and BLAMONTIER (*Paris méd.*, February 24th, 1923, p. 177) record two cases of severe epidemic encephalitis, in a girl aged 19 and a boy aged 16 respectively, treated by intravenous injections of large doses of sodium salicylate. In the first case, in which 4.5 grams of the drug were given daily for six days, there was almost complete cure for about a week, with cessation of the choreic movements and return of intelligence. A relapse, however, took place during which intravenous injections were impossible, owing to obliteration of the veins, and proved fatal, like three other cases of untreated acute choreiform encephalitis observed by the authors. In the second case, in which the disease was of the lethargic type, the symptoms rapidly subsided after injection of 50 grams of sodium salicylate in the course of a week, and recovery took place.

### 335. Chorea, Rheumatic Fever, and Heart Disease.

G. F. STRONG (*Canadian Med. Assoc. Journ.*, February, 1923, p. 92), from a study of 100 consecutive cases of chorea and 190 cases of acute rheumatic fever, undertaken to determine the incidence of cardiac disease in uncomplicated chorea, and to ascertain what influence the added occurrence of rheumatic fever and other factors has upon the frequency of cardiac implication, found that there was a history of previous acute rheumatic fever in 20 per cent. of the chorea patients, while the incidence of organic heart disease in chorea was 45 per cent., and in rheumatic fever 38 per cent. Recurrences of chorea increased the likelihood of cardiac invasion, and the incidence of such complications was greatest (70 per cent.) when chorea and acute rheumatic fever had occurred in the same patient. The occurrence of heart disease following chorea was apparently not affected by tonsillitis, and, although endocarditis could develop in an afebrile course of the disease, a concurrent fever slightly increased the tendency. Of the valves, the aortic was much more rarely, and the mitral more frequently, attacked in chorea than in rheumatic cases, while pericarditis, conduction defects, and auricular fibrillation were less common in chorea than in acute rheumatic fever.

### 336. A Frontal Reflex Indicative of a Cerebral Lesion.

I. HOLMGREN (*Acta medica Scandinavica*, February 22nd, 1923, p. 616) describes a reflex which he discovered more or less by accident early in 1916, when a man, aged 38, was admitted to hospital suffering from a recent attack of hemiplegia due to a cerebral haemorrhage. Tracing one finger rather firmly on the non-hemiplegic side of the forehead, the author saw both eyebrows rise and the forehead wrinkle on both sides. He could not elicit this reflex by pressure on the other side of the forehead, and he has never seen it in persons not suffering from a cerebral lesion. It is, indeed, comparatively rare in association with a cerebral lesion, and since January, 1916, the author has observed it in only 29 cases. In as many as 23 there were signs of cerebral haemorrhage; embolism, or thrombosis with hemiplegia. The reflex is evidently of some prognostic importance, for among the cases of cerebral haemorrhage the mortality was 58 per cent. when the reflex was demonstrable and only 32 per cent. when it was not so. In cases which came to necropsy, the

lenticular nucleus was found to be almost always affected, but there were a few cases in which the cerebral lesion was practically confined to the cortex. There were also two cases of frontal reflex associated with encephalitis. The reflex persists till death, and can be elicited whether the patient is comatose or conscious. In attempting to elicit the reflex, the degree of pressure exerted by the tracing thumb or metal instrument should be carefully graduated, for very light pressure excites no reflex, and pressure causing pain produces simply the expression anyone may show in response to a painful impulse.

### 337. Diabetic Oedema.

W. FALTA (*Wien. Arch. f. inn. Med.*, January, 1923, p. 581) records a number of observations respecting the oedema which occasionally occurs in severe diabetes mellitus, independently of kidney disease. This oedema is especially liable to occur when sodium bicarbonate is taken in large doses, but is checked by giving potassium bicarbonate or even potassium chloride. When large doses of alkalis are given in diabetes on account of acidosis a mixture of sodium bicarbonate and potassium bicarbonate is advisable in order to avoid the occurrence of oedema. When oedema has occurred under the influence of sodium bicarbonate in large doses it has been attributed to retention of chlorides. But the author records a series of careful observations on an interesting case in which, on a diet containing much salt, large doses of sodium bicarbonate were followed by great oedema, which disappeared when the sodium bicarbonate was replaced by potassium bicarbonate. On a diet containing very little salt (so-called salt-free) the administration of large quantities of sodium chloride produced marked oedema, but this disappeared when the sodium chloride was replaced by potassium chloride; also on this same salt-free diet large doses of sodium bicarbonate caused marked oedema, which disappeared when the sodium bicarbonate was replaced by potassium bicarbonate. The relation of oedema to acidosis is discussed. Oedema can occur unassociated with acidosis.

### 338. Endolumbar Injections of Sodium Bromide for the Pain and Spasticity of Tabes.

H. LIPPMANN (*Deut. med. Woch.*, February 23rd, 1923, p. 245) came to give therapeutic injections of sodium bromide by lumbar puncture in cases of tabes after he had given diagnostic injections of this drug. It throws an x-ray shadow, and he injected it into the spinal canal to ascertain the level at which a tumour of the cord might exist, obstructing the upward passage of the injected fluid. His experience with these diagnostic injections suggested they might be of therapeutic value, and he has given altogether forty such injections. Some of them were not quite harmless, but the reaction usually passed off in a day or two. The symptoms would appear to be due to acute transitory meningitis of chemical origin. Among 5 cases of tabes there were 2 in which marked improvement was observed, as shown by relief of pain and spasticity. Some improvement was observed in a third case. The author injects 10 c.cm. of a 1 or 1.6 per cent. solution after 10 c.cm. of the cerebro-spinal fluid have been withdrawn. The injections are repeated every fourteenth day, and altogether two or three injections are given to each case. It is not clear how the bromide acts; it is soon reabsorbed, and its prolonged beneficial action can therefore hardly depend on its retention in the spinal canal.

### 339. The Motor Nuclei of the Vagus.

G. MARINESCO and S. DRAGANESCU (*Ann. de Méd.*, 1923, xiii, p. 1) describe a case of thrombosis of the right vertebral artery, with resultant areas of softening in the right half of the medulla. There was paralysis of the right vocal cord and the right half of the soft palate, loss of the oculo-cardiac reflex on the right side, and hemiparesis affecting the left arm and leg. Examination of the medulla showed softening in the region of the right nucleus ambiguus, but the dorsal vagal nucleus was intact. From this and other evidence they conclude: (1) That the soft palate is innervated from the nucleus ambiguus by the ninth and tenth cranial nerves, and not by the seventh, as has been suggested. (2) That the recurrent laryngeal nerve arises in scattered large cells in the inferior part of the nucleus ambiguus. (3) The vagal branches to the heart appear to arise partly in the nucleus ambiguus and partly in the dorsal motor nucleus, but the evidence regarding this is very indefinite.

## 350. The Diagnosis of Cardio-vascular Syphilis.

W. D. REID (*Boston Med. and Surg. Journ.*, February 15th, 1923, p. 189), from an examination of clinical and post-mortem records of 100 consecutive deaths, found syphilis as the cause of cardiac disease in 11.5 per cent., and therefore urges that cardio-vascular syphilis should be given a place among the various diagnoses to be considered in any patient suffering from heart disease; and since every syphilitic is a case of potential cardio-vascular syphilis this cause should be borne in mind in every heart case of obscure origin. Seeing that a diagnosis of syphilis of the heart and aorta cannot be made on any single point alone, each case requires careful investigation, with, if necessary, x rays, Wassermann test, or even observations upon a short course of antisyphilitic therapy. While the condition may be symptomless, shortness of breath, substernal pain with angina-like radiation, are common, and among physical signs cardiac enlargement downward and to the left, an abnormal supra-cardiac dullness, a systolic murmur over the aortic area, and the aortic second sound duller than in arterio-sclerosis are the most frequent. A positive Wassermann reaction is of value in diagnosis, but a negative report does not invalidate the diagnosis of cardio-vascular syphilis, in the presence of other and sufficient data, and though x-ray findings are often of great value they cannot be relied upon to detect early cases. In doubtful cases the therapeutic test is of distinct value and should be used frequently. The chief conditions to be differentiated are non-specific aortitis, arterio-sclerosis, hypertensive heart disease, rheumatic heart disease, pulmonary tuberculosis, mediastinal tumours, and tabes dorsalis.

## SURGERY.

## 341. Treatment of Tuberculous Laryngitis by Finsen Light.

N. R. BLEGVAD of Copenhagen (*Rev. de Laryngol., d'Otol. et de Rhinol.*, February 28th, 1923, p. 139) gives a short summary of the previous ideas on tubercle of the larynx and the pessimism with which it was regarded. Tuberculosis of the larynx is much more fatal than tuberculosis restricted to the lungs. The author has treated more than two hundred cases of tuberculous laryngitis by means of light baths (Finsen). The light bath consists of exposing the patient completely undressed to the rays of three powerful arc lamps, with special thin carbons and a current of 25 ampères, the light of which is so intense as to cause pigmentation of the skin. The sun's light is more satisfactory, but climatic conditions make its use impracticable. The baths of light alone are able effectively to reduce the swelling, ulceration, and distress of the larynx in many cases. Much better results are, however, obtained if such local treatment as galvanopuncture of swellings of the ventricular bands and interarytenoid region, curettage of ulcers, application of lactic acid, and even amputation of the epiglottis, is resorted to concurrently. Absolute silence is an integral part of the treatment, the patients being merely allowed to whisper. This, the author admits, requires a very large degree of self-discipline. This light treatment rapidly eases the pain of tuberculous laryngitis. The pain caused by ulcers of the larynx, especially on swallowing or speaking, is very readily relieved. Usually the laryngeal and pulmonary conditions improve together, but occasionally it is found that the laryngeal condition improves but the pulmonary condition remains stationary or gets worse. The reverse may also be the case, and then more active local treatment is required. Of 178 cases 49 were completely cured and 22 almost completely cured, and only 33 cases did not show any improvement.

## 342. Ethylene as an Anaesthetic.

THE toxicity of ethylene for flowering plants suggested to A. B. LUCKHARDT and J. B. CARTER (*Journ. Amer. Med. Assoc.*, March 17th, 1923, p. 765) a series of experiments on animals and on man. From the animal experiments it appears that all the animals used (mice, rats, rabbits, guinea-pigs, and kittens) could be anaesthetized with a 90 per cent. ethylene mixture in half the time necessary to anaesthetize the same animals with the same percentage of nitrous oxide. Twelve subjects were anaesthetized, more or less deeply. One of the authors was anaesthetized six times in three days in three weeks; the other (J. B. C.) seven times on three days in three weeks. In neither instance did sugar or albumin appear in the urine as a result of the experiences, nor were there any other evil after-effects except a slight nausea and loss of appetite, both of very temporary nature. It seems evident, then, that deep surgical anaesthesia can be rapidly induced by ethylene without any sense of asphyxia, but, on the contrary, with a sense of well-being

and comfort. Analgesia, it appears, comes on easily long before complete surgical anaesthesia is established. At a time when there is complete muscular flaccidity the pulse rate is slightly decreased, if changed at all; respirations are slow but regular, and the countenance normal in colour for the individual, or slightly paler. No cyanosis was observed. No subject showed any sign even suggestive of asphyxia. The induction of anaesthesia was in no way unpleasant except possibly for the first few inhalations of the concentrated gas, which induced reflex swallowing. A period of excitement characterized by laughing or forced movement preceded the anaesthesia in some; in others such signs were absent during induction, but appeared during recovery from the anaesthesia. Recovery was always rapid on withdrawal of the gas mixture. Slight weakness and a sense of fatigue were always experienced if the person arose from the couch almost immediately on waking up. Vomiting occurred in one case early during recovery. In some cases there was slight transient epigastric distress. In others a slight nausea persisted for several hours after the administration of the gas. In none was nausea so pronounced or so prolonged as to interfere with the ingestion of the next meal. The possible advantages, according to the authors, of ethylene over nitrous oxide, if used for human anaesthesia, are: (1) Anaesthesia may be maintained (a) in the absence of all signs of asphyxia, (b) in the absence of effects on blood pressure, (c) in the absence of dyspnoea, (d) with complete muscular relaxation. (2) It may be used in obstetrics, a state of complete analgesia being possible at a concentration of 80 per cent. ethylene. (3) There is rapid recovery after long-continued administration, without evidence of after-effects. These advantages would make possible its use in many persons and conditions in which nitrous oxide is contraindicated.

## 343. Pharyngeal Aneurysm of the Internal Carotid.

G. PORTMANN and P. DUPOUY (*Arch. Méd. Belges*, February, 1923, p. 97) refer to the comparative frequency of errors of diagnosis in this disease. The sac has been incised by many eminent surgeons who had diagnosed either peritonsillar abscess or adeno-sarcoma. The authors describe a recent case—a farm labourer, aged 68, who had complained of vertigo and right retro-auricular pain. An examination of the fauces showed a smooth rounded pulsating swelling behind the left posterior pillar. The swelling was painless and expansile. The Wassermann reaction was negative. The authors discuss the pathology and etiology of aneurysms of the internal carotid, and their differential diagnosis from those of the vertebral, external carotid, ascending pharyngeal, and inferior palatine arteries. They state that prognosis is always grave; the swelling tends to increase and to compress neighbouring structures, it seldom undergoes spontaneous cure. It may burst beneath the skin of the neck or into the pharynx. Surgical treatment is usually necessary; according to Delbet ligature of the internal carotid (only practicable when the aneurysm does not extend as low as the bifurcation of the common carotid) is more dangerous than ligature of the common carotid—6 fatal results out of 7 cases. The authors state that ligature of the common carotid, though easier to perform, is more likely to produce cerebral ischaemia. They describe Liébault's proposed operation to suture the sac, and compression of the aneurysm by an aluminium band which may be regulated or flattened to compress the sac in hope of inducing thrombosis without cerebral ischaemia. They describe the classical medical treatment of aneurysm—rest, non-stimulating diet, and iodides (especially in syphilitic cases). They describe subcutaneous injection (in thigh or abdominal wall) of a 2 per cent. gelatin solution with 1 per cent. sodium chloride; they refer to the danger of tetanus if any but freshly sterilized solutions are used. The injections should be repeated at intervals of ten to fifteen days. Dujardin-Beaumetz has applied galvanic currents to the surface over the tumour.

## 344. Treatment of Varicose Ulcer.

J. MONTPELLIER, A. LACROIX, and P. BOUTIN (*Bull. Soc. Française de Dermatol. et de Syph.*, No. I, 1923, p. 53) consider that the danger of injecting thrombus-producing substances into veins has been exaggerated, and is purely theoretical. Many substances may be used for the purpose, but they prefer a 1 or 2 per cent. solution of mercuric iodide: it is always available, its escharotic action is trivial, and as there is a history of syphilis in many cases of "varicose ulcer" mercuric iodide may serve a double purpose. The authors have found it quite reliable; to render its chemical action on the tissues more certain they place a finger on the vein a few centimetres above the puncture and maintain pressure during the injection, which is performed slowly. The results are very satisfactory—disappearance of subjective symptoms, more or less painful,

healing of very chronic ulcers, cure of varicose dermatitis. The authors consider it an absolutely safe procedure—the risk being no greater than that entailed by complete phlebectomy. They give the results of examination of varices removed at periods varying from twenty-four hours to three months after injection. At the end of fifteen days the organization of the clot is still incomplete; in it relatively large spaces filled with blood still remain, lined with endothelium. The external coat is always deeply congested, and the muscular coat almost entirely sclerosed. At the end of three months the vein, greatly reduced in size, is converted into a fibrous cord in which a few concentric muscular fibres are recognizable. All the experiments were made on comparatively narrow veins in the forearm, and the examination was made at the point of puncture—that is, at the point of maximum damage. Obviously the phenomena of proliferating and obliterating endophlebitis would be less pronounced at a greater distance from that point. The authors state that there is less reaction in a varix than in a normal vein in which an experimental injection has been made.

### 345. Electro-coagulation in the Treatment of Lupus of the Nose and Throat.

A. VIBEDE (*Hospitaltidende*, February 14th, 1923, p. 140) gives an account of the results obtained at the Pinsen Institute in Copenhagen by the treatment of lupus of the nose and throat by electro-coagulation. This treatment is based on the observation that the high-frequency alternating current is much better tolerated by the body under certain conditions than is the constant current. One pole of the apparatus consists of a wet padded plate of lead, secured to the patient's arm; the other pole is connected with a small electrode of only a few square millimetres' surface, which is applied to the part to be treated. The electrode is kept applied to the tissues for a few seconds until the structures in its neighbourhood assume a white colour indicative of coagulation. However skilfully this treatment is applied it is very painful, and local anaesthesia is useless, for the nerves in the neighbourhood are subject to electrical and thermal irritation over an area much wider than the parts undergoing treatment. Thus there may be pain in the teeth when the nose is being treated. But as the duration of the application is very short, most patients can dispense with a general anaesthetic. Others need slight ether or ethyl chloride anaesthesia. In the period November, 1919, to August, 1921, there were 283 patients thus treated. A large proportion consisted of patients whose disease had proved refractory to every other form of treatment. Of the 283, as many as 90 discontinued treatment prematurely or could not subsequently be found. Of the remaining 193, as many as 160 were apparently cured, while 27 were improved and 6 were unaffected by the treatment. The only method with which this treatment can be compared is Reyn's electrolysis, and the author concludes that electro-coagulation is probably the more effective. It requires less time and fewer applications, and does not necessitate the administration of large doses of iodine. Compared with operative treatment, electro-coagulation has the merits of being a bloodless procedure, of not spreading infection, and of being feasible in cases in which the situation of the disease renders an operation difficult. The disadvantages of electro-coagulation are the cost of the apparatus, the need of special knowledge of the technique, the difficulty experienced in limiting the depth to which the effects extend, and the pain, which is unrelieved by the use of local anaesthetics.

### 346. Pyelotomy for Large Renal Calculi.

M. MARION (*Bull. et Mém. Soc. de Chir. de Paris*, February 20th, 1923, p. 250) alludes to the difficulties met with when carrying out nephrectomy for large renal calculi. In incising the renal parenchyma the stone may slip away if it is not fixed, whilst when lifting it out with the finger or forceps it frequently may break. Small fragments may be difficult to discover, and if left behind serve as the nucleus for new stone formation. Again, the sutures used in closing the opening in the kidney are a source of trouble; they provide a focus of infection in the renal substance, and may give rise to abscesses. Whilst in nephrotomy it is customary to place a drain in the kidney, this may cause serious haemorrhage on its removal; if no tube is employed, clots may block the ureter. To avoid these complications he describes a technique adopted by Pappa. After delivering the kidney a large opening is made in the renal pelvis; the index finger is then introduced into the pelvis and the stone pushed toward the periphery of the kidney; the stone thus being fixed, an incision is made over it and removal is simple. Pappa employs a special haemostatic suture which encircles the kidney without damaging it. The author, however, finds this mode of suturing is not always successful. With regard to drainage, a tube is placed in the renal pelvis; this is removed after three days and there is no urinary leakage.

The wound in the renal substance can then be completely closed. The writer emphasizes the value and advantages of this mode of approach for large calculi in the kidney and the avoidance of unpleasant complications by its use.

### 347. Radiography in Optic Atrophy.

R. E. WRIGHT and T. W. BARNARD (*Brit. Journ. Ophthalmol.*, March, 1923, p. 123) consider that an x-ray examination should be made in all those cases of optic atrophy in which the cause is at all doubtful, since many cases of pituitary disease, or of disease of the fossa eventually involving the hypophysis, show optic atrophy as the only obvious sign, and without x-ray evidence it is impossible in such cases to arrive at a correct diagnosis. Notes of five cases are given, in two of which the clinical evidence was typical, whilst in the other three the optic atrophy so overshadowed all other symptoms that without radiography the cause might easily have remained undiagnosed. It is the ophthalmologist who, in the majority of cases of hypophyseal implication, is first consulted, and the high percentage of such cases which show but slight glandular symptoms renders it all the more impossible to be certain of the cause without the evidence afforded by radiography.

## OBSTETRICS AND GYNAECOLOGY.

### 348. Inguinal Hernia of the Uterus.

F. S. LATTERI (*Arch. Ital. di Chir.*, February, 1923, p. 39) states that the first case of hernia of the female genitals was recorded by Soranus of Ephesus (97 A.D.), who found the ovary and Fallopian tube in a hernia of the labium majus. Similar cases were not recorded again until the eighteenth century, when examples were described by Verdier, Haller, Percival Pott, Camper, and others. All these cases, however, referred to hernia of the ovary with or without the Fallopian tube. The first instance of inguinal hernia of the uterus was reported in Pol's *Silesian Journal* in 1612, in a letter sent by Doering of Breslau to Fabricius di Hildanus. Latteri has collected 78 cases of hernia of the uterus from the literature, including a personal case, and classifies them as follows: (1) Complete hernia of the uterus (25 cases); (2) partial hernia (16 cases); (3) hernia of the gravid uterus (11 cases); (4) hernia of uterus masculinus (26 cases). Inguinal hernia of the uterus is always due to a congenital error of development. In order that the uterus should form part of an inguinal hernia it is necessary that there should be a close relation between a defect in the development of Nuck's canal and a developmental error in the genito-inguinal ligaments. Inguinal hernia of the uterus is in most cases irreducible, and is most frequently found on the left side. Pain and increase in size of the hernial swelling during the menstrual period, elongation and narrowing of the vagina, with deviation of it to the affected side, transmission to the hernial contents of movements of the vaginal canal on the cervix constitute the principal diagnostic symptoms. The pathognomonic features of inguinal hernia of the gravid uterus are rapid increase in size of the hernia and the existence of foetal movements, foetal heart sounds, and the placental souffle within the hernial swelling. The only treatment for inguinal hernia of the uterus is operation, which is necessitated by the possibility of strangulation on pregnancy. Latteri's case occurred in a woman aged 36, who had been married fifteen years, had never been pregnant, and had never menstruated. About five years previously a small swelling had appeared in the left groin, and had increased in size, especially in the last two years, after lifting a heavy weight. On operation a small uterus was found in the hernial sac, without any sign of a cervical cavity. The right adnexa were completely absent, and the left ovary and tube were atrophic.

### 349. Spontaneous Rupture of the Uterus during Pregnancy.

H. F. KANE (*Amer. Journ. of Obst. and Gyn.*, February, 1923, p. 158) records a case of this condition, and owing to its comparative rarity (only 34 cases having been recorded) goes somewhat fully into the etiology, pathology, and clinical features. None of the recorded cases were correctly diagnosed, but the symptoms were always such that laparotomy was clearly indicated. The author considers that the chief predisposing cause is multiparity, which gives rise to hyaline degeneration of the uterine walls, and this is aggravated in many cases by intrauterine manipulations at previous labours. In nearly every case there was a previous history of abortions, stillbirths, malpresentations, curettage for retained products of conception, or a manually removed placenta, and though it is thought by some that the scar tissue following such curettage, etc., is the cause of the weakness, the author believes that the damage to the myometrium is due to a mild infection, and substantiates this

claim by quoting cases, in which rupture followed, when at a previous labour an intrauterine douche had been given or a version performed, followed by a continued rise of temperature. When rupture occurs in a primipara infantilism of the uterus is found in practically every case, there being an extreme thinness of the uterine muscle. The pathological findings consist of hyaline degeneration in multiparae, and of round-celled infiltration and extreme friability of the uterine wall in the cases who had had previous interference; exceptional infiltration of decidual cells was noted in several cases associated with the above. Most cases had extensive internal bleeding which called for immediate operation, and the treatment usually performed was supravaginal hysterectomy, which, according to the pathological findings, seems to be the proper procedure, but stitching of the rent and packing the uterus have also been employed. The after-results have not been satisfactory, the maternal mortality being well over 50 per cent. whatever the treatment administered.

### 350. Pyometra and Cervical Carcinoma.

ACCORDING to R. ALAMANNI (*Rivista di Ostetricia e Ginecologia Pratica*, January, 1923, p. 9), from 3 to 10 per cent. of cases of carcinoma of the cervix uteri have been reported to be complicated by pyometra, the occurrence of which is favoured by multiparity, the post-menopausal state, and senility. Sometimes intermittent discharge of pus, as a rule following painful uterine contractions, renders the diagnosis of pyometra comparatively simple; but in many cases the pyometra is closed, evacuations of pus do not occur, and the clinical course, so far as the pyometra is concerned, is asymptomatic. Three such cases are related by the author: in the first, total hysterectomy was performed on a 7-para, aged 55, for cervical cancer of a uterus of which the body showed enlargement, regarded before and at operation as due to myoma; in the second, the pyometra was first revealed after insertion of Hegar's dilators in the cervix as a preliminary to diagnostic curetting, which showed early carcinoma of the endocervical mucosa; in the third, symptoms of early cervical cancer had manifested themselves for a few months only in a 5-para aged 73. In these cases, as is commonly found, pyrexia was absent. Palpation of a uterus which is the site of pyometra does not usually reveal fluctuation; and although the uterus in rare cases has become so distended as to form a tumour palpable above the umbilicus, it usually remains within the pelvic cavity.

### 351. Carcinoma of the Body of the Uterus.

A. E. MAHLE (*Surg., Gynecol., and Obstet.*, March, 1923, p. 385) has compared the clinical and pathological findings in a series of 186 cases of carcinoma of the body of the uterus coming to operation at the Rochester clinic. He finds that the degree of malignancy is inversely proportional to the degree of differentiation of the neoplastic cells as shown microscopically. The average duration of life after operation is greatest when the tumour shows macroscopically a papillary or polypoid shape, and microscopically the greatest differentiation in cells, while the most malignant carcinomata form diffuse or flat growths showing microscopically neither morphological differentiation nor alignment of the cells. Lymphocytic reaction is more marked in connexion with the more malignant tumours. Although 31 per cent. of cases in this series were associated with fibromyoma this connexion appears to have little etiological significance. A pathological basis for the belief that carcinoma of the body is less malignant than that of the cervix is afforded by the observation that a high degree of cellular differentiation is less common in the latter condition. Clinically it was found that in this series diagnosis was possible in 40 per cent. of cases before curetting or hysterectomy.

## PATHOLOGY.

### 352. Indican in the Blood in Kidney Disease.

G. BAAR (*Wien. Arch. f. inn. Med.*, Bd. v, Heft 2 u. 3, January, 1923, p. 353) records the results of the quantitative estimation of the indican in the blood (according to Jolles's method) in 126 analyses. In 55 cases the patients were suffering from kidney disease, in 41 from other affections. Excess of indican in the blood (indicanæmia) is due to retention of indican in the blood through defective excretion by the kidneys. Of the various nitrogenous products, indican is the one which is excreted with greatest difficulty by diseased kidneys, and consequently early accumulates in the blood. In chronic nephritis the indican in the blood is increased before the residual nitrogen as the disease advances. In cases of high blood pressure and granular kidney the indican blood test always gives us an indication

of the gravity of the kidney lesion. In congestion of the kidney, associated with cardiac failure, an increase of the indican in the blood points to a persisting permanent kidney lesion. In pernicious anaemia the indican both in the blood and in the urine is increased.

### 353. The Pathogenesis of Tumours and the Campaign against Cancer.

L. BARD (*Ann. de Méd.*, February, 1923, p. 93) indicates the therapeutic bearings of the theory of cancer pathogenesis which he advanced in 1885. His argument was based on two fundamental conceptions: (1) That any variety of body tissue, at any stage of its growth, can give rise to a cancer, which varies in type according to the tissue from which it springs; each tumour springs from a single focus of one or more young cells of the same age. (2) Cancer cells have not acquired new powers, but on the contrary have lost a fundamental property of normal cells—that of being governed by the bodily influences which regulate cell growth. The cancerous process is thus one of anarchy; the cells, by their malformation, are freed from the laws of the body and become destructive and parasitic. The laws governing the origin of a cancer and the formation of metastases are quite different. Primary tumours become more common with advancing age, whereas metastases form more rapidly with the tumours of young subjects. In this respect inoculated tumours in mice behave like metastases, and become established more often in young mice than in old. Inoculated tumours which grow for a time and then disappear confer on the animal immunity against any further inoculation of the same tumour; and an unsuccessful inoculation with a large piece of tumour may confer a similar immunity. There is thus some formation of anticancerous substances in the animal body, and in support of this Bard states that in the human subject, as in mice, metastases grow more rapidly after the primary tumour has been removed. All attempts to treat cancer on these lines, however, have so far failed. The specificity of the different forms of cancer is shown by the fact that lactation arrests the growth of inoculated mammary carcinomata, but has no influence on tumours of other nature. Similarly Regaud has found that the dosage in radiotherapy of cancer must be varied according to the nature of the tumour. The treatment of cancer thus presents, according to Bard, a different problem for each form of cancer, and the discovery of a royal road to the cure of all forms is improbable.

### 354. Transmission of the Virus of Disseminated Sclerosis to Animals.

W. JENSEN and G. E. SCHRÖDER (*Hospitalstidende*, February 14th, 1923, p. 133) have attempted to transmit to animals the virus of disseminated sclerosis from seven cases of this disease. They used 9 rabbits and 25 guinea-pigs, the injections being intraperitoneal and intracerebral as well as into the anterior chamber of the eye. Only in one case did they succeed. The patient was a man, aged 20, with typical disseminated sclerosis. The necropsy showed no spirochaetes nor other germs in the brain, but in the cord there were found spirochaetes, most of which were pointed at both ends. Cerebrospinal fluid, taken from this patient during life, was injected into 3 rabbits and 3 guinea-pigs by the intracerebral route. One of the guinea-pigs developed paralysis of the hind legs, and examination of its cerebrum and spinal medulla showed leptomeningitis and round-cell infiltration, as well as degenerative changes which could not be traced to incidental infection. Spirochaetes could not, however, be found in the central nervous system of this guinea-pig.

### 355. The Nature of Rickettsia Bodies.

F. M. NICHOLSON (*Journ. of Exper. Med.*, February, 1923, p. 221) has made a cytological study of the nature of Rickettsia in Rocky Mountain spotted fever with a view to determining whether or not they are true micro-organisms or constitute products of degenerated cells, as maintained by some. He found that the Rickettsia bodies found in this disease could be easily differentiated from mitochondria, phagocytosed blood pigment, nuclear debris, and all other known cellular constituents. Although lodged within the cytoplasm of endothelial cells, they were not observed to establish any definite relations with the nucleus or other cellular components. In contiguous cells which sustained the same degree of injury, as evidenced by nuclear changes, their numbers varied. Diplo-bacillary forms were most abundant in the early stages of the reaction and single bacillary forms towards its termination. Wofbach's account of the distribution of specific lesions with accompanying organisms in the tissues of guinea-pigs was confirmed and extended.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## MEDICINE.

### 356. Albuminuria and other Sequels to Severe Exertion.

J. K. HALD (*Tidsskrift for Den Norske Lægeforening*, April 1st, 1923, p. 365) examined the 50 competitors in a 30-kilometre ski race for albuminuria by Heller's test. The pulse was also counted, and the heart auscultated; no adventitious heart sounds were heard, and the pulse ranged from 69 to 120. Albuminuria was found in 4 competitors, 2 of whom insisted on taking part in the race, although advised not to do so. One of them suffered no ill effects, but the other came in late and in a very bad condition. Forty-six competitors were examined at the end of the race, and two were so weak that they had to be carried. Both had a pale grey complexion at the end of the race, for which neither had trained adequately. Both had lain down a few kilometres from home and had drunk ice water, and when they had resumed the race they could hardly stir. Brandy revived them, and they were completely restored after about twenty minutes. The average pulse rate of 39 men at the end of the race was 116, the extremes being 50 and 144. Among these 39 there were 9 without albumin, 9 with a trace, and 21 with more than a trace of albumin. These cases of albuminuria were equally distributed among the men who made good and bad times; there were, however, 3 competitors who made very bad times, and all had albuminuria, which in one case was as great as 0.15 per cent. It has been agreed by the medical authorities supervising ski races in Norway that a competitor with albuminuria before a race must be prevented from taking part in it.

### 3. 7. Congenital Syphilis.

E. A. MORGAN and M. A. COX (*Canadian Med. Assoc. Journ.*, March, 1923, p. 171), from a study of 100 cases of hereditary syphilis, found that the great majority (nearly two-thirds) did not come under supervision until late manifestations had developed, only one-fifth presenting early signs of sufficient severity to seek advice. In diagnosis, the authors declare, too much stress is generally laid upon unimportant and rare manifestations, whereas snuffling during early infancy is by far the most frequent early symptom, and this, together with an enlarged spleen, is pathognomonic. A "frog-like" or "fishy" appearance of the eyes, simulating a mild exophthalmos, is a sign, hitherto unrecorded, so uniformly present in the early stage as to be of considerable value. Two successive negative Wassermann reactions in a patient over 3 months old, and who has not previously received specific treatment, may be regarded as definitely excluding congenital syphilis. The routine treatment consisted in weekly intravenous injections of an arsenical compound for a period of six weeks followed by a six weeks' course of mercury, the routine being repeated if the Wassermann test still remained positive; and as the result of three years' work it is concluded that every case of early congenital syphilis can be permanently cured. The authors conclude that while interstitial keratitis is but little improved by specific therapy, cerebro-spinal syphilis can, if detected early, be greatly improved and sometimes cured, while in later cases the process may be arrested. The average time required to obtain a persistently negative Wassermann reaction is eleven months in the latent cases, and sixteen and a half months in the tertiary. Successful treatment depends upon the persistency and regularity of the treatments combined with the maintenance of general health and nutrition.

### 358. Anaphylactic Purpura.

HANNS and WEISS (*Revue de Médecine*, An. 40, No. 2, p. 104), discussing the question whether there is such a thing as anaphylactic purpura, refer to the many different views on the origin and kinds of purpura; for example, clinically there are purpura simplex, purpura haemorrhagica, purpura urticae, purpura rheumatica, Henoch's purpura, and Werlhof's disease. Glanzmann divided purpuras into two groups—(1) anaphylactic, and (2) Werlhof's disease, characterized by the presence in the first group of infectious symptoms, while the intensity of the cutaneous or mucous haemorrhages, anomalies in coagulation and the number of blood plates are confined to Werlhof's disease. The conception of purpura as an anaphylactic phenomenon is based partly on its appearance after serum injections and partly on the analogy between the symptoms of purpura and those of serum disease, especially as regards gastro-intestinal

symptoms and Henoch's purpura. According to some writers, toxic phenomena are in many cases really anaphylactic manifestations; the coagulability of the blood is normal. The authors are not prepared to accept Glanzmann's theories in their totality, and suggest that one way to test them would be to produce serum anaphylaxis in an old purpuric patient, and see if a fresh outbreak of purpura developed subsequently; they describe a case in which, after serum injections in a purpuric subject, a typical outbreak of urticaria took place but no purpura. They do not deny that an anaphylactic type of purpura may occur as an isolated clinical entity, but are not prepared to accept a whole group of purpuras and treat them as anaphylactic.

### 359. Intravenous Injection of Urotropine for Retention of Urine in Nervous Diseases.

H. GUNDERT (*Klinische Wochenschrift*, March 19th, 1923, p. 571) was induced, by the successful results obtained by Vogt in the treatment of post-operative retention of urine by intravenous injection of urotropine, to try this treatment in similar conditions occurring in various nervous and mental diseases. He has employed Schering's preparation—"40 per cent. urotropine solution, sterile in ampullae"—and has injected 5 to 10 c.cm. (once or several times) in cases of retention of urine. The patients were suffering from general paralysis, tabes, multiple sclerosis, katatonia, etc. In a great number of the cases treated regular normal micturition followed one or two injections. In other cases, after a longer or shorter interval, further injections were required. In some cases after an initial intravenous injection, when micturition was once excited, it was possible to maintain the regular normal action of the bladder by giving daily 2 to 3 grams of urotropine by the mouth. In some cases of general paralysis the intravenous injections failed, or only produced irregular results. No bad effects were noted from the injections. The urotropine or its derivatives are excreted into the bladder after injection and cause a sensory irritation of the bladder mucous membrane, and bring about micturition. The author considers a trial of this treatment should be made before the catheter is used in these nervous and mental diseases.

### 360. The Action of Pituitary Extract.

M. PERRIN, A. HANNS, and M. STEFANOVITCH (*Paris méd.*, March 10th, 1923, p. 229), as the result of their observations on the effect of the extract of the posterior lobe of the hypophysis on coagulation of the blood, the blood pressure, and the pulse, came to the following conclusions: (1) Its action in accelerating clotting was most constant, being present in different degrees in 8 out of 10 cases. It did not appear to last much longer than two hours. It was not proportional to the dose of the extract injected. (2) Its action on the blood pressure was much less constant. In 4 cases it was nil, in 4 it was slight (a fall of 1½ to 2 cm. Hg.), and in four considerable (a fall of 3 to 4 cm. Hg.). In no instance was a rise of blood pressure observed. The fall of blood pressure bore no relation to the quantity of extract injected, as in one case a considerable fall was produced with only 1 c.cm., and in two cases where 2 c.cm. were given only a slight fall of blood pressure resulted. (3) The action of pituitary extract on the pulse was also very variable. In 5 cases it was nil, in 3 cases slight (a slowing of 12 to 14 beats a minute), in one case considerable (the pulse changing from 80 to 40 beats a minute—possibly heart-block), and in one case there was acceleration of the pulse. The irregularity of the action of pituitary extract appeared to be due either to the difference in activity of the ampoules, or to the different degrees of reaction of the organs or systems affected by the extract as a result of past disease or congenital predisposition.

### 361. Kala-azar.

B. SANJIVA RAO (*Madras Med. Journ.*, January and March, 1923), from an experience of over 50 cases of kala-azar, concludes that, while the bed-bug is suspected as being the vector of the disease, the evidence is not conclusive, and the incubation period is variable, but usually not more than a few months. Clinically the most constant features are irregular pyrexia, splenic and hepatic enlargement, emaciation, freedom of the gastro-intestinal system from symptoms, and liability to pigmentation, cancrum oris, and dysentery. In diagnosis, cases of "enteric fever" without alimentary or nervous symptoms and giving no serum reaction are suspicious, while in cases suggestive of pulmonary tuberculosis the possibility of kala-azar must be borne in mind. Progressive enlargement of the spleen, though occasionally

absent, is characteristic of the disease, but the aim in diagnosis should be the demonstration of the parasite in the body fluids. Peripheral blood taken after the injection of 1 c.cm. of 1 in 1,000 adrenaline solution increases the chances of finding the parasite. When other methods of diagnosis have failed splenic puncture should be resorted to in all cases presenting no contraindications, and if performed under proper precautions it is a safe procedure. Treatment consists in intravenous injections twice a week of 2 c.cm. of a 1 or 2 per cent. solution of potassium or sodium antimony tartrate in normal saline in gradually increasing doses until about 2 grams of the salt have been given.

### 362. The X-ray Treatment of Toxic Goitre.

J. H. MEANS and G. W. HOLMES (*Arch. Intern. Med.*, March, 1923, p. 303) record the results of their careful researches undertaken (in 58 cases) in order to determine if the x-ray treatment of toxic goitre (exophthalmic goitre and toxic adenoma) did any good or harm. Their results are recorded in detail, and the authors conclude that the x-rays probably have a beneficial effect in toxic goitres. About two-thirds of the patients with exophthalmic goitre so treated show either recovery or improvement coincident with the treatment. The remaining third neither improve nor grow worse. If good results are not obtained in exophthalmic goitre by x-ray treatment in a few months surgical treatment should be employed. Prolonged x-ray treatment in patients showing no response is undesirable. In toxic adenoma (adenoma with hyperthyroidism) there seems to be a similar improvement under x-ray treatment, but this treatment was used only for patients who refused operation. In toxic adenoma surgical treatment removes the actual cause of the disease, the adenoma. The indication for surgical treatment would therefore seem more definite than in exophthalmic goitre.

## SURGERY.

### 363. Plastic Surgery of the Face by Tubular Grafts.

(H. LENORMANT (*Bull. et Mém. Soc. de Paris*, March, 1923, p. 372) describes the method of plastic surgery on the face by tubular grafts, which he has adopted with extremely satisfactory results. The technique depends on taking a skin graft from the scalp, which is brought down and includes the temporal artery in its base. By suturing the edges of the graft together a tubular flap is obtained, and this can be utilized at considerable distances and made of large size. Further, the tubular graft is ensured of a sufficient blood supply to maintain its nutrition. The use of the tubular graft enormously enlarges the opportunities for plastic surgery of the face; the graft can be taken not only from the scalp but from the cervical or dorsal region. The scalp graft, however, has the double advantage of possessing an extremely rich blood supply, and furnishes a graft which can be used to replace the moustache or beard. The graft is prepared after estimating the size and the distance which separates it from the area to be covered. The two borders of the pedicle are enfolded and sutured together, the resulting exposed surface being covered with a vaseline dressing. The skin graft thus receives its blood supply at first along the tubular pedicle. After two or three weeks the transplanted skin is divided from its pedicle, which is unrolled and returned to its original position. No skin is lost by this method, and the elasticity of the skin enables the raw surface which is left to be filled in. The grafted portion has now obtained an adequate blood supply by its own new vascular connexions. It then remains, by patient and repeated care and treatment, to obtain a good aesthetic result. Further, it may be necessary to depilate the skin, when this is obtained from the scalp, by electrolysis or x-ray applications. Photographs are shown to illustrate this method applied to cases of epithelioma of the face, lips, and nose, with excellent aesthetic results; while by allowing the removal of large areas of skin in cases of cancer it increases the chance of permanent cure.

### 364. The Death Rate of Operations on the Thyroid Gland.

At the Mayo Clinic, during the year 1922, there were nineteen deaths following 1,983 operations on 1,355 patients for diseases of the thyroid gland, giving an operative mortality rate of 0.96 per cent. CHARLES H. MAYO and WALTER M. BOOTHBY (*Journ. Amer. Med. Assoc.*, March 31st, 1923, p. 891) state that such percentages, which are the common method of presenting statistics on goitre, not only fail to reveal the real truth, but conceal facts which, when brought out by a more detailed study, prove to be of great value. Statistics on surgery for goitre should be carefully and accurately analysed, and the results presented for each disease on the basis of the number of cases. An accurate basal metabolic rate is an index of the intensity of the disease in both

exophthalmic goitre and adenomatous goitre with hyperthyroidism, and therefore, in conjunction with other factors, is of help in selecting the best time and type of surgical procedure. The basal metabolism is of even more importance as an aid in the establishment of a correct differential diagnosis of the various thyroid diseases, and as a result of its use many unnecessary and sometimes harmful operations are avoided. In this report all patients who died while under immediate observation in Rochester after surgical intervention on the thyroid gland during their present visit are classified as having died from surgical procedures, regardless of the cause of death. The surgical mortality by case, according to Plummer's classification of thyroid diseases, is: Adenomatous goitre without hyperthyroidism, 0.15 per cent.; adenomatous goitre with hyperthyroidism, 3.48 per cent.; and exophthalmic goitre, 1.99 per cent. The mortality rate for thyroidectomy in exophthalmic goitre is 0.96 per cent. The surgical mortality represents the combined work of eight surgeons.

### 365. Carcinoma of the Tongue.

E. S. JUDD and G. B. NEW (*Surg., Gyn., and Obstet.*, February, 1923, p. 163) point out that in spite of its early detection the treatment of carcinoma of the tongue has been unsatisfactory because the importance of the diagnosis and treatment of precancerous conditions has not been appreciated. Any apparently insignificant lesion should be completely removed and its exact character determined. Leucoplakia is an example of a benign lesion becoming malignant. Every case is curable if treated early; if left, malignant changes may occur. Small ulcers, cracks, or papillomata may have been present for years and then become malignant. In nine cases out of ten cancer of the tongue occurs in men; the use of tobacco is undoubtedly a factor. The diagnosis must be made microscopically. A high percentage of recurrences follows operation, largely because many patients are operated on at an advanced stage of the disease. The most favourable situation is at the tip, though only a few occur here. Treatment is satisfactory if the lesion is on the dorsum and does not encroach on the floor of the mouth; lesions at the root of the tongue are unfavourable for treatment. The average age is 45 to 60 years. The growth is nearly always squamous-celled epithelioma. Seventy per cent. of recurrences take place in the glands and not in the operation scar. Operable cases of cancer of the tongue should not be treated with radium; many operable cases are made inoperable by radium. Precancerous conditions should not be treated with radium. Radium applications should be used after operation over or into the tongue and side of the neck. Of 303 cases which attended the Mayo Clinic from 1910 to 1922, 185 were inoperable; of the operable cases 30 per cent. are free from disease after more than three years; 24 per cent. after more than five years; and 7 per cent. after more than eight years. Most of the cases were operated on in two stages, the first stage being removal of the glands; when these were affected the glands of the opposite side were also removed. At a later date a wide removal of the lesion on the tongue is carried out. Cautionary excision is preferred. The Kocher operation was done in 6 cases with good results at the time, but they eventually died from recurrence.

### Traumatic Hernia.

366.

R. J. GRAVES (*Boston Med. and Surg. Journ.*, March 29th, 1923, p. 454) summarizes the problem of the causation of hernia, particularly from the standpoint of the employer. He says that the rapid increase in the amount of payments on account of hernia cases has been one of the chief sources of expense to industry in general on account of personal injuries to employees. The majority of authorities on the subject, he says, consider that hernia, especially oblique hernia, is seldom, if ever, due to a single shock or blow, but is a matter of slow development over a considerable period of time. This, however, is not admitted by a large number of medical practitioners, compensation boards, and laymen. In the author's opinion true traumatic hernia is a very rare condition; hernia is practically always due to pressure of a preformed sac or open pouch of peritoneum, to which is often added the presence of structural weakness in the neighbourhood of the hernial orifices. He lays down the following conditions for demonstration by a claimant in order to obtain compensation for hernia: It must appear suddenly; it must be accompanied by pain and tenderness; it must immediately follow some adequate accident; there must be proof that the hernia did not exist prior to the accident. The medical and surgical section of the American Railway Association has investigated the subject of traumatic hernia, and has adopted the position outlined above. Its report has been presented to and adopted by numerous American and Canadian medical societies.

## 367. Renal Tuberculosis.

FERRIA (*Rif. Med.*, March 19th, 1923, p. 281) discusses his experience of 126 cases of renal tuberculosis. These were 47 per cent. of the total number (269 cases) treated recently in the urological department, rather a high percentage. In 106 the disease was unilateral, and of these 89 were nephrectomized. The commonest type of lesion was ulcero cavcosous. In the rare instances where cure takes place some form of exclusion can be noticed. As shown by cystoscopy the bladder, especially at the ureteral orifices, is affected in 80 per cent. of the cases, and bladder symptoms are far more prominent than renal. The urine is usually acid, containing pus and blood; sometimes haematuria is an early symptom. Tubercle bacilli were found in 84 per cent. The ureter, especially in the pelvic portion, can often be felt thickened and enlarged. Medical treatment may, the author considers, cure some cases, but valuable time may be lost in the attempt. Surgical treatment depends mainly on whether the complaint is one-sided and on the state of the other kidney. Of the 89 nephrectomies, 6 died as a result of the operation, and 6 in the first six months after. Tubercle of the other kidney occurring later was only noted twice. Death is more often due to tuberculosis of other organs, such as the lungs or meninges; this was noted in 7 cases.

## 368. Radium in Cancer of the Prostate.

J. ORAISON (*Journ. d'Urologie*, December, 1922, p. 496) finds that in cases of malignant disease limited to the prostate itself surgical treatment may be carried out with satisfactory results; if the disease involves surrounding structures it is of little use. Until recently all cases of advanced carcinoma were condemned to severe suffering and death. Cancer of the prostate usually starts with indefinite symptoms which do not send the patient to the surgeon for examination. It is only later that dysuria, retention, haemorrhage, and cystitis draw attention to a condition which has by now passed the limits of operability. The author has treated six cases with radium, and finds that locally there is a great improvement in the dysuria and pain with diminution in the size of the prostate. The general state of the patient, however, shows progressive cachexia, but in some cases the condition appears to be arrested for a time. He considers that radium improves the condition so far as local symptoms are concerned, but it does not affect the general cachectic state of the patient. These results are superior to those obtained by simple cystostomy. The radium may be introduced either through the bladder, the perineum, or the rectum; the urethral route is not advised. The best access is obtained through the bladder; the tubes can then be placed into the growth under direct vision.

## 369. Amaurotic Family Idiocy.

MARTIN COHEN (*Arch. of Ophthalmol.*, March, 1923, p. 140) reports a case which presents all the features of amaurotic family idiocy, but which is of non-Jewish parentage. In the year 1881 Warren Tay first described the condition of amaurotic family idiocy from the ophthalmological aspect. At a later period Sachs, unaware of Tay's earlier work, gave the designation "amaurotic family idiocy" to the symptom complex the eye findings of which had been previously described by Tay. In consequence the condition is sometimes spoken of as Tay-Sachs disease. The outstanding features of this symptom complex are: (1) the familial factor; (2) the age of onset of symptoms—third to six months; (3) the Jewish parentage; (4) the progressive mental impairment; (5) the striking eye signs—the cherry-red spot at the macula. There is a somewhat similar condition, which, however, occurs at a later age period and in which the Jewish parentage is not a feature; this other condition has been called the juvenile type of amaurotic family idiocy, and it is held by some that the two conditions cannot be sharply differentiated. Very few cases have been reported of the infantile type in which the Jewish parentage could not be substantiated, and in consequence this case is of unusual interest.

## 370. Surgical Treatment of Angina Pectoris.

W. B. COFFEY and P. K. BROWN (*Arch. Intern. Med.*, vol. 31, No. 2, February 15th, 1923, p. 200) point out that F. Franck long ago suggested resection of the cervical thoracic sympathetic for the relief of angina pectoris, but did not perform the operation. In 1920 Jonnesco reported the cure of a case of angina by resection of the left cervical sympathetic system under local anaesthesia. Coffey and Brown now record five cases of angina pectoris, two of them presumably due to syphilitic aortitis, in which sympathetomy was done (cutting of the direct connexions between the heart and the superior cervical ganglion). In one case the superior cervical sympathetic ganglion was removed; in the other cases merely the main trunk below the ganglion and cardiac

branches were severed. Death occurred in one of the cases six hours after the operation. Marked improvement was noted in the other four cases. Space limits do not permit an account of the details of the operation, nor a criticism of the cases and the results of the operation, but the authors consider that the relief obtained was sufficient to warrant further trial of this or similar operative procedures.

## OBSTETRICS AND GYNAECOLOGY.

## 371. Treatment of Abortion.

B. J. KOUWER (*Nederl. Tijdschr. v. Geneesk.*, March 10th, 1923, p. 970) records his experience of 1,938 cases treated at the Utrecht Obstetrical Clinic from 1911 to 1921. Twenty cases ended fatally, so that the mortality was 1.03 per cent. In 14 cases, however, the clinic was not responsible, death being due to criminal manoeuvres, so that the mortality was only 0.31 per cent. In cases of abortion without fever the mortality was 0.07 per cent., and in febrile cases 0.77 per cent.; 1,592 women were treated in their homes and 346 in the hospital. In the treatment of the former group the following procedure was adopted. The woman was ordered to remain in bed for at least seven days after the haemorrhage had ceased. If it recurred on the sixth day confinement to bed was enforced for about seven days. No drugs were given except opium on a few occasions. The woman was visited daily and the temperature taken at each visit. If the haemorrhage continued and was considerable in amount, without the cervix being fully dilated, the vagina was cleaned out with some antiseptic such as hydrogen peroxide or lysol, and plugged with vioform gauze, the accessible part of the cervical canal being treated in the same way. Vigorous uterine contractions often resulted, and within twenty-four hours the complete ovum was found in the plug. The uterine cavity was then explored with the finger and any portions of the decidua remaining were removed. Before treatment of any kind the patient's temperature was taken. This was necessary in the first place to exclude the possibility of infection, and secondly to protect the practitioner himself owing to the frequency of criminal abortion. If the temperature was found to be raised at the first visit the friends were informed. When the temperature was below 99.4° a careful bimanual examination was made. If the cervix was dilated the uterus was emptied after previous cleansing of the external genitals. When the temperature was above 99.4°, if nothing was found to indicate spread of infection to neighbouring parts, such as peritonitis, salpingitis, parametritis, or thrombo-phlebitis, the same procedure was carried out. An almost identical routine was followed in the treatment of patients in the clinic.

## 372. The Prophylactic Treatment of Eclampsia.

STROGANOFF (*Journ. Obstet. and Gyn. of the British Empire*, 1923, No. 1, p. 1) gives a full account of his improved method of treatment, which has been so successful as to reduce the maternal mortality of eclampsia to 1.7 per cent. and the foetal to 12.5 per cent. in 230 cases, whereas the maternal mortality in the cases collected for the Congress of Obstetrics and Gynaecology in this country was about 25 per cent. The author's fundamental idea for his method of treatment is that the fits play a predominant part in the results of the disease, and every fit brings the patient nearer death; therefore a method of treatment which diminishes the number of fits seems to be the ideal; this can be done by causing a diminution of toxins in the blood and preventing their action on the nervous system. The treatment advised is as follows: (1) Removal of all sources of irritation by keeping the patient in a darkened room which is also quiet, and by carrying out any catheterization, etc., under chloroform. (2) Treatment of fits: (a) Morphine hydrochloride 0.015 gram injected under chloroform. (b) One hour later 2 grams chloral hydrate in 200 c.cm. saline per rectum given under chloroform. (c) Three hours after beginning 0.015 gram of morphine subcutaneously under chloroform. (d) Seven hours after beginning 2 grams chloral hydrate as above. (e) In thirteen hours 1.5 grams chloral hydrate without chloroform if there have been no fits nor prodromata for twelve hours. (f) In twenty-one hours 1.5 grams chloral hydrate without chloroform if no fits or prodromata for twelve hours. (g) If the patient has been free from fits for twenty-four hours and is undelivered chloral hydrate is given every eight hours. (h) No enema is given unless the rectum is loaded. (i) It is advisable if the patient is seriously ill not to allow her to remain lying always on the same side, but to turn her frequently so as to minimize the risk of hypostatic pneumonia. (j) Chloroform should be given after the delivery of the placenta, as that seems to be a

likely time for fits to recur. (3) Hastening delivery. The author formerly recommended such action in many cases, but now, as a result of the usual stoppage of fits by his treatment, he rarely finds such treatment necessary. (4) Improving the condition of the vital processes. This is done by giving salines per rectum, or if conscious milk by the mouth, the amount averaging a litre a day. Digitalin is given if the pulse rate is above 110, and diaphoresis is induced if possible by hot bottles, especially to the loins and feet. The author is very much opposed to subcutaneous salines, as he considers they increase the strain put upon the kidneys, many bad results being obtained by such a method of administration. (5) Venesection. This is employed if fits recur three times despite other treatment, and the patient cannot be delivered during the next two to four hours, 400 c.cm. of blood being withdrawn. It is also advised when a patient has had numerous fits before admission. (6) Narcotics. As soon as the prodromata of a fit occur, such as increased headache, restlessness, high blood pressure, chloral hydrate and chloroform are given. The author is against giving large doses of morphine, and quotes references to cases in which unfavourable results have followed. By his method not more than 0.04 gram per diem is given. (7) Oxygen is given at the end of a fit to remove asphyxia. Professor Stroganoff has demonstrated this method of treatment in many clinics in Europe outside Russia with unvarying success, and the usual result has been for the clinic to follow his method for the future. He has offered to come to this country, and hopes to be given an opportunity to demonstrate his methods on cases of eclampsia occurring here.

### 373. The Course of Syphilitic Infection in Pregnant Women.

J. E. MOORE (*Johns Hopkins Hosp. Bull.*, March, 1923, p. 89). from a series of 200 cases of pregnant women with positive Wassermann reactions and of non-pregnant mothers with syphilitic children, comes to the following conclusions regarding the course of syphilis in pregnancy. (1) In many cases the usual manifestations of syphilis are milder in nature—in fact, in some cases no symptoms occur at all, though syphilis was contracted at impregnation. In a few cases the normal time between the primary lesion and the early secondaries is lengthened, but in such cases tertiary phenomena are apt to occur early, and are often grave in nature. These findings contradict the usual textbook teaching, which states that primary and secondary syphilis are exaggerated by pregnancy. (2) Among the multiparae only 5.3 per cent. of their children were definitely known to be free from syphilis, 41 per cent. having abortions or stillbirths. (3) The Wassermann reaction is often anomalous during pregnancy, and may be positive during pregnancy but negative after, which has been shown by Williams and Meuten; but the opposite phenomena may occur, and it has even been known to vacillate during pregnancy, being one day negative and the next day positive. (4) The protection against the early lesions of syphilis afforded by pregnancy may persist for a long time, and even for a lifetime, spontaneous cure seeming to be the ultimate result in a few cases. (5) Multiparae seem to be singularly free from remote grave complications of syphilis. (6) If late syphilis develops, the viscera and cardio-vascular apparatus, especially the latter, are most prone to be involved.

## PATHOLOGY.

### 374. An Attempt to Isolate Bacteriophages of Unequal Activity.

A. GRATIA and L. DE KRUIF (*C. R. Soc. de Biologie*, March 10th, 1923, p. 629) made a series of dilutions of the *coli* lytic principle, each of which was ten times more dilute than the preceding one. Placing 5 c.cm. of each dilution in a series of tubes, they added one drop of a young culture of *B. coli* to each. After incubation it was seen that lysis was only visible up to the eighth tube. The first and the eighth tubes were now heated to 58° C. Two principles were thus obtained, of which the former was very powerful and the latter very weak. What is the nature of this difference? A drop of the strong principle deposited on a tube of agar freshly sown with *B. coli* causes a complete zone of clarification, while a drop of the weak principle is insufficient to prevent an abundant growth of organisms. Does the difference between these two principles depend on the fact that one consists of a virulent strain of bacteriophage and the other of a weakly virulent strain, both of which were present in the primary principle from which they were derived? To test this 10 c.cm. of agar containing 1 c.cm. of a broth culture of *B. coli* were poured

into a Petri dish, and on the surface 0.1 c.cm. of a dilution of 10<sup>-1</sup> or 10<sup>-5</sup> of the original principle was spread by means of a spatula. After twelve hours' incubation little circular spots of clarification were visible. Of these 30 were picked off into tubes of broth, incubated overnight, and heated the following day to 58° C. On testing the 30 samples of principle thus obtained it was found that 23 were feeble ones, while 7 were strong ones. Now if these were pure strains it would be expected that however much they might be diluted each would give rise to a principle of the same degree of strength. But such is not the case. Dilute the strong principle down to 10<sup>-8</sup> and it gives rise to a feeble principle, just as was found in the original case. The hypothesis of pure virulent and pure weakly virulent strains must be abandoned. Further work showed that the strength of a given principle depends on the number of organisms into which it is inoculated; if it be mixed with a large number of organisms only a feeble principle is regenerated; if, however, a relatively large amount of principle be mixed with a relatively small number of organisms a strong principle is regenerated.

### 375. The Arrest of Albumoses and Peptones by the Liver.

IN view of the conflicting functions assigned by various authors to the liver—particularly in regard to its action in breaking down albumoses and peptones—H. DELAUNAY and J. DESQUEYROUX (*C. R. Soc. de Biologie*, March 17th, 1923, p. 710) have made some careful experiments on dogs in an endeavour to throw more light on the subject. The general technique consisted in starving them for twenty-four hours, anaesthetizing them with chloral, injecting known quantities of peptone, collecting the urine by catheters introduced just above the vesical entrance, and examining the urine for albumoses. This was done by precipitating the albumins with metaphosphoric acid, neutralizing the filtrate with sodium hydrate, and testing it with Tanret's reagent in such a way as to obtain quantitative information as to the amount of albumose present. It was found that injection of peptone into either the mesenteric or the splenic veins was followed by a marked albumosuria, which came on during the actual introduction and persisted for some considerable time afterwards. Similarly with injection of peptone into the saphenous vein. In fact there appears to be no difference whether it be introduced into the portal or the general circulation so far as the resulting albumosuria is concerned. But when the peptone was injected—even in large quantities—into an isolated loop of the jejunum no albumose was detected in the urine, although it could be shown that the peptone had been almost completely absorbed. From these experiments it appears that the small intestine is the only organ essential to the arrest and transformation of albumoses and peptones resulting from digestion. The liver does not seem to have any greater power than other organs to fix these substances.

### 376. Changes in the Islands of Langerhans in Diabetes Mellitus.

M. J. CONROY (*Journ. of Metabolic Research*, September, 1922, p. 367) reports the results of a study of quantitative and qualitative changes in the islands of Langerhans. A thorough study was made of all parts of the pancreas in 12 cases of diabetes and 12 controls of similar age, and a less thorough study of 95 routine autopsies of non-diabetics. Both quantitative and qualitative differences were found in the diabetic and non-diabetic groups. In the diabetic group an enumeration of the islands in sections from serial blocks of tissue through the entire organ showed a marked reduction in the amount of insular tissue. The average number of islands per cross-section was 73.6, as compared with 183.6 in the controls. In only one non-diabetic case was the count as low as the highest figure in the diabetic group. Every case of diabetes showed more or less qualitative changes in the islands, chiefly hyalinization and fibrosis, the latter lesion being quite widespread in some cases. Hyalinization of the islands was seen in only two cases of the non-diabetic group, and in these it was not so pronounced as in the majority of the diabetic cases. Definite hydropic degeneration of the islands was observed in only one of the diabetic cases and in none of the controls, but it is possible that the tissue in most cases was not fixed sufficiently early after death for a satisfactory study of this lesion. Changes involving the acinar tissue, particularly interacinar and interlobular fibrosis, were seen in both series, but were more marked in the diabetic cases. From this study the author concludes that both quantitative and qualitative changes are operative in leading to a functional insufficiency of the insular tissue as manifested by clinical diabetes.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## MEDICINE.

### 377. Aseptic Purulent Meningitis.

LISBONNE, LEENHARDT, and Mlle SENTIS (*Bull. de la Soc. des Sci. Méd. et Biol. de Montpellier*, etc., November, 1922, p. 28) observe that since Vidal's description numerous cases of aseptic purulent meningitis have been published. All recent authors attribute it to an intense meningeal congestion. This may be due to localized septic lesions of the meninges or of neighbouring structures—otitis media, sinus phlebitis, cerebral abscess. Jumentié and Mlle Sentis have described aseptic purulent meningitis following chronic inflammation of cranio-cerebral wounds. The syndrome is frequently produced by toxic irritation; intrameningeal injection of an anaesthetic, or of animal or human serum; alcoholism, or antityphoid vaccine intoxication; syphilis or uraemia. A few cases are of uncertain origin. The authors' patient was a boy, aged 9, who on July 14th, 1922, was exposed to the sun for several hours on a very hot day. He complained of violent headache and vomiting. There was no history of digestive disturbance. In the night he was feverish and had convulsions. Next day a lumbar puncture yielded, under marked pressure, a green turbid fluid containing an enormous number of cells, chiefly polynuclears, which stained well and showed no changes. No micro-organisms were found directly or after cultures. There was considerable albuminuria with marked decrease of urea and of chlorides; no oedema. On admission, two days later, all the symptoms of acute cerebro-spinal meningitis were present—severe headache, rigidity of the spine and limbs, constipation. He vomited once just after admission. The temperature was normal. The next day he passed a large quantity of urine: sp. gr. 1011, trace of albumin. The cerebro-spinal fluid was clear, with excess of polynuclears. Eight days after the onset there was green diarrhoea with abdominal tympanites; the temperature rose to 104° F.; bilious vomiting. The cerebro-spinal fluid was once more under high pressure, and meningeal symptoms intense. Two days later the temperature was normal, and in seven days the cerebro-spinal fluid was normal. The urine was free from albumin, and convalescence was uninterrupted. Forty days after the onset he was discharged in perfect health; all cultures were sterile. Three injections of antimeningococcal serum were given during the illness, but appeared to have no effect on its progress. The authors state that although retention of urea and of chlorides has been considered to be due to a uraemic factor in these cases, Jumentié and Mlle Sentis have observed it in aseptic meningitis due to local infection. This patient had no sign of uraemia. Blayac has reported three cases of retention of urea and of chlorides in cerebro-spinal meningitis. The authors conclude that this form of meningitis often produces an acute and transient uraemia, which is not connected with that of chronic nephritis. Dopfer has recorded nine similar cases due to heat-stroke. A full bibliography completes the article.

### 378. Electrical Methods in the Diagnosis and Prognosis of Paralysis due to Nerve Lesions.

G. BOURGUIGNON (*Journ. de Radiol. et d'Electrol.*, vi, p. 565) has devised an apparatus whereby the chronaxie (the duration of passage of a constant current, of abrupt start, with which to stimulate any particular muscle) of nerves and muscles may be measured indirectly by means of condensers. He claims that this method is much more rapid than the direct measurement with currents of known duration. He has in this way measured the chronaxie of all the skeletal muscles, and finds that: (1) The proximal muscles of the limbs have the shortest chronaxie, the extensors of the fingers and the plantar flexors of the foot and toes having the longest chronaxie. (2) Muscles which act against gravity in the erect position of the body have a shorter chronaxie than those which act with gravity. (3) Synergic muscles—those acting together to produce a movement, as, for example, extensor carpi radialis and flexor longus digitorum—have the same chronaxie. (4) The chronaxie of a muscle and of its nerve must be closely related. If the chronaxie of the muscle becomes unduly long, even if the nerve is intact, the muscle is paralysed. (5) When a muscle is paralysed by a lesion of its nerve its chronaxie lengthens gradually; as the nerve regenerates the chronaxie shortens until it returns to normal. (6) In the absence of an apparatus for measuring chronaxie, muscles should be tested with the galvanic current only. The exact duration and strength of each induction shock being unknown, the faradic current gives very uncertain results. (7) Examinations for polar inversion should be discarded. On

"making" a current the negative pole alone stimulates; on "breaking" the current, the positive pole alone. The appearance of polar inversion therefore depends on whether the stimulating pole is in relation to nerve or muscle. (8) The "reaction of degeneration" is present when (a) there is no contraction of the muscle on stimulating its nerve by a strong current (at least 15 milliamperes), and (b) when similar contractions result from stimulating the motor point and from longitudinal stimulation of the muscle.

### 379. Acute Tuberculous Meningitis following Traumatism.

VEDAL, G. GIRAUD, and SIMÉON (*Bull. de la Soc. des Sci. Méd. et Biol. de Montpellier*, etc., January, 1923, p. 130) refer to the frequent latency of cerebral lesions in adult tuberculosis until the occurrence of an accident, often a very violent one. Occasionally, particularly in pulmonary tuberculosis, sudden coma, which may be preceded by convulsions, ushers in the acute meningitis. These patients are in a state of unstable equilibrium; an accident or an operation—for example, curetting of osteo-articular tuberculous foci—may set free bacilli which, traversing the general circulation, attack the meninges. Blows or falls on the head have been the determining factor in many cases. Gullain has observed meningeal symptoms following simple lumbar puncture and abstraction of cerebro-spinal fluid in cases of Pott's disease. The authors' case was that of a tramway employee, aged 23, who fell from the platform of a car as the result of a collision. The fall was not severe, nor was the head directly implicated. The patient, however, immediately lost consciousness and never regained it. He had complained of lassitude and persistent frontal headaches for some weeks; he had also had a slight cough, but had lost no time from work. Next day the symptoms of tuberculous meningitis were obvious. Stiffness of the neck and Kernig's sign were present. The patient neither spoke nor groaned; he could not be aroused. The lungs showed signs of advanced bilateral tuberculosis; there were no signs of external injury. The cerebro-spinal fluid showed marked lymphocytosis with negative Wassermann reaction. The patient died four days after the accident. The autopsy confirmed the diagnosis; in addition to the meningeal and pulmonary lesions, a tuberculoma as large as a haricot bean was found beneath the pia mater of the anterior end of the right frontal lobe; it was surrounded by a deep zone of congestion and may have been the point at which the meningeal invasion commenced.

### 380. Treatment of Syphilis of the Newborn.

R. DUPÉRIÉ and R. ENCONTRE (*Gaz. Hebdom. des Sci. Méd. de Bordeaux*, March 11th, 1923, p. 110) have treated fifteen babies suffering from congenital syphilis in the following manner. Mercury was first given both by inunction and by the mouth for two to four days. They then gave a series of ten to twenty subcutaneous injections of sulpharsenol, in doses rising from 5 to 15 mg. per kilogram of body weight, at intervals of three to four days. After this series the mercurial treatment is continued for one to one and a half months; then another series of ten injections of sulpharsenol; then one and a half months of mercury, and so on for at least two years, four or five series of injections being given each year. The subcutaneous injection of sulpharsenol in concentrations lower than 0.06 gram per cubic centimetre of distilled water seemed to be completely painless, and did not usually cause any induration of the tissues. All the fifteen babies treated in this way were at the time of writing alive and in good health. The authors insist on the importance of breast-feeding for syphilitic babies, as the lesions of the liver and kidneys make it almost impossible for them to digest cow's milk and eliminate the drugs used in treatment at the same time; whereas the mother's milk, if she is herself undergoing treatment, acts as an antisyphilitic remedy. Under this treatment the infants at once began to put on weight, and lesions of the skin and mucous membranes rapidly disappeared. Bony lesions were more slowly resolved. Dentition was, however, affected in most cases. In some of their cases slight rickets appeared between the tenth and twelfth months, but yielded rapidly to special treatment. Enlargement of the spleen and lymphatic glands did not usually disappear till the end of the first year of treatment. The liver usually remained enlarged. Affection of the nervous system was often manifested by slight hydrocephalus, mental backwardness, and slowness in walking. The Wassermann reaction of the blood became either feeble or completely negative at the end of two years; but the authors do not consider themselves justified in saying that any infant

was completely cured, and advise continuation of mercurial treatment in all cases, with further courses of sulpharsenol on the appearance of any new manifestation of syphilis.

### 381. The Treatment of Peliosis Rheumatica.

E. RAUTENBERG (*Deut. med. Woch.*, January 26th, 1923, p. 112) has since 1915 been practising a treatment which he invariably found successful in the 23 cases admitted to his hospital. The treatment consists of injecting into the spinal canal by lumbar puncture 4 c.cm. of normal saline solution containing 0.02 gram of novocain. While under ordinary antirheumatic treatment and rest in bed the bright red or violet spots of peliosis rheumatica take at least a week or two to disappear, they vanish in a few hours after an injection of novocain, and never take more than a day or two to disappear. This rapid disappearance of the spots suggests that they are not formed by actual extravasation of blood, but by stagnation of blood within temporarily dilated vessels of the skin. This hypothesis has been confirmed by examination under the microscope of sections of the skin, which showed only dilatation of the blood vessels, oedema, and infiltration with leucocytes, but no extravasation of blood. The author's explanation of the success of his treatment is that the primary site of the lesion in peliosis rheumatica is not the skin but the central nervous system, probably the lower section of the cord or the cauda equina. According to this view, the spinal injection of novocain acts by blocking morbid impulses which pass from the central nervous system to the periphery, and by giving the peripheral structures time and opportunity to recover. The author has applied this treatment to other forms of skin disease, such as erythema nodosum, but with little success. It would therefore seem that peliosis rheumatica occupies a peculiar position with regard to its etiology, which appears to be analogous to that of herpes zoster. Other symptoms, such as pain in the muscles, responded as promptly to the injections as did the rash.

## SURGERY.

### 382. Treatment of Fractures of the Upper End of the Humerus.

L. RITTER (*Zentralbl. f. Chir.*, February 23rd, p. 245) describes the method of treating these fractures, as employed at the Augusta and Bürger Hospitals at Cologne. The method follows closely that recommended first by Bardenheuer. Where there is much displacement, ethyl chloride anaesthesia is used, in getting the best reposition possible. Impacted fractures are not disimpacted unless the position of the fragments is bad. A strip of adhesive plaster 6 c.cm. broad is applied, beginning on the flexor aspect, over the upper part of the biceps. This passes down over elbow and wrist (these regions being well padded with wool), and over the extended fingers, leaving a short loop to take a stirrup; the plaster is then applied along the extensor aspect of hand, forearm, and arm, up to the posterior axillary fold. Circular turns of plaster are then applied round forearm and arm, and a moist bandage over all. The arm is abducted to an angle of about 125 degrees, and a weight of 10 to 12 pounds attached to the stirrup, the cord passing over a pulley attached high up to a neighbouring bed. The elbow is kept slightly flexed, to an angle of about 135 degrees, a sandbag being placed over the region of the elbow-joint, to preserve the angle. (Full extension of the elbow is very liable to lead to stiffness, especially in the aged.) In cases where treatment in bed is contraindicated, plaster is applied to the sides of the upper arm, with a loop under the elbow for extension, using a square piece of lead as the weight. From the second week, passive movements of the shoulder are practised; from the third week active movements also. The distal joints are moved daily, from the first day. The average length of time during which the extension is kept up is three weeks. In describing a large number of cases, the author distinguishes between fractures of the surgical neck and trans tuberculous fractures at a slightly higher level. Of the first group, 17 patients got complete restoration of function; 13 almost complete; 6 a fair and sufficient result; and 3 were unsatisfactory. Only a small number showed an ideal result by  $\alpha$  rays. Of transtuberculous fractures, the result was excellent in 4, good in 9, fair in 6, and bad in 2. The average age of the second group was 63.5 years. A description and comparison is given of various methods of treatment employed by other workers.

### 383. Pericardiotomy in Diagnosis and Treatment.

J. B. ROBERTS (*Arch. of Surgery*, January, 1923, p. 101) says that diagnosis may be established in obscure conditions occasionally, and permanent relief given to the patient, with only a negligible risk, by a digital exploration of the heart sac. The differential diagnosis between effusion, empyema, or bleeding into the pericardium and hypertrophy or dilatation of the heart may be obscure; the outlook for the patient may be gloomy. In such circumstances the surgeon is driven to exploration of the

interior of the pericardium. Pericardiotomy is not an operation requiring an unusual amount of surgical skill; it should be performed on the left side of the breast bone, both in instituting diagnosis or treatment. A large hypodermic needle may be used to establish the presence or absence of fluid in the heart sac when pericardiotomy is being considered. The author believes that pericardial pus may be evacuated and the cavity drained and sterilized by frequent irrigation with phenol, as may be done in pleural suppuration; he does not advise resection of ribs. Diagnostic pericardiotomy should be employed in the interval between the fourth and fifth ribs, or, if room, between the fifth and sixth ribs. An elliptical flap with the convexity downwards should be turned so as to expose the fourth interspace. The pericardium is opened and its interior explored with the finger. If the pleura is damaged no great harm is done unless pus is present. To expose the heart for a wound an osteoplastic flap should be turned up by dividing the fourth and fifth cartilages. The author reports a case of a child where the diagnosis of pericardial effusion was made. Diagnostic pericardiotomy showed the condition to be due to cardiac hypertrophy. Recovery followed the operation.

## OPHTHALMOLOGY.

### 384. Radiotherapy in Ophthalmology.

ROLLET (*Journ. de m d. de Lyon*, March 20th, 1923, p. 151) states that improvements in technique have done away with the injurious effects of  $\alpha$  rays upon the eye, and that experiments made on rabbits by Malot and himself in 1914, subsequently confirmed by Terrien in 1919, have shown that numerous radiations did not produce any ocular lesions. During the last ten years Malot and his collaborators at Lyons have carried out 2,050 ocular irradiations proving the invulnerability of the eye of the adult patient and of the radiologist, provided a certain technique (small doses with appropriate filtration) is followed. The method was employed in four diseases—namely, tuberculosis, cancer, inherited syphilis, and trachoma—with the following results: (1) Incipient tuberculosis of the anterior segment of the eye may be cured by  $\alpha$  rays. Three illustrative cases of tuberculosis of the iris cured by Rollet with this method are reported. Tuberculosis of the lacrimal sac was always treated surgically by extirpation of the sac, and irradiations were never employed. (2) In early cancer of the lower lid excision is the best treatment, but when the lesions are extensive  $\alpha$  rays should be substituted, though they do not always produce an aesthetic scar. Radiotherapy is also indicated in cases of recurrence. Palpebral lymphoma is very amenable to  $\alpha$  rays and may subside as the result of this treatment. Extirpation is the best mode of dealing with encapsulated cancer of the orbit (sarcoma or endothelioma). Recurrences, which often take place as late as eleven or twelve years afterwards, should be treated by  $\alpha$  rays. In cancer of the eye such as choroidal melanoma or retinal glioma no improvement can be expected from  $\alpha$ -ray treatment. Epithelioma of the sclero-corneal limbus can be cured by excision followed by radiotherapy. (3) Rollet has treated about 20 cases of interstitial keratitis with  $\alpha$  rays. The efficacy of the treatment on the inflammatory signs was shown by disappearance of photophobia, lacrymation, blepharospasm, and pain. It is important in such cases that general treatment should be combined with radiotherapy. (4) In trachoma the conjunctival granulations may disappear under  $\alpha$ -ray treatment but often recur. The applications are painless and are specially indicated in patients who are afraid of operation and the use of copper sulphate. Radiotherapy is chiefly suitable for recent cases, as in old-standing cases with marked sclerosis little improvement can be obtained.

### 385. Ocular Tuberculosis.

A. L. WHITEHEAD (*British Journ. of Ophthalmol.*, December, 1922, p. 529) observes that ocular tuberculosis is comparatively rare in pulmonary tuberculosis and in serious cases of surgical tuberculosis, though ocular lesions are often followed by other manifestations in after years. The author quotes recent (1921) German statistics—92 "scrofulous" eye cases followed up for ten to thirty years showed pulmonary changes in 13.9 per cent. and active tuberculosis in 13 per cent.—and differentiates acute severe infections leading to more or less complete destruction of the globe, and the more chronic forms. In the former, giant cells and tubercle bacilli are found frequently; in the latter they are seldom found and inoculation tests usually fail. *Tuberculous choroiditis*: In acute infantile tuberculosis miliary tubercles of the choroid are frequently found as well as in nearly all fatal cases of tuberculous meningitis. Whitehead has not seen them in patients over 30. He has seen two cases of vitreous haemorrhages preceding general tuberculosis; in one a typical nodular iritis supervened and cleared up under treatment. Several observers have reported favourably on tuberculin in recurrent retinal haemorrhages. *Tuberculous iritis* frequently appears in

young and apparently robust adults, usually females, with no other symptoms, but a definite family history is generally obtained. Tuberculin, in proper doses, usually proves valuable. The author has had a case of chronic dacryocystitis occurring in a girl who has been under treatment for various manifestations of tuberculosis during a period of five years. The patient looks "the picture of health." *Tuberculous conjunctivitis*, in the author's experience, is usually mild; "cockcomb excrescences" are rare; he is not convinced that all cases of phlyctenular conjunctivitis in children are of tuberculous origin, but considers that the type found in young adults—small, closely set phlyctenules near the corneo-scleral junction, seldom ulcerating and very resistant to ordinary treatment—are definitely tuberculous. The von Pirquet reaction is frequently positive, and in all cases, either evidence of other tuberculous lesions or a clear family history can be obtained. Tuberculin treatment in these cases gives immediate and striking results. The author gives full details of the doses which he employs. He regards all these minor lesions as due to toxic infection from foci elsewhere—for example, infected tonsils and adenoids; hence the necessity of careful search for such focus, followed by appropriate treatment. Whitehead quotes Stewart's observations—in autopsies on 100 soldiers of good physique, dying from wounds: evidence of old tuberculosis was found in 54, and in 32 per cent. definite glandular infection. Whitehead strongly recommends excision of a strip of conjunctiva all around the corneo-scleral margin with careful scarification of the larger vessels invading the cornea. *Tuberculous keratitis* is rare, but in some cases simulates that of congenital syphilis; the corneal surface is, however, more irregular, though ulceration is rare; the vascular invasion is much more superficial and the opaque patches less regularly distributed. Peritomy is valuable in tuberculous pannus, but useless in syphilitic keratitis. Possibility of mixed infection must be remembered. *Tuberculous scleritis and episcleritis*, often with invasion of the iris and cornea, may be due to direct infection. Whitehead concludes that ocular tuberculosis is much more frequent than is usually taught.

### 388. Correction of Certain Forms of Squint.

JOSEPH L. MCCOOL (*Amer. Journ. Ophthalmol.*, February, 1923, p. 107) has studied eleven cases of spasm of the inferior oblique, of which seven cases were secondary to a palsy of the opposite superior rectus. Of the remaining four cases he was unable to determine which muscle or muscles were primarily responsible for the spasm. Three of these cases were associated with convergent squint. It is noteworthy how often a long-standing convergent squint is complicated by a pronounced upward tilt of the squinting eye. Cases in which graduated tenotomy of the inferior oblique can be adopted with success may be classified as follows: (1) paresis of the superior rectus with spasm of the opposite inferior oblique; (2) paresis of the superior rectus with spasm of the opposite inferior oblique and also spasm of the inferior rectus of the paretic eye; (3) paresis of the superior oblique with spasm of the inferior oblique of the same eye. In arriving at the diagnosis of spasm of the inferior oblique, the possibility of too high an insertion of the internal rectus must be kept in mind. If the upshoot of the eye is present in convergence as well as when the eye is rotated laterally a misplaced internal rectus should be suspected, but when the upshoot of the eye is not noticed in convergence then spasm of the inferior oblique is probably present. With regard to the technique of the operation of tenotomy of the inferior oblique, McCool favours a graduated tenotomy by a series of cross cuts rather than a complete division of the tendon. This, he holds, will weaken the action of the muscle sufficiently, whereas in complete tenotomy, owing to the lack of check ligaments to this muscle, there is danger of the result being overdone.

### 387. Therapeutic Use of Weak Atropine Solution in Asthenopia.

W. E. GAMBLE (*Arch. of Ophthalmol.*, March, 1923, p. 160) draws attention to the well known fact that extreme discomfort may be caused by the instillation of eserine drops into the eye. This discomfort is caused by the spasm of the sphincter iridis and ciliary muscle which is induced by the eserine. He points out that an increasing number of people are unable to tolerate the accommodative spasm which is induced by prolonged close work. As always, rest would appear to be the treatment for this condition, and he suggests that this rest can be most satisfactorily obtained by the use of high dilutions of atropine. The dilution of atropine which is to be used must be sufficiently high so that the pupil is not unduly dilated and so that close work is not interfered with. The method which he employs is to use a solution of atropine of a strength of 1/200 of a grain of atropine sulphate to an ounce of water, and to instil a drop of this solution into the eyes on Saturday afternoons. This procedure, he says, will not interfere with the doing of close work during the ensuing week, and will afford much relief. He reports several cases in support of his suggestion.

## OBSTETRICS AND GYNAECOLOGY.

### 388. Radium and Surgery in the Treatment of Non-malignant Uterine Haemorrhage.

E. A. WEISS (*Amer. Journ. of Obstet. and Gyn.*, February, 1923, p. 128) has used radium in a series of 100 cases of uterine bleeding, 83 of which were fibromyomata. From the author's experience the opinion is expressed that radium should only be used in fibroids when bleeding is the only symptom and the tumour is not larger than a three months' pregnancy; also one should be sure that there is no degeneration occurring in the tumour and no inflammation of the adnexa, as radium causes fresh exacerbations in the latter cases. This occurred in two of his series and operation was required. The author recommends radium as the ideal treatment when the patient is severely anaemic and would not stand the strain of operation, as the bleeding is stopped, the patient's general condition improves, and operation can be done at a later date, if necessary, with the patient's general condition vastly improved. Radium is not recommended for patients under 35, as the menopause is usually produced, and thus myomectomy is a better method of treatment whenever possible. The author strongly recommends radium in small doses (25 mg. for eight hours) for cases of severe uterine bleeding in adolescents and young women, which resists all other treatment. In such cases amenorrhoea is only temporary, and Clark, Stacey, and others have reported several cases of pregnancy following thereafter. Radium is also strongly recommended for severe menopausal bleedings, after cancer has been excluded by curettage and gross pelvic lesions and cardiovascular disease eliminated (50 mg. of radium for twenty-four hours produced a complete cessation of bleeding in each such case); the author asserts that for climacteric bleedings classified as hyperplasia, fibrosis, chronic metritis, etc., no surgeon should resort to hysterectomy to obtain a cure if radium is available: 40 cases were relieved at once without bleeding returning and 35 menstruated once. Leucorrhoea was prevalent for two to five months, and was best treated by sodium bicarbonate douches. The chief distressing symptom was nausea and vomiting, which occurred in many cases when the radium was *in situ*; to this condition the author has applied the name of "radium sickness." The menopausal symptoms were more acute than normal, but were relieved by ovarian residue or corpus luteum.

389. S. E. TRACY (*Amer. Journ. of Obstet. and Gyn.*, February, 1923, p. 135) discusses the treatment of fibromyomata with radium, and concludes that very few cases are really available for such treatment, as 30 per cent. of fibroids are degenerating and in another 40 per cent. of cases there is some abdomino-pelvic pathological condition associated with the fibroid (for example, salpingitis); thus 70 per cent. have complications, which are quoted to contraindicate radium therapy. These are the figures for all fibroid tumours, but if one considers fibroids in women over 40, which are the radiologist's ideal, complications are further increased, and only 16 to 18 per cent. are found to be uncomplicated; the diagnosis of such is extremely difficult, if not impossible in many cases. Pain always contraindicates radiotherapy, as it is not relieved by such treatment (Miller). The author advocates radium in the treatment of (1) simple uncomplicated small or medium-sized tumours causing bleeding at the menopause; (2) when bleeding occurs after myomectomy; (3) when the patient's general health is so impaired that an operation would be attended with undue risk; (4) climacteric bleeding due to chronic fibrosis. He asserts that if the mortality for all cases of fibroids operated on is 2 per cent., the mortality for uncomplicated cases such as are suitable for radium would be practically nil, and the complications which may occur after radium, due to the impossibility of determining some pathological condition, is eliminated.

### 390. The Operative Treatment of Sterility.

E. GRAFF (*Arch. f. Gyn.*, December, 1922, p. 368) draws attention to the fact that though great strides have been made in operative gynaecology during the last thirty years, little progress has been made in the operative treatment for sterility. The operations performed are (1) those for dilating the cervix, which have been indifferently successful; (2) those for replacement of a displaced uterus; and (3) salpingostomy, which up to now has only been done in special cases. The author points out that many cases of sterility are caused by impermeability of the tubes, and this is especially the case when any signs of inflammation of the uterus or adnexa can be found by bimanual examination, this being found to be so in 72 per cent. of his cases. He therefore urges that before any operation is performed the tubes should be inflated by Dr. Rubin's apparatus for the induction of transuterine pneumoperitoneum to find if they are permeable or not. If permeable, then a dilatation or

replacement-operation can be done, but if not, such operations are useless and salpingostomy seems to be the only rational procedure. It is too early to give the results of this operation for sterility, but it is by no means a certain cure; still it gives the woman a chance of becoming pregnant, which the other operations do not if the tubes are impermeable.

### 391. The Treatment of Essential Uterine Haemorrhage.

A. THEILHABER (*Arch. f. Gyn.*, December, 1922, p. 282) thinks that x-ray treatment for uterine haemorrhage has been a decided advance, but in some cases, especially in the haemorrhage occurring in young women, most medical practitioners are chary of x rays as they are apt to produce an artificial menopause. Thus it is necessary to have another means at one's disposal for the treatment of such cases, and as the author states that such haemorrhage is due to venous stasis, a treatment which will cause an acute inflammation of the endometrium ought to be curative by inducing an increased arterial supply which will remove any venous stasis. For such a treatment the author applies cauterization by diathermy, a sound with a small metal head of about 1/3 cm. in diameter being used. The current is applied for twenty to thirty seconds, and eight to ten points may be cauterized. By this treatment the author has had fair success, over half of his cases being cured with one application. He also recommends the same treatment for very chronic and resistant gonorrhoeal endometritis without tubal involvement, and has had over 60 per cent. successes, but his numbers are too small yet to draw any conclusions. He states that the treatment is practically painless and can be done for out-patients without any untoward after-effects.

## PATHOLOGY.

### 392. Gastric Carcinoma of the Intestinal Type.

F. RAMOND, JANET, and M. LEVY (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, February 29th (sic), 1923, p. 294) show that carcinoma of the stomach may assume the appearances of carcinoma of the intestine. This type of cancer is common, and is perhaps more often found than true gastric carcinoma. There may be found in the gastric mucosa small areas of intestinal mucous membrane. These islets have been examined by the writers in sixty specimens obtained from operations and *post mortem* and show all the characteristics of the intestinal epithelium. The contrast between these areas and the rest of the gastric mucosa is most striking, especially when stained with mucicarmine. These islands of cells appear to be the starting point of many cases of gastric carcinoma. The authors report the case of a patient who died after perforation of a gastric ulcer. Examination of the stomach showed that in the non-ulcerated portion the epithelium was of the gastric type, practically normal; as the ulcer was reached the mucosa underwent a change, with a gradual disappearance of cells of the gastric type and showing the appearances of intestinal mucous membrane covering the whole thickness of the mucosa, with glands of Lieberkühn. The appearances suggested that it was a piece of ileum when examined under the microscope. At the site of the ulcer malignant cancer cells could be detected in the superficial layers of the epithelium. This fact is of importance, as other writers have maintained that cancerous changes always start in the deeper layers and never on the surface. These observations show that cancer or ulcer of the stomach may develop in areas of the mucosa having the appearances of intestinal mucous membrane. Whether these areas are congenital or of acquired origin is of importance. If congenital it is difficult to see how cancer or ulcer may be prevented; if acquired it may perhaps be possible to prevent the metaplasia taking place and the complications which arise.

### 393. Specific Haemagglutinins and Serum Disease.

A. DALLA VOLTA (*Arch. di patol. e clin. med.*, March, 1923, p. 21), who records six cases illustrating the production of specific haemagglutinins in man following the administration of heterogeneous serum, comes to the following conclusions: (1) Parenteral injection of normal or immune horse serum in man gives rise to the formation of hetero-agglutinins as well as specific precipitins. (2) Side by side with specific agglutination of a high degree there is a group reaction for red cells of kindred species. (3) The quantity of horse-serum to be injected is always considerable and should be given within a brief space of time (seventy-two hours). (4) Haemagglutination appears after a latent period of six days and becomes most pronounced on the twelfth day. (5) The phenomenon is still present and is equally intense at the end of four months. (6) Its appearance coincides with the manifestations of the serum disease, of which it represents a characteristic serological reaction. (7) The intensity of the phenomenon proceeds *pari passu* with the severity and

intensity of the cutaneous manifestations (urticaria) of the serum disease. (8) The phenomenon may be a means of diagnosing a serum rash from urticaria due to other causes.

### 394. The Complement Fixation Reaction in Tuberculosis in the Dog.

J. VERGE (*C. R. Soc. de Biologie*, March 3rd, 1923, p. 562) has confirmed in the dog what has already been observed several times in cattle—namely, that subcutaneous injection of tuberculin into a healthy animal gives rise to no antibody production, while the same injection into an animal which is suffering from tuberculosis stimulates the formation of specific antibodies. Using the complement fixation reaction as a measurement of the antibody content of the serum, he injected 0.5 to 1.5 c.cm. of a 1 in 10 dilution of tuberculin into healthy dogs, and found that the serums of these animals, examined from four to thirty-three days after the injection, failed to show any evidence of the presence of specific antibody. Working, however, with four definitely tuberculous dogs, each of which gave a positive fixation reaction, he observed that the injection of tuberculin invariably gave rise to an increase in the amount of antibody present. The titre rose to a maximum ten to fifteen days subsequent to the injection, and then fell slowly. In one dog, the titre of whose serum before the injection was 5 units, a rise was observed up to 30 units on the eleventh day; this titre remained constant till the fifteenth day, after which it dropped rapidly to 6.6 units on the nineteenth day; the animal died twelve days later. This rapid decline before death has already been noted by Besredka.

### 395. Otosclerosis and Rickets.

A. B. KAUFFMANN, FRANCIS CREEK, and O. T. SCHULTZ (*Journ. Amer. Med. Assoc.*, March 10th, 1923, p. 681) have found, in young rats which have been maintained on a diet low in fat-soluble vitamin A and in calcium, that there occur abnormalities of the osseous capsule of the internal ear identical with those changes in the long bones which are characteristic of experimental rickets. These alterations, since they occur in structures concerned in the function of hearing, may result in an impairment of hearing. The analogies between the changes in the temporal bones in experimental rickets and the lesions which have been described in otosclerosis suggest, in the author's opinion, that the latter condition may be a late result of rickets or a manifestation of a dietary deficiency still existent during adult life.

### 396. The Genesis of Ovarian Tuberculosis.

E. WERTHEIMER (*Arch. f. Gynäk.*, March 17th, 1923, p. 136) examined serial sections of both ovaries in 18 patients whose primary tuberculous infection appeared to be pulmonary and who were found at autopsy to have generalized haematogenous infection as shown by the presence of miliary tubercles in certain viscera. The patients ranged in age from 1 to 53 years. Ovarian tuberculosis was found in 7; 3 showed tuberculous peritonitis and tuberculous disease of the Fallopian tubes, so that the ovary had been infected by direct extension, but in 4 patients one or both ovaries showed the presence of miliary tubercles without presenting macroscopic evidence of infection, and in the absence of local peritoneal or of tubal or uterine tuberculosis. Haematogenous ovarian infection was noticeably less common in these cases than that of spleen, liver, adrenals, or the cerebral meninges.

### 397. Excess of Albumin in the Cerebro-spinal Fluid in Syphilis

M. BROCH (*Paris méd.*, March 3rd, 1923, p. 221) remarks that excess of albumin in the cerebro-spinal fluid is not infrequently the only manifestation of syphilis, as was pointed out by Ravaut many years ago. The condition, however, is met with in many other diseases besides syphilis, such as compression of the spinal cord by tumours, Pott's disease, etc., as well as in intracranial compression by tumours, in commotion and in meningeal haemorrhage, as a residue of meningo-encephalitis due to different causes, in chronic affections such as disseminated sclerosis, dementia praecox, melancholia, epilepsy, some cases of myxoedema, and certain forms of neuralgia, such as intercostal neuralgia, lumbago, and sciatica. All these causes, therefore, must be excluded before syphilis can be regarded as responsible for excess of albumin in the cerebro-spinal fluid. If clinical symptoms are present, the excess of cerebro-spinal albumin may be merely the residue of an extinct lesion, but there is nothing to prove that the virulence of the disease is extinct, and such cases require careful watching. If there is an absence of nervous symptoms and the syphilis is of recent date intensive treatment should be instituted. On the other hand, when the syphilis is of old standing the prognosis of monosymptomatic excess of albumin in the cerebro-spinal fluid is less serious and intensive treatment is not required.

## Medicine.

### 299. Active Immunization against Diphtheria in Adults.

P. H. KRAMER (*Nederl. Tijdschr. v. Geneesk.*, April 7th, 1923, p. 1406) records the results of Schick testing and injection with toxin-antitoxin of the nursing staff at the Rotterdam Municipal Hospital before taking up duty in the diphtheria pavilion. Of 114 persons (113 women and 1 man), all above the age of 20, 47 (all women) who gave a positive Schick reaction received toxin-antitoxin. Of the remaining 67, 55 gave a completely negative reaction, and 12 a pseudo-reaction. Among 10 persons who had formerly had diphtheria the reaction was negative in 7 and positive in 3. Of the 114 nurses 90 remained sufficiently long in the diphtheria pavilion to justify conclusions: 38, or 42 per cent., were injected with toxin-antitoxin, and 52, or 58 per cent., who gave a negative Schick reaction, were not injected; 12 diphtheria bacillus carriers were found—6, or 16 per cent., among the immunized, and 6, or 11 per cent., among those with a negative Schick reaction. Three cases, 2 of whom had not been injected on the strength of a negative Schick reaction, developed a follicular tonsillitis which was cured without serum treatment. Two sisters who had given a negative Schick reaction contracted severe attacks of diphtheria, complicated in one case by paralysis of the palate. None of those injected with toxin-antitoxin developed diphtheria. Under these conditions Kramer has decided not to perform Schick reactions any more, but to treat all cases likely to be exposed to diphtheria infection with toxin-antitoxin without Schick testing, as is also done at the Wilhelmina Hospital, Amsterdam.

### 300. Herpes Zoster Generalisatus.

M. B. PAROUNAGIAN and H. GOODMAN (*Arch. Derm. and Syph.*, April, 1923, p. 439) review the literature of herpes zoster generalisatus, and record a case of that form of herpes zoster with the associated well distributed varicella-like eruption of vesicles. The patient, a man aged 64, looked fatigued and older than his years, and presented a typical herpetic eruption on the right abdomen with, in addition to the well marked zona, numerous vesicles and small papules scattered on the trunk, back, sides, axillae, thighs, shoulders, and arms. Mostly occurring in elderly not very robust persons, such cases appear to be a definite clinical group quite distinct from any fortuitous association of herpes zoster and varicella, though many of the cases in the literature were originally reported as being a combination of the two diseases, the authors unwittingly describing herpes zoster generalisatus. Cases of associated herpes zoster and generalized vesicular eruption are of four classes: (1) herpes zoster in one patient followed by varicella in others; (2) herpes zoster generalisatus—that is, herpes zoster followed by varicella-like eruptions in the same patient and without any occurrence of varicella in others exposed; (3) herpes zoster followed by varicella in the same patient and in others exposed; (4) varicella in one patient followed by herpes zoster in others exposed. Etiologically it is assumed that when the herpetic eruption is accompanied by much local disturbance of sensation the inflammation, by extending along sensory roots into the grey substance of the posterior horns, becomes apparent cutaneously in the discrete widespread eruption of herpes zoster generalisatus.

### 300. Hereditary Tylosis.

J. D. ROLLESTON (*Brit. Journ. Child. Dis.*, January-March, 1923, p. 16) records a case of hereditary tylosis, otherwise known as keratoderma palmaris et plantaris hereditaria, keratoma palmare et plantare, congenital ichthyosis, and acrokeratoderma, and remarks that, though the condition is well known to dermatologists, it has received little attention in pediatric literature. His patient, a girl aged 2 years, showed a symmetrical thickening of the epidermis of the palms and soles, the thickening ending abruptly at the border of the palmar and plantar surfaces and being separated from the normal skin by a narrow pinkish halo. The keratosis was more marked on the palms than on the soles. The condition had first been noted a few months after birth, and had gradually become more pronounced. Exfoliation of the palms and soles occasionally took place. The nails were not affected, and there were no skin lesions elsewhere. Like most of the cases on record, the family to which the child belonged consisted of very poor and ill educated persons, so that the pedigree obtained was incomplete. The disease, however, was said to have been present on the father's side for five generations. The mother

was not affected. Rolleston has collected eight other examples from the literature of the disease, occurring in five generations, including those reported by Date (*BRITISH MEDICAL JOURNAL*, 1887, ii, 718), Vaughan Pendred (*Ibid.*, 1893, ii, 1132), and Jacob and Fulton (*Ibid.*, 1905, ii, 125). Tylosis is usually congenital or appears within a few months of birth, as in the present case. Much less frequently it is acquired. Histologically it consists in a hypertrophy of the stratum corneum of the epidermis similar to that found in an ordinary callosity. Treatment is usually ineffective. Although the thickened epidermis can be made to exfoliate by such substances as salicylic acid, resorcin, pumice stone, starch poultice, and strong solutions of sodium bicarbonate, it invariably re-forms, and the condition becomes as bad as before. Tylosis possesses an epidemiological interest in that it has been endemic for about 150 years in the island of Meleda off the coast of Dalmatia, where it was first mistaken for leprosy.

### 401. Intravenous and Intragluteal Injections of Quinine in Pneumonia.

M. JONAS (*Deut. med. Woch.*, March 23rd, 1923, p. 360) has given intravenous and intragluteal injections of quinine bihydrochloride in 197 cases of croupous pneumonia treated in hospital. The dosage of a 25 per cent. aqueous solution for an adult was 2 c.cm., or 0.5 gram of quinine. One or two intravenous injections were followed by two intragluteal injections, and, in protracted cases, by a third intragluteal injection. Although considerably more than 2,000 such injections were given, they never provoked ocular symptoms, and only once did deafness of several hours' duration occur. When this treatment was instituted as early as the first or second day of the disease, it was often aborted. But after the third to the fifth day, the institution of this treatment seldom cut the disease short or brought the temperature down rapidly. It also failed to prevent extension of the inflammation in such comparatively late cases from one lobe to another. On the other hand, the injections had a remarkable effect on the general condition, and on such symptoms as dyspnoea, cyanosis, and partial loss of consciousness. In the period before he began this treatment—that is, 1911 to 1916—the author treated annually 40 to 60 cases of croupous pneumonia in his hospital. His mortality in these years ranged from 29 to 41 per cent. During 1921 and 1922, when he treated 53 cases with injections of quinine, the mortality was only 9 to 10 per cent. He adds one practical hint: while an intravenous injection is being given, great care should be taken to avoid introducing any of the quinine into the subcutaneous tissues, where it may cause necrosis.

### 402. Pituitrin in the Treatment of Herpes Zoster.

S. N. VENDEL (*Ugeskrift for Læger*, March 29th, 1923, p. 222) has treated 18 cases of herpes zoster since 1915. Every second case was given the usual local and symptomatic treatment, while the remaining 9 cases were given subcutaneous injections of 1 c.cm. or less of pituitrin. The difference in the results of treatment in the two classes was very striking. In the first class the disease ran its characteristic and painful course. In the second class the injection of pituitrin was followed in a few hours by almost complete disappearance of the pain, and in a few days by the disappearance of the eruption. By the second or third day the patient felt a little more sensitive to heat and cold than usual, but he felt otherwise well. In all these cases the origin of the herpes was spontaneous, and in none were there signs of gross changes in the central nervous system to which the herpes might be traced. The author did not venture to give pituitrin when the herpes was complicated by pregnancy, high blood pressure, or advanced age, and as the injections were apt to cause slight malaise, he took the precaution to keep the patients lying down for fifteen to twenty minutes after an injection. He does not state how he came to think of giving pituitrin in such cases, and he does not discuss its rationale, but he urges his colleagues to investigate further a procedure which may prove an advance on the rather negative and symptomatic treatment hitherto recommended for herpes zoster.

### 403. Is Neo-salvarsan an Anthelmintic?

K. K. LUNDGAARD (*Hospitaltidende*, March 7th, 1923, p. 180) raises this question in connexion with a man, aged 67, who was admitted to hospital for a cataract operation. Glaucoma, irido-cyclitis, and obscure abdominal symptoms supervened, and, chronic appendicitis being suspected, he was transferred to a surgical ward, where this diagnosis was negatived. As the irido-cyclitis did not subside, enucleation was proposed, but was refused by the patient. On January 5th, 1923, there were

definite signs of sympathetic ophthalmia. Accordingly intravenous injections of neo-salvarsan were given on January 5th, 6th, 8th, 12th, and 18th, the dosage on these five occasions being respectively 30, 30, 45, 60, and 90 cg. On January 30th a large ball of much decomposed *Taenia mediocanellata*, looking like a ball of yellow wool, was discharged per rectum. Decomposition had progressed so far that it could not be ascertained whether the head of the worm had come away or not. During the following days small fragments of much decomposed segments escaped. Considering that salvarsan is partly excreted by the intestines, it is possible that it may prove a useful anthelmintic, and if this is the case it may supersede certain anthelmintics the exhibition of which is tedious and disagreeable. Whether the risks of salvarsan treatment of intestinal parasites outweighs its advantages is an open question.

#### 404. Pruritus Ani.

F. C. KNOWLES and E. F. CORROW (*Arch. Derm. and Syph.*, April, 1923, p. 505) investigated the treatment of pruritus ani with bacterial injections in eighteen cases, working upon the lines previously adopted by Winfield and Murray with similar favourable results. Cultures made from six of these patients showed the presence of the colon bacillus and *Streptococcus faecalis*, and in several instances in which the opsonic index was determined it was found to be constantly below normal. In one case the effect of a stock colon bacillus vaccine, irrespective of the culture obtained locally, was apparent cure after three injections; five of the six patients who were thoroughly treated with *S. faecalis* vaccine were cured after receiving twelve to twenty injections each, two requiring a second series, after two to four months' intervals respectively, to clear up a tendency to relapse. Small doses (less than 100 million) of killed organisms are useless, benefit only resulting where the number of bacteria was increased from 175 to 1,000 million. Injections of *S. faecalis* vaccine offer the best means of cure, and should be given at weekly intervals, and continued over a considerable period. Before treatment by vaccine is considered all pathological conditions must be excluded, and injections of *S. faecalis* vaccine are given to raise the opsonic index, which, according to the authors, is always below normal in this type of case.

### Surgery.

#### 405. Operation in Two Stages for Carcinoma of the Stomach.

H. ZIEGLER (*Zentralbl. f. Chir.*, April 7th, 1923, p. 562) has made a practice during the last year of operating in two stages for gastric carcinoma, in all cases where the disease is at all advanced or the patient cachectic or reduced in strength. At the first operation posterior retro-colic gastro-enterostomy is performed; some weeks later the resection is made. After the first operation the patient usually puts on weight, and in a few weeks is much more fit to undergo the operation of resection than originally. The primary mortality is apparently reduced; moreover, cases which at first sight appear to be inoperable may often be subjected to operation if done in two stages. The author refers to the fact that most German surgeons perform suprapubic prostatectomy in two stages, in cases where the patient's strength is reduced by defective excretion and more particularly by superadded infection, and considers that the reduction in mortality associated with this method may also be attained in operations for gastric carcinoma if the same principle is applied.

#### 406. Deep X-ray Treatment.

H. FLECKER (*Med. Journ. Australia*, February 24th, 1923, p. 201) records several cases of malignant and other diseases treated by deep x-ray radiation, illustrating the great scope and possibilities of such treatment. The large proportion of success was due, he says, to cases being treated early without waiting for other measures to be tried first, and the best results are obtained by team work between the clinician, physicist, pathologist, and radiologist. Although only seven months had elapsed since commencing treatment the clinical results were so good as to warrant the belief that some of the cures were permanent. Remarkable results were obtained by even a single intensive dose in sarcoma of the humerus, lymphoma of the pharynx, glioma of the cerebellum, oesophageal and mammary carcinoma, metastatic growths in bones, rodent ulcer, lupus and tuberculous dactylitis, and cervical adenitis, and the advantage of the greater penetration compared with that of smaller outfits was demonstrated in many by the rapid improvement following deep radiation. In uterine, gall-bladder, and colon disease, where cure was impossible, relief of pain and of other symptoms followed. The treatment, suggests the author, should be adopted as early as possible, and not as a last resort; it should be used in conjunction with surgical and other measures, the best results being obtained with dosage both before and after operation.

#### 407. Obstruction at Duodeno-Jejunal Junction as a Cause of Duodenal Ulcer.

E. P. SLOAN (*Journ. Amer. Med. Assoc.*, April 7th, 1923, p. 977) says that since 1911 he has demonstrated fifty-two times at operation that duodenal ulcer and partial obstruction at or near the duodeno-jejunal flexure were present at the same time, and that surgical relief of the partial obstruction permitted the duodenal contents immediately to pass freely down into the jejunum. This makes, with the two cases reported in the present paper, 54 cases. In 14 a definite jejuno-mesocolic band was present. In 10, veils or light adhesions, seemingly of inflammatory origin, definitely kinking the jejunum near its origin, were found. In 9, the obstruction was due to the irregular shape of the opening through the mesocolon or to the ligament of Treitz; in 6 of them ptosis of the duodenum was present to such an extent that a very acute angle was formed at its terminal portion. In 15 cases the obstruction was due to more than one of these causes. These 54 cases of duodenal ulcer in which gastro-enterostomy was not done were selected from a series of 264 consecutive cases of duodenal ulcer. In the other 210 cases gastro-enterostomy was performed.

#### 408. The Results of Operative Treatment of Graves's Disease.

O. HILDEBRAND (*Deut. med. Woch.*, March 16th, 1923, p. 338) has performed partial resection of the thyroid in Graves's disease in a great number of cases, and has had 24 deaths among 666 operations—that is, a mortality of 3.6 per cent. He has traced 234 of his patients, and has found that 125, or 54 per cent., were cured. By "cure" he means disappearance of tachycardia, tremor, diarrhoea, nervous restlessness, and exophthalmos, and recovery of general good health and gain of weight. Further, this result had been maintained for several years. In 79 cases, or 34.3 per cent., marked improvement was effected, and in 25, or 10 per cent., there was some improvement. Thus altogether in 87 per cent. operative treatment was beneficial. But in many cases these benefits were not obtained until the patient had undergone several operations. With regard to the operative deaths, the author points out that he has lost patients both under general ether anaesthesia and under local adrenaline-novocain anaesthesia, and he deplors the fact that there is no sure means of diagnosing a persistent thymus and status thymico-lymphaticus before operation. Only the general appearance of the patient may be suspicious, and when a persistent thymus is suspected, he suggests that it is well to treat it by the x rays before attempting an operation.

#### 409. Intracapsular Cataract Extraction.

W. ZENTMAYER (*Amer. Journ. Ophthalmol.*, March, 1923, p. 202) presents an analysis of the results of ten cases of cataract operated upon by Professor Ignacio Barraquer with the erisiphake. Zentmayer had previously observed a series of cataract cases operated upon by Colonel Smith by his intracapsular method, and consequently is able to make a rough estimate of the merits of the two methods compared with each other and with the usual extracapsular method. He first describes Barraquer's method in full and points out that ten cases are too few from which to draw fair conclusions, though an interesting commentary can be made. In these ten cases a first-class result was obtained in 70 per cent. of the cases. Zentmayer, in his comments, points out that a method should be judged by its results in the hands of the average operator, and not by the results of its most skilful interpreter. In unskilful hands the Smith operation appears to be the safer, as loss of vitreous is the one serious danger, whereas in the Barraquer operation there is the additional danger of serious injury to the iris and the possibility of loss of the entire contents of the globe. In skilled hands, judging from the available statistics, the Barraquer method, however, appears the safer. In conclusion Zentmayer draws attention to the excellent results which are daily obtained by the more usual extracapsular method, the safe technique of which is so much more easily acquired.

#### 410. The Treatment of Irreducible Acquired or Congenital Hip Dislocations.

ADOLF LORENZ of Vienna (*New York Med. Journ. and Med. Record*, February 7th, 1923, p. 130) describes his method of "bifurcation" of the upper end of the femur in order to produce stability in such conditions as (1) pseudarthrosis colli after non-union of fractures of the femoral neck, (2) loss of femoral head following tuberculous disease or osteomyelitis, (3) old-standing dislocations, congenital or pathological. The operation is, briefly, an oblique osteotomy of the femoral shaft made with its upper limit at the level at which the shaft faces the acetabulum. The pointed upper end of the distal fragment is then made to engage the acetabulum or, in cases where the femoral head is still filling the acetabulum, the groove below the lower lip of the acetabulum. The limb is then abducted

to 35 degrees. The cut edge of the proximal fragment then lies against the outer aspect of the shaft, and, after fixation in a long plaster-of-Paris bandage for twelve weeks, union results with a Y-shaped ("bifurcated") upper end to the femur. After union has occurred massage and exercises of the pelvi-trochanteric group of muscles is commenced and a range of movement is gradually developed at the new articulation. The upper pointed end of the shaft becomes to some extent rounded off and in certain cases a range of flexion of 90 degrees has been attained. Stability takes the place of instability and the pain is relieved. Lorenz has performed the operation in a large number of cases, and, whilst counselling care in the selection of suitable cases, particularly advises the operation as expedient in those patients who suffer severe pain or who are unable to walk on the unstable limb.

## Obstetrics and Gynaecology.

### 411. Importance of Digital Exploration of the Uterus.

G. DEUCHEN (*Schweiz. med. Woch.*, March 15th, 1923, p. 277) raises this question: Is it sufficient to curette and examine with the microscope the lining of the uterus, or should this invaluable method be supplemented by digital exploration of the uterus? He notes that such digital exploration in non-puerperal cases is the exception rather than the rule. To ascertain whether this omission is justifiable or not, he has studied the records for the past eighteen months of the University Gynaecological Hospital in Zürich. There were 120 consecutive unselected cases in which exploratory curetting and digital exploration had been performed. All the patients had been sent to hospital on account of menorrhagia or metrorrhagia. Most were married women of pre-climacteric age or in the menopause; the youngest patient was aged 18, the oldest 62. In as many as 18 cases the evidence of exploratory curetting alone was negative or inconclusive, and among these cases there were 2 of malignant disease, 7 of submucous myoma, and 6 of uterine polypus. There was also one case of pregnancy, one of incomplete abortion, and one of malformation of the uterus. The author considers these figures an indictment of the policy of trusting simply to a pathologist's report on scrapings from the uterus. In none of the 120 cases did the combination of curetting with digital exploration prove fatal. But there was one case in which parametritis ensued. A small tear of the wall of the cervix occurred once, and the cervix was once partially perforated. There were also 2 cases in which the procedure gave rise to violent pain. In 13 cases it was found necessary to give a general anaesthetic; in the remainder anodyne drugs were sufficient. The author concludes that the advantages of dilating the non-puerperal uterus sufficiently to allow digital exploration of its interior definitely outweigh the disadvantages in the class of case under discussion.

### 412. Primary Sarcoma of the Fallopian Tube.

A. GRISI (*Annali di Ostetricia e Ginecologia*, February 28th, 1923, p. 121) states that sarcoma of the Fallopian tube, an extremely rare tumour, may originate in the connective tissue of the mucosa or in that separating the bundles of the muscular wall, and may occasionally attain enormous bulk. It is usually unilateral and may affect any region of the oviduct; the permeability of the tube is not affected, and the ostium abdominale in the absence of antecedent inflammatory disease is not occluded. Pain is a constant symptom, but menstruation is not necessarily affected. In a case recorded by Grisi the patient was a nullipara aged 51, who twelve months after the menopause suffered from severe and continuous abdominal pain, accompanied after six months by metrorrhagia. The pre-operative diagnosis was ovarian carcinoma; the abdomen contained a little free fluid, and the Fallopian tube affected showed soft sarcomatous masses protruding at the abdominal ostium. Within, the growth produced sessile vegetations beneath the mucous membrane; microscopically it was found to be a mixed-celled sarcoma in which spindle cells predominated.

### 413. Ectopic Pregnancy at Term, with Living Child.

A diagnosis of pregnancy of about eight months with impending eclampsia having been made in a case, an immediate Caesarean operation was performed by B. J. O'NEILL and W. W. CRAWFORD (*Journ. Amer. Med. Assoc.*, March 31st, 1923, p. 913). The abdomen was opened by a right rectus incision, and a dark, bluish, smooth mass, resembling an ovarian cyst, was revealed. On palpation, foetal parts were felt, separated from the hands by a thin membrane, which ruptured almost at once, with a gush of water. The baby was lifted out in the usual way, the head offering considerable resistance, and was revived with no more difficulty than is usual in a Caesarean

section. The left tube was about 6 inches long, and the expanded sibilated extremity was directly continuous with the cavity formed by the membranes. The placenta was thin and widespread, being planted on the posterior surface of the left broad ligament and on the sigmoid and the intervening pelvic wall, beside being adherent to both the large and the small intestine. The placenta thus formed the left and upper side of the sac. The left ovary was not identified. Actively bleeding vessels entered through adhesions from the large and small intestines, and some very large vessels entered the placenta from the broad ligament. The baby, a boy, weighing 6 lb. 3 oz., had hair and well developed nails, indicating birth at practically complete term. The skull was somewhat deformed from resting on the sacrum, and there was a moderate calcaneo-valgus of the right foot, a marked talipes equino-varus of the left foot, and a partial dislocation of the left hip, with indication of some bony pathological process in the left knee. The recovery of both mother and child was uneventful.

### 414. The Surgical Significance of Menstrual Changes in the Breasts.

A. ROSENBERG (*Zentralbl. f. Chir.*, March 31st, 1923, p. 510) has found certain histological changes in the mammary glands associated with the menstrual periods. In the pre-menstrual phase numerous lobules are found, with solid processes ending in small single-layered alveoli—a condition hitherto supposed to be found only during the early months of pregnancy. After the onset of menstruation retrogression takes place, with increase of fat deposit, and continues after menstruation has ceased, till at the mid-period only a few large and medium-sized ducts are found, and the smallest ducts and alveoli have entirely disappeared, reappearing at the next premenstrual period. The premenstrual hypertrophy may be mistaken for a pathological condition. A case is described where a breast, removed on account of pain and tenderness, and diagnosed as fibroma, was examined microscopically by the author, and showed only premenstrual changes. Inquiry elicited the fact that menstruation was due, and took place, four days after operation. The author considers that operations for innocent tumours of the breast should take place at the mid-period, as there is then less danger of injuring healthy gland parenchyma.

### 415. The Phloridizin Test of Early Pregnancy.

L. TARP (*Ugeskrift for Læger*, April 5th, 1923, p. 238) has carried out the phloridizin test in 142 women, most of whom were not pregnant. The solution he used contained 0.03 gram of phloridizin, 27.5 grams of distilled water, 3 grams of concentrated alcohol, and 0.015 gram of novocain. Immediately after the intramuscular injection of 2 c.cm. of this solution, given on an empty stomach, the patient drank 200 c.cm. of water and another 200 c.cm. half an hour later. Samples of urine passed half an hour, one hour, and an hour and a half after the injection were examined for sugar. Of the 108 non-pregnant women only 5 developed glycosuria. Of 8 pregnant women, 5 developed glycosuria, the pregnancy in all 5 cases being of three months' duration or less. Of the 3 pregnant women failing to develop glycosuria, 2 were in the fifth month of pregnancy—that is, in a stage too late for the test to be of much value. All the 12 women who had recently aborted completely failed to develop glycosuria; but of the 8 who had aborted, but who had not yet submitted to complete evacuation of the uterus, 2 showed glycosuria. Six women, who were suckling their infants, were also tested, and 2 of them developed glycosuria. As the author's figures show, the test is fairly reliable, but does not afford absolutely irrefutable evidence either way.

### 416. Pernicious Anaemia During and After Pregnancy.

E. RUMPF (*Deut. med. Woch.*, April 6th, 1923, p. 438) calculates that only 72 cases have been recorded in which pregnancy or the puerperium was complicated by anaemia deserving the adjective pernicious. These records show that the prognosis is considerably better for this class of case than for true pernicious anaemia unassociated with gestation. But even in the former class the mortality is about 58 per cent. Transfusion of blood, with or without the interruption of pregnancy, is probably better treatment than other remedies such as arsenic, and the author records in detail a case showing how promptly effective transfusion of blood may be. The patient was a married woman, aged 29, who, six hours after delivery showed the following blood condition: haemoglobin 14 per cent., erythrocytes 980,000, and leucocytes 7,400. Anisocytosis, megalocytosis, and slight polychromasia and poikilocytosis were observed. There were 67 per cent. polynuclear leucocytes, 30 per cent. lymphocytes, 2 per cent. monocytes, and 1 per cent. eosinophils. The good effect of blood transfusion was the more dramatic as the patient was moribund at the time. Forty days later the haemoglobin was 62 per cent., and the erythrocytes numbered 4,185,000.

## Pathology.

### 417. Chemical Variations in the Blood following the Radiation of Tumours.

M. LOEPER and J. TONNET (*Bull. de l'Assoc. française pour l'Étude du Cancer*, February, 1923, p. 103) have studied the effect on the chemical constituents of the blood of repeated exposures of cancerous tumours to  $\alpha$  rays. Following the fifth or sixth application of doses varying from 5 to 10 units H. to tumours of the stomach, breast, or mediastinum, for example, there is found (1) an increase in the total albumin of the serum by 4 to 12 per cent.; this increase is largely dependent on the rise in the quantity of globulin; (2) an increase in the amino-acid content of the serum, often rising from 0.06 to 0.11 per cent., or even to 0.18 per cent.; (3) an increase in the total lipoids of the serum, largely affecting the non-cholesterine portion; (4) a rise in the sugar titre of the serum to as much as 2 to 3 per cent.—a rise due largely to an increase in the protein sugar, not to that of the free sugar. What is the cause of these modifications? Do they result from the breaking down of the leucocytes, as Nurnberger believes? The authors think not. To elucidate this point they submitted a cancer of the pleura to several exposures of  $\alpha$  rays. Before the fifth exposure and immediately after it a puncture was performed, and the two specimen fluids thus obtained were carefully analysed, both from a chemical and a cytological aspect. It was found that after the exposure there was a notable increase in the globulin and in the amino-acid titre of the fluid. Now the lymphocytes of the fluid had scarcely altered in numbers, while the cancer cells, on the other hand, had not only diminished in numbers, but the ones that were left showed evident signs of degeneration and cytolysis. From this they conclude that the effect of repeated doses of  $\alpha$  rays is to disintegrate the cells of cancerous tumours, and liberate quantities of globulins, amino-acids, sugar, and lipoids, which then pass into the blood stream and give rise to the changes observed.

### 418. Modification of the Properties of Streptococci.

INTERESTING results have been obtained by M. BROCC-ROUSSEU, FORGEOT, and A. URBAIN (*Ann. de l'Inst. Pasteur*, March, 1923, p. 322) on the modification of a streptococcus obtained from nasal discharges in horses. A serum prepared against this type of streptococcus, when titrated by the method of Calmette and Massol, was found to contain 1,500 units of antibodies. Various strains of the organism were then passed through animals, including mice, rats, rabbits, and guinea-pigs, the organism cultured after each passage, and its ability to fix complement measured. It was found that after each passage this power diminished, till after a number, varying from four to nine passages, it disappeared altogether. The longer the organism was resident in the animal—that is, the longer it took to kill it—the fewer were the number of passages required to effect the modification. A similar change was effected *in vitro* by growing the organism in bouillon containing 20 per cent. of the blood of the animal in question. In this case, however, from ten to eighteen culture passages were required before all complement-fixing power was lost. Accompanying this change an alteration in the morphological aspect of the organism was noticed: whereas previously it grew in long chains, it now grew in the form of diplococci or in very short chains, and frequently showed evidence of a capsule.

### 419. Physiological Youth in Bacteria.

ARE the young of a unicellular organism, like the young of higher organisms, more sensitive to the influence of environment than the more mature cells of the same species? J. M. SHERMAN and W. R. ARBUS (*Journ. of Bact.*, March, 1923, p. 127) report experiments which indicate that physiological differences exist between young and mature bacterial cells and that the newly formed cells pass through a period of physiological youth. Tests with *B. coli* showed that cells taken from a culture of this organism during its period of rapid growth were sensitive to certain mild exposures which caused no mortality among the cells of an older culture, instances of which were obtained by brief exposure to cold and to 2 per cent. solutions of sodium chloride. Experiments conducted upon the effect of heating to relatively low temperatures showed that young bacterial cells were more rapidly destroyed than are the older ones; the same was true of the action of phenol. That there actually exists a difference in the physico-chemical condition of bacterial cells of different ages is indicated by differences in their agglutinability, as was revealed by acid agglutination tests. Since the young of bacteria, like the young of higher forms of life, are more susceptible to the hazards of their environment, it is not improbable that in the struggle for existence among these organisms there occurs an "infant mortality" among the young cells. Young and old cells may differ also in their abilities to stimulate antibody production.

420.

### Genesis of Blood Platelets.

S. P. BEDSON (*Journ. of Path. and Bact.*, April, 1923, p. 145), in order to study the morphology of platelets in experimental purpura, injected guinea-pigs with sublethal doses of anti-platelet serum. On the second day after inoculation, when the platelet count was still very low, the platelets no longer presented the characteristic morphology of the mature platelet, but appeared as small circular discs, more regular in outline, devoid of granules and showing definite basophile staining. These forms persisted until the fourth day, when they were gradually replaced by platelets more normal in appearance. From the second to the fourth day after inoculation nucleated precursors of platelets were seen, cells smaller in size than red corpuscles, oval or circular in shape, and of definite outline; other forms were seen which possessed what appeared to be a chromatin rest. In studying the morphology of the platelet in the embryo and very young animal Bedson noticed that already in the guinea-pig embryo of four to five weeks the majority of the platelets in the circulation were mature. He concludes that the mammalian platelet does not take its origin from any of the elements of the blood, such as the red cells, leucocytes, or plasma proteins, and he advances the hypothesis that the platelet is the homologue of the thrombocyte of avian blood, the nucleus being lost, however, before the cell reaches maturity, and that it appears in the circulation in the non-nucleated form, just as in the case of the red corpuscles.

### 421. Alterations in the Coagulation Time of the Blood following Proteinotherapy.

IT is usual in patients suffering from haemorrhagic syndromes to find that after treatment by calcium chloride, peptone, or non-specific serum the coagulation time of the blood is accelerated. On the other hand a reverse effect is sometimes noticed, and it is a case of this kind that R. BÉNAUD (*Bull. et Mém. Soc. Méd. des Hôpitaux*, March 15th, 1923, p. 369) reports here. The patient, a man aged 25, had suffered since infancy from gingival haemorrhages, epistaxis, purpura, and ecchymoses, and had received short courses of treatment by both auto- and hetero-serotherapy. When he first came under the observation of the author, in 1916, his coagulation time, as measured by Hayem's method, was thirteen minutes. The effect of four injections of his own serum, varying from 4 to 18 c.cm. at a time, was to increase this time to thirty-seven minutes. The patient's general condition, however, was very greatly improved. Within a month the coagulation time had returned very nearly to the figure at the commencement of treatment, and, as the patient himself no longer felt so well, resort was made to another series of injections. Studied closely during the period directly following the injections, the coagulation time was found to diminish considerably within half an hour, then to increase to a maximum after two and a half hours, after which a second diminution occurred, which in its turn was succeeded by a fresh retardation. A month later an injection of 20 c.cm. of anti-diphtheritic serum was given. This determined a very marked general disturbance—urticaria, insomnia, adenopathy, and arthralgia—lasting for a week. The patient, however, seemed to receive considerable benefit from this treatment—a benefit which persisted for about two years, when the author lost sight of him. When last tested the coagulation time still remained very low. From these observations the author concludes that there is no necessary correlation between the general condition of the patient and his coagulation time, and that auto-serotherapy appears to be less dangerous than hetero-serotherapy.

422.

### The Internal Secretion of the Pancreas.

J. WOHLGEMUTH and T. KOGA (*Klinische Wochenschrift*, February 26th, 1923, p. 386) refer to the published works of the former on the diastatic ferments of the serum, lymph, liver, spleen, muscle, etc., an investigation which was interrupted by the war. The authors describe their experiments on dogs, in which they succeeded in obtaining an activator (hormone) from the blood plasma of the pancreas, which is constant in action, soluble in alcohol, but insoluble in ether, petroleum ether, and benzol. It only activates "animal" diastase, but is inert in the presence of any vegetable diastase—for example, malt, yeast, or taka-diastase; this substance therefore furnishes a reliable distinctive test for the origin of diastase. Although the authors' experiments did not furnish entirely uniform results, generally they found that the blood of the pancreaticoduodenal vein contained a substantially larger amount of the activator than the portal or peripheral blood. The quantity of this substance varies from time to time, but in a fasting animal it is secreted in larger quantity. The authors state that all body cells contain these activators, but in smaller amount. Hunger also increases the production of liver diastase, and the hormone then produced stimulates glycogen secretion; this has been proved by the experiments of de Meyer. On transfusing the liver of a depancreatized dog with blood containing pancreatic extract, glycogen was immediately formed in larger quantity.

E. SIGNORELLI (*Arch. di pat. e clin. med.*, March, 1923, p. 89), who records a case in a boy aged 16, states that diabetes insipidus is a comparatively rare sequel of epidemic encephalitis, contrary to what might have been expected from experimental and clinical data, which tend to localize the centres of diuresis in the areas principally affected by the virus of epidemic encephalitis. In the present case diabetes insipidus, which developed about six weeks after the onset of encephalitis, was associated with other disturbances of vegetative life, such as acrocyanosis, dermatographism, bradycardia and tachycardia with arrhythmia. The fact that these disturbances were not accompanied by symptoms characteristic of lesions of one or more endocrine glands is a proof of the importance of the mesencephalon as a regulator of vegetative life. The diuresis in the present case was relatively refractory to injections of pituitrin. Signorelli maintains that three factors must be considered in the regulation of diuresis. The first factor is a special hormone in the pars intermedia of the hypophysis, which both in man and animals exercises an inhibitory action on the kidney as regards diuresis, this effect being particularly marked in cases of diabetes insipidus. The second factor is the influence on diuresis of special centres at the base of the third ventricle. The stimulation of these centres gives rise to polyuria and diminution of the concentration of the urine. The third factor is the nervous system of the kidneys, as is shown by physiological and clinical experience.

#### 

L. SPENGLER (*Schweiz. med. Woch.*, March 22nd, 1923, p. 309) has treated 42 cases of spontaneous tuberculous pneumothorax in the past thirty years, and in as many as 16, or 38 per cent., the patient recovered from the pneumothorax. In 10 of these cases the patient also recovered from the pulmonary tuberculosis; at least it was permanently arrested. With regard to the fatalities, there were only 4 cases in which death occurred within two to seven days. But there were as many as 15 cases in which death occurred from two weeks to two years after the accident. With regard to treatment, the most important measures are those which favour closure of the tear in the lung. A pleural effusion may be beneficial in this connexion because it yields fibrin, which plugs the tear. It may therefore be advisable, when the pneumothorax is dry, to introduce some pleural irritant, such as a 30 per cent. solution of grape sugar in saline solution, with a view to exciting a pleural effusion.

#### 

L. E. VIKO, H. M. MARVIN, and P. D. WHITE (*Arch. Intern. Med.*, March, 1923, p. 345) record the results of careful clinical observations on quinidine sulphate in cardiac affections. In 75 cases of non-paroxysmal auricular fibrillation, or auricular flutter, the normal rhythm was restored by quinidine in approximately two-thirds of the cases, and still remained normal in approximately one-third. Cases with fibrillation of short duration (under six months) are more likely to be restored to the normal condition and more likely to remain normal. Such cases give the best clinical results. Cases with and without objective congestive failure (oedema, enlarged liver, pulmonary oedema, etc.) were restored to the normal rhythm by quinidine; but the former relapse very much more frequently. In cases presenting objective congestive failure or tachycardia digitalis should be given before the quinidine treatment is commenced. Most cases responding to quinidine do so with small dosage, but many of the most satisfactory cases required large doses. Embolism and sudden death (possibly also due to embolism) occurring under quinidine treatment are probably most likely to occur in cases with fibrillation of long duration and in cases with objective congestive failure. The clinical results appear to justify the use of the drug in cases with fibrillation of short duration and with little or no congestive failure. In such cases bad results are probably no more common than under other methods of treatment. At present quinidine should probably not be used in a routine way in other types of cases—its use should be confined to hospitals where careful observation is possible.

#### 

BELIEVING in the essentially dermatological origin of eczema, J. R. GERSTLEY (*Journ. Amer. Med. Assoc.*, April 21st, 1923, p. 1141) has attempted to bring the skin of the predisposed fair-haired, blue-eyed children to the best possible state of nutrition. If the skin of an infant is maintained in good nutrition from the time of birth, and at the same time protected from irritants, eczemas, says the author, rarely appear. He believes that the active dietetic treatment, from the standpoint of the pediatrician, is that which most rapidly brings the child to the best possible state of nutrition. No one particular diet helps; no one diet harms. The main consideration of the pediatrician is to place the welfare of the whole body above that of an individual organ. If he steadfastly adheres to this principle, local symptoms gradually disappear in proportion to improvement in the general condition. Indications for restriction of diet are said to be only two. In an overfed baby with an oozing eczema reduction of food intake is of value. In an infant whose eczema has become secondarily infected, reduction of diet, by depleting the tissues of fluid, dries the cheeks and leaves a field less fertile for bacterial growth. In these cases there is said to be no particular reason for reducing one element of food, and restriction of quantity is all that is necessary.

#### 

A. CARNIOL (*Bull. et Mém. Soc. Méd. des Hôpitaux de Bucarest*, January 31st, 1923, p. 1) has during the last year observed the variations of local temperature in a series of cases of hemiplegia. One patient, aged 45, syphilitic, had aortitis with hypertension and a left hemiplegia (since 1916). Prior to an injection of 1.5 mg. of atropine sulphate the temperature of the right leg was 88.4° and that of the left (paralysed) leg was 85°. During six hours after injection of atropine the temperature of the right leg was approximately stationary, but that of the left leg rose to 96.8° four and a half hours after the injection; then it began to fall slowly. This experiment has been repeated many times on this patient with uniform results, but in recent hemiplegia the results are not so striking, neither are they so definite in infantile hemiplegia. In another case of left hemiplegia in a patient aged 50 the author found a similar result, but on comparing the temperatures of both thighs, legs, and feet he found that the temperature of the left leg rose 2° while that of the right (normal) foot fell 4°. Carniol has experimented with other alkaloids and also with calcium chloride and adrenaline with little, if any, result. He has also found that hypodermic injection of atropine yields less definite results than intravenous injection. He concludes that these remarkable differences in the healthy and paralysed limbs are due to vasomotor disturbance.

#### 

G. REDLIN (*Dent. med. Woch.*, March 30th, 1923, p. 415) has investigated the subsequent fate of children treated in hospital for pylorospasm. In the past decade 29 such cases were treated in the University Children's Hospital in Greifswald. Ten of them could not be traced. Of the remaining 19, only 4 were found to have died, death in 3 of these cases being connected with the pylorospasm. As many as 10 of the 19 children were the offspring of brain workers, and in 10 cases there was a family history of disease of the nervous system. As many as 6 of the 19 were first-born children, and 17 of the 19 children were boys. In as great a proportion as 84 per cent. the children had been breast-fed. More than half the number were found to be taller than normal, and only those children who were under the age of 5 were well developed physically. The older children were tall, lanky, and prematurely developed. The author concludes that the prognosis for children who have recovered from pylorospasm is good, and though they are, as a rule, predisposed to nervous symptoms, their susceptibility to other diseases is hardly in excess of the average.

#### 

S. ROHLER (*Ugeskrift for Læger*, March 23th, 1923, p. 217) examined the lungs of 1,048 of the 1,053 inhabitants of a district in North Greenland, and found signs of pulmonary disease in 142, or 13.4 per cent. of the total population. A characteristic feature of pulmonary tuberculosis in Greenland is the benign and chronic course of the disease, which,

on the other hand, frequently gives rise to haemoptyses. The author investigated 178 cases of haemoptysis, 147 of which occurred while the patient was at rest—that is, asleep or sitting quietly and doing nothing. Only in 31 cases did the haemoptysis occur while the patients were straining—for example, rowing or cutting up seals. These figures support the teachings of Bang, according to whom movements of the body play little part in provoking haemoptysis, for, did they play an appreciable part in the genesis of haemoptyses, they would not be so uniformly distributed as they are over the twenty-four hours. Although the author found haemoptyses to be very frequent, they seldom caused much discomfort, and in 82 per cent. the patients did not stay in bed for as long as twenty-four hours after the haemoptysis. Not once did the author find a case of acute progressive caseous tuberculosis, and only in 4 cases were there signs of cavities. Of twenty sputum examinations only two were positive. It would therefore seem that in most cases pulmonary tuberculosis usually runs a sputum-negative course; and in this connexion it is noteworthy that the author found only one case of laryngeal tuberculosis and no case with signs indicative of intestinal tuberculosis.

## Surgery.

### 430. Radiotherapy in Gastric Disease.

I. SOLOMON (*Bull. Soc. de Thér.*, March 14th, 1923, p. 77) states that more than twenty years ago a French physician named Despeignes first treated a gastric tumour by x rays and obtained some improvement. It is only within the last few years that radiotherapy has been applied to other gastric affections than new growths. In treatment of gastric cancer by x rays two methods have been employed. The first is transcutaneous radiotherapy, the results from which have been only palliative. The supposed cures have occurred only in cases in which the diagnosis of new growth was incorrect. In 205 cases of gastric cancer published by Werner in 1915 most of the patients had been treated by the transcutaneous method and injections of enzytol (choline borate). In a certain number of these cases there was temporary improvement, shown by increase of weight and disappearance of pain, but there was no permanent cure. Solomon himself treated three cases of gastric carcinoma by the transcutaneous method. One patient was almost cachectic, and radiotherapy had only an analgesic effect, while in the other two after a period of apparent cure, shown by considerable increase of weight and disappearance of pain, the growth pursued its inexorable course. The second method is radiotherapy after exteriorization of the stomach. In 48 cases treated by Werner according to this method considerable temporary improvement was obtained with very rapid absorption of the growth. In one patient who died of pneumonia histological examination showed that all the cancer cells had disappeared. Solomon is of opinion that the failure to produce a permanent cure is due not so much to the fault of radiotherapy as to absence of an early diagnosis, which is essential for a permanent success. In gastric affections, apart from new growth, irradiation of the gastric area has been employed with success in hyperchlorhydria, gastric ulcer, and disturbances following gastro-entero-anastomosis. In two cases of gastric ulcer and two of gastro-entero-anastomosis treated by Solomon good results were obtained from radiotherapy.

### 431. "Migration" Peritonitis.

N. MÜLLER (*Deut. med. Woch.*, March 16th, 1923, p. 351) discusses the mechanism of what he calls "Durchwanderungs-peritonitis." By this he means the peritonitis which, on laparotomy or necropsy, is found to be unassociated with any macroscopic lesion. Little is known of the frequency of this form of peritonitis, and, though several cases have recently been published, it is ignored in some textbooks. The author suggests that this form of peritonitis may account for some at least of the cases in which, at operation or after death, old adhesions are found in the abdominal cavity. He records two cases, in one of which the patient came to operation thirty-one hours after the onset of stormy symptoms—violent abdominal pain, vomiting, diarrhoea, a temperature of 33° C., and a pulse of 116. The laparotomy revealed much distended and hyperaemic coils of gut lightly plastered in places with a fibrino-purulent membrane. The appendix, which was removed, was macroscopically and microscopically normal. A pure culture of streptococci was grown from the fibrino-purulent effusion. Uneventful recovery followed. In the second case death occurred forty hours after the onset of stormy symptoms of peritonitis. The necropsy showed no macroscopic lesion through which germs could have entered the peritoneal cavity. The author recommends surgeons to bear in mind the possibility of a simple "migration" peritonitis when they are baffled by finding no macroscopic lesion.

### 432. A Macular Perception in Advanced Cataract.

G. YOUNG (*British Journ. of Ophthalmol.*, April, 1923, p. 167) describes a method for determining the macular perception in cases of cataract. An excellent operative result has often been obtained in a case of senile cataract, but the end-result is disappointing because of small localized changes at the macula. Such cases, prior to operation, have good perception and projection of light, and in fact it is not possible to determine beforehand the condition of the actual macula itself. The method which Young has devised consists in first of all accurately centring a spectacle frame upon the patient's face and then putting a black disc in the frame in front of the eye to be observed. This black disc has a pinhole perforation in it so placed as to be exactly in front of the centre of the eye. The room is darkened and bright light is placed immediately in front of the patient. The patient is then requested to look for a spot of light, which is said to look like a little moon. If he sees this another disc is placed in the frame. This disc is perforated by two pinholes, one at each end of a diameter of an exactly central circle of 1.5 mm. radius. The patient should see two "moons" overlapping each other. The disc can be rotated so as to alter the position of the "moons"—vertical, horizontal, or oblique. Finally, a disc, with three pinhole perforations placed within the same central circle, is put into the frame, when three slightly overlapping "moons" should be seen. Young states that if the test is negative a sound macula is not excluded, but that if it is positive it is certain that the macula is normal in function.

### 433. Myeloma of the Vertebrae.

R. S. OSGOOD (*Boston Med. and Surg. Journ.*, March 22nd, 1923, p. 380) draws attention to the mistakes made in diagnosing this condition. Though the course of the disease may not be altered, unnecessary treatment may be avoided and a correct prognosis given. Its termination is always fatal and no treatment is known to control it, yet many years may elapse between the onset and its fatal termination. Myeloma seems to arise from the supporting tissue of the blood vessels and not from the blood-forming cells themselves; these adventitial cells are closely allied to endothelium. Radiograms in myeloma show circumscribed areas of diminished density, often seen in the skull. In the spine it may be difficult to identify the individual tumours, whilst in the long bones frequent fractures make definite diagnosis impossible. Specimens show a thinned cortex and the dark red tissue of the tumour mass somewhat vascular and containing trabeculae. Multiple tumours are commonly found; they are probably primary and do not represent metastases. Albumosuria and the presence of the so-called Bence-Jones protein in the urine, looked upon as a classical sign of the disease, cannot be demonstrated in a considerable number of cases of typical myeloma, probably in about half. The cause of the albumosuria remains obscure. The disease resembles a nutritional disorder, grouping itself with osteomalacia, osteitis fibrosa, and rickets. Three cases are reported where spinal symptoms predominated; in other cases pain was a dominant symptom. Mental symptoms may be present early or late, whilst the blood findings are negative. Radium and high voltage x rays are worthy of a trial in treatment. Spinal symptoms may be lessened by recumbency and immobilization. In spontaneous fractures, if fixed, the bones may unite. Numerous radiograms of the condition are shown.

### 434. The Treatment of Nocturnal Enuresis by Thermopenetration.

I. V. BUBEN (*Zentralbl. f. Gynäk.*, April 14th, 1923, p. 608) lays stress on the scanty knowledge of the causation of nocturnal enuresis, and also on the very diverse methods of treatment which have been tried with varying success. The cause of this distressing complaint has been attributed to too deep sleep, inflammation of the bladder, internal secretory disturbances, congenital changes in the spinal cord, and congenital syphilis—to mention only a few of the more important theories. The treatment employed has been varied—drugs such as belladonna, strychnine, urotropine, etc., having been recommended, bladder irrigation with gradual increase of the bladder capacity, dietetic treatment, and psychotherapy having also their advocates. Lately electricity has played an important part, as also has the treatment by hot and cold baths, both of these increasing the tone of the bladder and stimulating the nervous system. The author, having seen the improvement obtained by thermopenetration in the cases of women with incontinence of urine due to weakness of the internal sphincter of the bladder, decided to try this treatment in cases of enuresis. In all he has treated twelve cases, most of whom have improved greatly, and though the number is too small to derive conclusions therefrom, he thinks the results are good enough to warrant further investigation. Thermo-

penetration can be applied in two ways—extravesical and intravesical. The former is done to begin with, and consists of placing an electrode in the vagina and a lead plate the size of the palm of the hand over the symphysis, the current when applied passing through the bladder. In many cases this was sufficient to bring about a cure. If the intravesical method is employed the bladder is filled with normal saline by means of an insulated metal catheter fitted with a stopcock; when full the stopcock is closed and the current is passed between the electrode and the plate over the symphysis; by this means intensive heat is given to the bladder wall in its whole extent, and thus deep trophic nerve endings and deep tissues are acted upon and not only the superficial tissues, which is the case with external electrical methods and the hot and cold bath therapy. The treatment was performed three times a week, and was continued from one to two months.

#### 435. Congenital Dislocation of the Shoulder.

D. M. GREIG (*Edinburgh Med. Journ.*, April, 1923, p. 157) says that in approaching the consideration of congenital dislocation of the humerus at the shoulder it is necessary to define what is meant by congenital dislocation. It might be held to include a dislocation present at birth due to injuries inflicted during parturition and paralytic dislocations occurring later from puerile affections during birth. True congenital dislocation is of very great rarity. Smith of Dublin in 1839 first brought this condition forward in practical form. The author has collected twelve cases of true primary dislocation of the shoulder. As to the mechanism whereby this is produced it is difficult to dogmatize. It is said that experimental dislocation has never been produced in the dead foetus after death, and this suggests that direct internal trauma in the last months of pregnancy could not produce dislocation unless through fracture of the glenoid. There is no evidence of amniotic bands causing it, nor has hydramnios or oligo-amnios been reported. Could it have been brought about, asks the author, by muscular action? In the true cases there was no muscular paralysis and they reacted normally to stimuli. Perhaps an unequal development or a temporary spasm of one set might conduce to the condition by drawing the bones from their normal relationship. Again, direct compression of the foetus by the uterus might produce the condition. The attachments of the pectoralis major or teres major might serve as a point d'appui, so that pressure on the elbow might lever the head out of the glenoid. Muscular action and uterine pressure together seem to give, in the author's opinion, a possible explanation of the affection.

#### 436. Eosinophilia in Prostate Affections.

MARIO NEGRO (*Journ. d'Urologie*, February, 1923, p. 99) has made a series of investigations to show the relationship between the presence or absence of eosinophilia and simple hypertrophy or carcinoma of the prostate. This work follows upon that previously undertaken by Professor Leguen. Negro takes as his basis the *formule leucocytaire* adopted by French haematologists, who regard the normal percentage of eosinophils as varying from 0.5 to 2 per cent., and the author arrives at the following conclusions: After excluding all other causes which may give rise to a modification of the eosinophil count, such as parasitic diseases, shocks, and industrial poisonings—as, for example, in celluloid workers—in simple hypertrophy of the prostate he finds an increase of eosinophils in 75 per cent. of cases, whereas the neutrophil polymorph leucocytes always remain normal in number. In carcinoma of the prostate, however, he finds a diminished eosinophil count in 45 per cent. of cases, while the neutrophil polymorph count is always increased. This research shows that a blood count, together with the routine investigations for arriving at the differential diagnosis between carcinoma and simple hypertrophy of the prostate, may be of value in doubtful cases. When an increased eosinophil count is accompanied by an increased neutrophil polymorph count the author considers that one's suspicions should be aroused, for this finding, in view of the above conclusions, may well indicate that one is dealing with a case of carcinoma. The author gives numerous examples in support of his views.

#### 437. Prolonged Survival after Gastrectomy for Carcinoma.

G. LION (*Paris méd.*, April 7th, 1923, p. 319) records the results of gastrectomy in 41 cases of gastric carcinoma between the years 1903 and 1919. Sixteen died immediately after the operation—a mortality of 39 per cent. Of the 25 survivors 6 died in the course of the first year, 6 lived for less than two years, 1 lived to the second year, and 1 lived for two years and a few months; 11, of whom 5 were still alive, survived for more than four years. The proof of the cancerous nature of the disease in these 11 patients was

furnished in 7 cases by naked-eye and microscopical examination, in 2 by naked-eye examination confirmed later by local or remote recurrence, and in 2 by naked-eye examination only. In contrast with these 41 cases of gastrectomy with a mortality of 39 per cent. Lion had had a series of 49 cases of gastro-entrostomy performed during the same period with a mortality of 20.4 per cent. Gastro-entrostomy, however, is a purely palliative operation, and though in most cases it is followed by a considerable improvement the duration of survival is always very limited, being six months on the average, and hardly ever exceeding eighteen months to two years. After gastrectomy, on the other hand, the return to normal is much more complete than after gastro-entrostomy. Although Lion has seen only one case of gastrectomy in which survival was sufficiently long to justify its being regarded as a complete recovery—the patient was operated on in 1898, and was still in good health—several cases of survival from twelve to fifteen years have been recorded.

## Obstetrics and Gynaecology.

#### 438. Hydatid Cysts in the Pelvis.

N. BLASCO (*Ann. de la Soc. Gin. Españ.*, 1923, p. 6, in *Arch. de med., cir. y esp.*, March 10th, 1923), in a report of an illustrative case at a recent meeting of the Spanish Gynaecological Society, states that the frequency of hydatid disease differs considerably in different countries. While some gynaecologists of considerable experience have not seen a single case, others have observed a fairly large number. Thus Freund in twenty-five years saw 18 examples and Schanta in thirteen years 9; Frauta collected 36 cases of difficult labour due to hydatid disease, and Fargas in his work stated that he had operated on 6 cases. In Spain cases of this kind are rarely seen. Blasco's patient was a woman aged 25, in the third month of pregnancy, who had given birth to a dead foetus by breech presentation seven months previously. On examination the pelvis was found to be filled by a cystic mass pushing forward the uterus, the fundus of which could be felt in the hypogastric region. An ovarian cyst was diagnosed and laparotomy was performed, when the cyst was found to be independent of the adnexa and situated between the rectum and right iliac vessels entirely covered by the posterior parietal peritoneum. On removal the tumour proved to be of the size of a foetal head. Complete recovery took place, and the patient subsequently gave birth to a child by normal labour. In the subsequent discussion Luque reported a case of pelvic hydatid cyst simulating extrauterine pregnancy. An exploratory puncture was made through Douglas's pouch and clear fluid obtained. The diagnosis of hydatid cyst was confirmed by laparotomy.

#### 439. The Place of Pubiotomy in Obstetrics.

ACCORDING TO A. H. BILL (*Amer. Journ. of Obstet. and Gynecol.*, March, 1923, p. 258), pubiotomy, an operation which is little employed in America, is to be regarded as a competitor, not of Caesarean section, but of craniotomy of the living child. Its advantage is seen in cases in which, by reason of manifest or probable infection, a Caesarean operation is contraindicated or at least appears dangerous; since there is no communication between the pubiotomy wound and an infected genital tract, pubiotomy is no more objectionable than craniotomy. An important application of pubiotomy is its prophylactic use in delivery of the after-coming head in cases of moderately contracted pelvis; in such cases the accoucheur is not at an early stage able to assess the relation of the proportions of the foetal head and pelvis by pressing the one into the other, and the saw may, therefore, be passed around the pubic bone before delivery, to be used only if the course of events proves it necessary. Similarly the saw may be used prophylactically in cases in which it is judged best to deliver by podalic version rather than by forceps. In the author's experience the subsequent union of the divided pubes is invariably firm, but usually fibrous.

#### 440. Congenital Septa of the Vagina.

CARTSO (*Il Morgagni*, April 5th, 1923, p. 155) reports six cases of congenital septa of the vagina. In the first case haematocolpos was present. In the second an incomplete transverse septum caused sterility, and was relieved by dilating with Hegar's dilators. In the third case there was a septum of the hymen. When pregnancy occurs the septum becomes softer, vascularized, and hypertrophies, and, according to its density, interferes more or less with labour. In most cases it becomes necessary to incise the septum to accomplish delivery. Owing to the risk of haemorrhage it is better, says the author, not to incise these septa during pregnancy.

#### 441. Turpentine Injections for Inflammation of the Uterine Appendages.

P. MORVILLE (*Ugeskrift for Læger*, April 5th, 1923, p. 235) has collected the literature of this treatment and has found that the opinions thereon differ widely. He has carried it out in a hospital in Copenhagen in thirty-three cases of inflammation of the uterine appendages, the disease in most cases being gonorrhoeal. There were, however, five cases in which the disease had followed abortion. The turpentine was administered by intramuscular injection, the dosage being 0.5 c.cm. of a solution containing ethereal oil of turpentine in olive oil in the proportion of 2 to 8. A little éucupin was added to this solution. As it often gave rise to violent reactions, and its effects were remarkably inconstant, the author concluded that impurities in ordinary oil of turpentine must be responsible, and he therefore abandoned it in favour of a proprietary preparation sold in Berlin as "terpichin," which contains specially purified oil of turpentine in olive oil to which a little quinine and anaesthesin have been added. The reaction to this preparation was almost negligible, and there was no fever nor leucocytosis. But with neither preparation was the author much impressed, and in not one of the thirty-three cases could he convince himself that this treatment was responsible for any improvement the patient might have made. Only about half the number were symptom-free after six to seven weeks' treatment, which in nine cases had to be supplemented by operative treatment.

### Pathology.

#### 442. Non-protein Blood Nitrogen in Pregnancy and Eclampsia.

K. HELLMUTH (*Arch. f. Gynäk.*, March 17th, 1923, p. 18) found that the non-protein nitrogen in the blood of women in the ninth month of pregnancy varied from 21 to 28 mg. per cent.—figures which are somewhat small compared with those of healthy non-pregnant subjects. At this time the urea nitrogen forms a reduced proportion of the total non-protein nitrogen—about 30 per cent. as compared with 50 per cent. in the absence of pregnancy; by the second week after labour the normal has been regained. The uric acid in the blood attains somewhat high values during labour. Creatin and creatinin appear to be present in normal amounts during late pregnancy and labour. From examination of the blood of 18 patients with pregnancy nephropathy and 9 with eclampsia Hellmuth finds that in those presenting comparatively slight signs of renal affection (slight albuminuria and oedema in the absence of increased blood pressure, headache, or urinary casts), the total non-protein blood nitrogen and its partition are normal for pregnant subjects; in more severe pre-eclamptic conditions, however, as well as in eclampsia, although the total nitrogen shows little increase, the urea fraction is abnormally large, both absolutely and also with respect to its relation to total non-protein nitrogen. During eclamptic convulsions an increase of the uric acid was constantly observed, and it frequently attained thrice the normal values. These findings, for which a pathological rather than a diagnostic significance is claimed, confirm the clinical finding that benefit ensues from reduction of protein intake in threatened pre-eclamptic conditions. It is said that estimation of the blood uric acid affords the most sensitive indication of *restitutio ad integrum* in the after-history of patients who have suffered from pregnancy nephropathy and who, according to grosser clinical signs, appear to be cured.

#### 443. Homologues of Adrenaline.

C. E. DE M. SAJOUS (*New York Med. Journ. and Med. Record*, March 21st, 1923, p. 325) considers vitamin C as vegetable and animal tyrosin and tyrosinase, jointly the homologues of adrenaline tests and food values. Deficiency of adrenaline underlies the genesis of scorbutus as a deficiency disease, the fundamental function inhibited by vitamin deficiency being tissue oxidation. Scurvy and infantile scurvy are due to an inadequate power to take up oxygen from the air owing to deficiency in the blood of the adrenal secretory product, this adrenia being attributable to deficiency of the food constituent tyrosin and its oxidizing enzyme tyrosinase, which as adrenaline and its adrenoxidase endow the haemoglobin with the power to take up oxygen and carry on tissue oxidation. The vitamin C of foods subserves the needs of metabolism and prophylaxis, and in disease sustains the efficiency of the defensive processes, and during convalescence not only promotes tissue oxidation but is the fundamental factor in all processes of repair. The effect of heat on foods shows that, while tyrosinase stands 100° C., tyrosin is destroyed by cooking above 67° C., thereby impairing its reactive activity in proportion to the protection afforded by its external covering and the rapidity of the cooking. Tests on various

foods showed that cooking in water above 67° C. tends to destroy their tyrosin if the fluid can penetrate the tissues of the food, and in these circumstances the vitamin C ceases to become a source of adrenaline even if tyrosinase, which withstands 100° C., remains undestroyed. Scurvy results because tyrosin is lacking, thus accounting for the fact that foods autoclaved at high temperatures cause scurvy in animals, which were saved by the same but unheated foods.

#### 444. The Effects on Lymphatic Glands of Exposure to Radium.

J. C. MOTTRAM (*Amer. Journ. Med. Sci.*, April, 1923, p. 469) records observations made on the iliac lymphatic glands of the rat after the exposure of the whole animal to radium. Prolonged exposure results not only in a great destruction of lymphocytes, but also in an actual inhibition of their production. That phagocytosis of lymphocytes by follicle cells occurs is undoubted, but it is not altogether certain that follicle cells are converted into plasmoidocytes (cells of plasma cell character), though appearances point to that conclusion. Briefly, the changes noted are as follows: Lymphocytes enter the gland by afferent lymphatics and are devoured by endothelial cells, which gradually change into follicle cells. A process of cell division now takes place and the follicle cells are converted into plasmoidocytes or myelocytes. The plasmoidocytes are found to divide into lymphocytes, and these leave the gland by efferent lymphatics or possibly blood vessels. The author points out that observers at the Rockefeller Institute, noting the increase of mitosis following exposure to x-rays, have taken it as evidence of a stimulation of the formation of lymphocytes, whereas he is of opinion that it is due to an accumulation of degenerated lymphocytes as a result of the changes summarized above. The whole has an important bearing on the problem of lymphocytes and cancer immunity.

#### 445. Natural Immunity.

R. W. MENDELSON (*Philippine Journ. of Science*, February, 1923, p. 115) has been impressed by the natural immunity to infection and the resistance to disease manifested by the Siamese. During the last epidemic of cholera in Bangkok, the east side of which city is supplied with pure water, while the west receives impure water, the morbidity and absolute mortality rates were significantly lower on the east side as compared with the west side, yet the case mortality was higher on the east side than on the west. This is explained by the argument that the people on the east side, having for the past few years used a perfectly pure water, had lost a certain acquired immunity previously gained as the result of constantly using an infected water supply, while the inhabitants of the west bank of the river still retained their immunity. Typhoid fever is rare amongst the lower class Siamese in spite of insanitary conditions of life; this is probably due to a racial immunity, acquired as the result of using for many generations an infected water and food supply. Specific immunity to typhoid infection could be demonstrated in 15.5 per cent. of the people. The conditions in Siam are ideal for the propagation of plague, which, though endemic in the country, rarely increases to epidemic proportions. Although serum reactions fail to demonstrate specific immune bodies in the blood towards plague, it is probable that the natives are protected by a slowly acquired immunity. The author notes that the nervous system of orientals is much more resistant to the effects of germ infection than is the nervous system of occidentals; syphilis of the nervous system is rare in Siam, although primary and secondary syphilis are rampant; and cerebral malaria is only infrequently met with, though large numbers of Siamese harbour malaria parasites in their blood.

#### 446. Antibodies to Filter-passing Virus of Influenza.

SPECIFIC antibodies against *Bacterium pneumosintes* have been proved by OLITSKY and GATES to exist in the serum of experimentally infected rabbits, and they now record (*Journ. Exper. Med.*, March, 1923, p. 303) observations on the agglutination of this filter-passing virus by human serum. No agglutinins or precipitins for *Bacterium pneumosintes* were found in the serum of normal persons, but agglutinins were demonstrated in the serum of seventeen persons among nineteen who were examined from ten days to five months after recovery from epidemic influenza. The serum of ten persons who had influenza, followed in three cases by pneumonia, two and a half to three and a half years before, proved negative. In one instance the appearance of specific agglutinins against *Bacterium pneumosintes* was found to be coincident with an attack of uncomplicated influenza. In twelve of fifteen instances in which agglutinins were found precipitins against *Bacterium pneumosintes* were demonstrated also. These antibodies may exist in the blood at least five months after recovery from the disease.

#### 

J. HENDERSON (*Glasgow Med. Journ.*, April, 1923, p. 209), in considering the treatment of high blood pressure, points out that in many cases some degree of high pressure may be compensatory, its existence, without associated symptoms, not calling for attempts at reduction, the aim rather being to prevent further rise. In this direction much may be done by regulation of the diet, bowels, and exercise, and restriction in food intake, especially fluids; no meat, seasoned foods, alcohol, strong tea, or coffee should be allowed. Purgation by drugs which remove large quantities of fluid—for example, calomel, julep, and elaterium, with morning salines—is important. Suitable exercise is essential, but all mental and physical overexertion must be avoided, and when there is evidence of cardiac distress complete rest in bed may be needed for a time. Venesection may be of use as a temporary measure in a crisis, and carefully regulated hot baths are of value in increasing elimination by the skin and lungs. Vaso-dilators should not be employed too early; amyl nitrite and nitroglycerine produce a sudden temporary lowering effect, while sodium nitrite in 3-grain, or even 5-grain, doses several times a day gives the best sustained effect and may be beneficially combined with a diuretic or diaphoretic. The best results from potassium iodide are obtained when it is given in small doses over long periods with occasional intervals of rest; digitalis is not contraindicated in the presence of threatened heart failure. It is claimed that high frequency currents have a sustained action in lowering pressure without undue cardiac depression, but the author's experience of an extensive trial did not support this, although the patients often feel temporary benefit. The importance of prophylaxis is pointed out, and it is suggested that people over the age of 40 would do well to be overhauled occasionally from this point of view.

#### 

F. GRAESER (*Deut. med. Woch.*, April 27th, 1923, p. 551) has given intramuscular injections of 1 to 2 c.cm. of ether every other day to 21 children suffering from whooping-cough, and he has used as controls 12 children suffering from whooping-cough who were treated by other drugs, such as bromides and antipyrin. The age of the patients treated with ether was from 2 months to 3 years; in 3 cases complete recovery was effected, and in 14 other cases the injections of ether were followed by the cessation of vomiting and other symptoms and by improvement in the condition of the lungs. The attacks of coughing also became fewer and slighter. A comparison of these cases with the controls was definitely in favour of the treatment with ether, but the author does not recommend it in slight cases uncomplicated by vomiting or other alarming conditions. Indeed, this treatment seems to be more effective in reducing the complications of whooping-cough than in mitigating the cough itself, though it does so in a certain number of cases. Great care should be taken to inject the ether deeply into the gluteal muscles, for if it is deposited in the subcutaneous tissues it is likely to provoke necrosis. When he began this treatment the author experienced this accident in 4 cases, but it did not greatly hurt the child or detract from the benefits of the injection. It took, however, some time for these lesions to heal, and they left deep scars. Apparently it does not matter at what stage in the disease treatment with injections of ether is instituted.

#### 

M. W. SCHELTEMA (*Nederl. Tijdschr. v. Geneesk.*, March 24th, 1923, p. 1225) remarks that erythema infectiosum, or the "fifth disease," is attracting at present more attention, and with perhaps more justification, than the "fourth disease" of Duker-Filatow, as is shown by articles in recent works on children's diseases and general medicine. The incubation period ranges from seven to fourteen days. In 6 cases observed by Scheltema it was ten days. The disease occurs mainly in children, but cases have been recorded in adults and infants. Prodromal signs are usually absent. Ochsenius, however, mentions conjunctivitis, and Weber describes constitutional disturbances such as lassitude, vomiting, and headache. The most important and almost invariably the only sign of the disease is the eruption, which presents the following peculiarities: (1) It is remarkably changeable

and polymorphous, so that Pospischill has suggested the designation "erythema variabile." (2) Some regions and forms are specially typical. In some areas, such as the neck and loins, it is discrete, while in others, such as the cheeks and arms, it is thickly set and circinate. The principal region attacked is the face, which is sometimes exclusively affected. Erythema suddenly appears on the cheeks, where the eruption is somewhat irritating and resembles urticaria. The swollen skin is sharply marked off from the pale areas round the ears, mouth, and chin. On the forehead the lesions are more discrete. The other parts chiefly affected are the extensor surfaces of the upper arms and forearms, the shoulders, loins, calves, and front of the knees. On the extensor surfaces of the arms the lesions rapidly coalesce in a large bluish-red patch, and near the elbows assume a circinate appearance. The back of the feet are rarely attacked, and the back of the hands and soles never. (3) The eruption may be visible one moment and gone the next. Rubbing, striking, or warming the parts makes the rash more distinct. The rise of temperature in most cases is only slight, but Scheitema has seen a case with a temperature of 103° F., and Weber one with a temperature of 104° to 105.8°. Constitutional disturbance is not pronounced, coryza is absent, sore throat is very slight, and there are no Koplik's spots or strawberry tongue. Sometimes there is slight bronchitis or conjunctivitis, especially of the lower lid. The submaxillary, cervical, and axillary glands are sometimes a little enlarged as well as the spleen, but considerable cervical adenitis, as in rubella, does not occur. The urine rarely contains albumin, and the diazo-reaction is negative. The blood shows leucopenia with a lymphocytosis of 35 to 37 per cent., and eosinophilia. Erythema infectiosum must be distinguished from scarlet fever, measles, rubella, erythema multiforme, erysipelas, serum disease, and drug eruptions.

#### 

M. LAUZE (*Bull. Soc. des Sci. Méd. et Biol. de Montpellier*, January, 1923, p. 120) refers to three previously recorded cases of poisoning by phenolphthalein, one of them, a girl aged 19, having died in coma. Lauze has recently seen two cases of purpura following the use of phenolphthalein. The first was a woman, aged 50, suffering from mitral stenosis, who was taking small doses of digitalin, with occasional doses of castor oil or sodium sulphate. Acting on a neighbour's advice she took phenolphthalein. Next day she had vertigo, abundant haemorrhagic stools, a purpuric eruption on the lower limbs, and increased cyanosis. These symptoms recurred on four different occasions, and ceased when the patient returned to saline aperients. The second case was a man, aged 60, who constantly experimented with new drugs; a chemist gave him 4 grains of hellebore, and an easily prepared laxative cocoa which contained 0.1 grain of phenolphthalein. After taking a cup of this cocoa at bedtime he had tenesmus, many blood-stained evacuations, followed by collapse. During the following days he had swelling of the lower limbs with typical purpuric patches. Lauze treated both patients by Sicard's "homohaemotherapy"—subcutaneous injection of human blood—and after three injections the purpuric rash faded. Lauze refers to the cases recorded (*Arch. Derm. and Syph.*, March, 1922) by Wise and Abramowitz of New York. Phenolphthalein is a very popular laxative in America, and these authors have observed cases (among susceptible patients) of eruptions of the skin and mucous membranes, very similar to those caused by antipyrin and arsenobenzol—a polymorphic erythema which, instead of fading without any trace, leaves pigment deposits of brownish-yellow colour in the affected regions.

#### 

G. PETGES (*Paris méd.*, March 17th, 1923, p. 256) states that more attention has been paid to the superficial reactions in the skin due to yeasts in foreign countries, and particularly in America, than in France, where there is too great a tendency to deny yeasts any pathogenic action and to regard them merely as saprophytes. As long ago as 1908 Whitfield described an intertrigo due to yeasts, and subsequently Blanchard, Heubner, Boeck, Ibrahim, and Kaufmann-Wolff described various forms of erythema (papulo-vesicular, papulo-pustular, and papulo-squamous) as due to saccharomyces. More recently cases of eczematoid epidermomycosis due to parasaccharomyces have been published by Castelfani in Ceylon, Chalmeis and Christopherson in America, Berchardsen

**Embolectomy in Circulatory Disturbances.** (Surg., Gyn., and Obstet., March, 1927.)

454. **Embolectomy in Circulatory Disturbances.** E. KEY (*Surg., Gyn., and Obstet.*, March, 1923, p. 309) says that in suitable cases the removal of an embolus by means of arteriotomy is a most satisfactory operation. This has been made possible through the development of the technique in operations on the vessels of the body. The symptoms of an embolus may set in slowly or suddenly, and serious disturbance to the circulation may occur and gangrene of the limb caused. The degree of circulatory disturbance depends on whether the vessel is completely blocked, on the collateral circulation, and on the action of the heart. When the vessel is completely blocked the diagnosis is seldom difficult; localization depends on the fact that the embolus generally lodges where an artery bifurcates and is usually central to the boundary of the circulatory disturbance, and by observing the pulse one can generally succeed in localizing it. In performing embolectomy proper technique is of vital importance; the slightest mistake might cause thrombosing of the sutures, by which the good result of the operation might be lost. Carrel's technique, using fine needles and fine silk sterilized in vaseline, is employed. A solution of sodium citrate, which prevents the blood coagulating, is used during the operation. The artery is exposed above and below the site of the embolus and then incised; the embolus is removed, clamps are placed on the vessel, and the opening in the vessel wall is closed. The prognosis depends on the time of operation: the sooner this is done the better is the outlook. Fifty per cent have been collected by the author from this series. The operation appears to be fully successful. Efforts have been made within twenty-four hours.

[illegible]

THE principle of "notching" has been employed by J. J. MOORHEAD of "Long Bones." *Journ. Amer. Med. Assoc.*, April 28th, 1925, p. 1207 in a series of cases of fractures, and success by this procedure has been very gratifying. The time to operate,

**Treatment of Exophthalmic Goitre.**

P. PAJZS (*Zentralbl. f. Chir.*, March 24th, 1923, p. 472) has treated 15 cases of Graves's disease with success, during the last eight years, by a method of which the rationale is to destroy the secreting tissue of the goitre by means of alcohol injections. First, a single injection of 1 to 2 c.cm. is made deeply into the parenchyma on one side; a marked general reaction usually follows, and diarrhoea is common. These phenomena are pronounced, the tachycardia is increased, thyrotoxin set free by the local effect of the alcohol. The injections are carefully continued, first on alternate days, then daily; one to two injections are made on both sides; later, two to three injections are made on the posterior side, as long as improvement continues. If general or local reaction is marked the injections are stopped for a day or two. A fine platinum needle is used; the large vessels of the neck, the recurrent nerves, and the posterior capsule are to be avoided—the last in order not to injure the parathyroids. There is some pain locally at the injection, and sometimes pain for a few minutes at the back of the neck. After a week the goitre begins, says the author, to diminish in size, and after three to four weeks the general

**Treatment of Exophthalmic Goitre.**

P. PAJZS (*Zentralbl. f. Chir.*, March 24th, 1923, p. 472) has treated 15 cases of Graves's disease with success, during the last eight years, by a method of which the rationale is to destroy the secreting tissue of the goitre by means of alcohol injections. First, a single injection of 1 to 2 c.cm. is made deeply into the parenchyma on one side; a marked general reaction usually follows, and diarrhoea is common. These phenomena are pronounced, the tachycardia is increased, thyrotoxin set free by the local effect of the alcohol. The injections are carefully continued, first on alternate days, then daily; one to two injections are made on both sides; later, two to three injections are made on the posterior side, as long as improvement continues. If general or local reaction is marked the injections are stopped for a day or two. A fine platinum needle is used; the large vessels of the neck, the recurrent nerves, and the posterior capsule are to be avoided—the last in order not to injure the parathyroids. There is some pain locally at the injection, and sometimes pain for a few minutes at the back of the neck. After a week the goitre begins, says the author, to diminish in size, and after three to four weeks the general

says the author, is within the first thirty-six hours, if possible, the earlier the better, if there are none of the usual operative contraindications. The fragments are notched by a rongeur, chisel, saw, or "bone notcher." The advantages claimed for this method are: (a) More accurate coaptation means firmer, earlier union in more exact alignment. (b) With the assurance that definite coaptation has been obtained, there is less danger of the interposition of soft or hard parts which would prevent or impede union. (c) Primary neural or vascular damage is more readily discovered and corrected; secondary neural or vascular damage from pressure or callus inclusion is very unlikely. The disadvantages given are: (a) Fractures are put into the operative class with the attendant risks. (b) The method is needlessly severe and dangerous, since good results have heretofore been obtained by simpler methods. (c) It is inapplicable for general use. (d) It produces shortening; this, however, is usually slight and of no importance. The method is stated to be particularly adapted to recently displaced or old malunited fractures of the shaft of the radius, ulna, tibia, and humerus, in the order named.

#### 457. Treatment of Laryngeal Tuberculosis by Paralyzing the Recurrent Laryngeal Nerve.

LEICHSENBRING (*Klinische Wochenschrift*, March 12th, 1923, p. 498) considers that the first principle in the treatment of tuberculosis of joints, of the lungs, and of the larynx is rest for the affected organ. Rest for the affected lung can be secured by artificial pneumothorax, and for the affected joint by a plaster-of-Paris bandage. In laryngeal tuberculosis rest for the larynx is more difficult to secure. Often strict silence cannot be obtained and an irritable cough cannot be checked. To secure rest for the larynx the author has paralysed the recurrent laryngeal nerve on one side by contusion or division. Only cases of unilateral laryngeal tuberculosis are treated by this operation, and only the nerve on the side of the disease is paralysed. Nine cases of the operation are recorded. The rest secured for the tuberculous larynx had a very favourable effect on the laryngeal disease, and no bad results followed. The recurrent laryngeal nerve was exposed in the neck on one side, under local anaesthesia, at the level of the cricoid cartilage. In some cases the nerve was paralysed by pinching it with artery forceps, but it was found that the functions returned in about two months, which was too short a period of rest. Hence the author now paralyzes the nerve by dividing it; then five or six months elapse before the function returns. The operation is suitable for cases in which the disease is chiefly unilateral and the changes not too extensive. The author allows that it is difficult to say how much of the improvement is due to the operation and how much to improved general resistance of the body; but he is convinced that in some of his cases the laryngeal condition improved in spite of the lung condition, and that further trial of the treatment is justified.

#### 458. Cancer of the Breast.

L. TIXIER (*Lyon Chirurgial*, November-December, 1922, p. 673) has investigated the results of the surgical treatment of cancer of the breast from the years 1902 to 1914. He operated upon 211 cases in this period; of these, 57 cases were living six years after operation; 68 died within two years. Three factors are of importance in considering the prognosis of cancer of the breast: (1) Age of the patient. Under 50 years of age only 30 per cent. of cases lived more than six years; between 50 and 55 years of age 43 per cent. of cases survived more than six years. (2) The presence of ulceration at the time of operation. This is a feature of great gravity; out of 14 patients where the growth had ulcerated through the skin 11 died during the first two years. (3) The date of operation after the appearance of the tumour; this is, of course, open to mistakes on the part of the patient. Where the growth had been discovered for less than a year 23 cases out of 70 were alive after six years. The author points out that patients who come to the surgeon within the first year are often affected with a rapidly growing cancer, and the presence of pain draws their attention to it. These are operated upon relatively early owing to the malignancy of the tumour; in view of this the percentage of recoveries may be low. At the operation he removes a large area of skin, and the pectoral muscles and overlying fascia. A careful dissection is made of the fatty tissue in the apex of the axilla, and stress is laid on the removal of a gland lying under the clavicle on the axillary vein. He has used radium in a number of cases both before and after operation. In cases of recurrence he has seen no cures following radium. It is, he says, impossible to make a prognosis from microscopic examination of the tumour after removal.

## Obstetrics and Gynaecology.

459.

#### The Use of the Vaginal Pessary.

THE two most important indications for the use of the vaginal pessary, according to E. NOVAK (*Journ. Amer. Med. Assoc.*, May 5th, 1923, p. 1294), are prolapse and retrodisplacement of the uterus, but only in certain cases and under certain conditions. Retroversions offer a far more hopeful field than the backward flexions. With the latter the fundus is apt to be large and heavy, so that it falls backward over the posterior arm of the pessary. Puerperal retrodisplacements furnish, according to the author, one of the most frequent and most important indications for the employment of the pessary. In a large proportion of the cases, he says, the wearing of the pessary for a short time, usually only a few weeks, is all that is necessary, and there is no tendency to a recurrence of the retrodisplacement. Retrodisplacement or prolapse with pregnancy is also a most important indication for the use of the pessary. In case of prolapse in old women the indication is particularly strong when there is extensive ulceration of the everted and thickened mucosa covering the cervix or vagina, so that the danger of malignancy becomes a real one. The type of pessary best suited for complete prolapse is some form of ring pessary made of hard rubber. A rather large ring is usually necessary, although the size must of course be adapted to the individual case. In many cases in which, on purely physical grounds, operation is indicated clearly enough, but in which the patient simply cannot or will not submit to radical measures, the pessary may be worn as a temporary measure until the necessary operative procedure can be carried out. As a test to determine the pathological importance of retrodisplacements the pessary is often an aid. There are three chief contraindications to the employment of pessaries in the treatment of retrodisplacements: (1) the inability to replace the uterus to at least approximately its normal position before inserting the pessary; (2) the existence of a marked degree of perineal relaxation; and (3) the existence of chronic pelvic inflammatory disease.

460.

#### Treatment of Placenta Praevia.

ACCORDING to H. GÄNSSLE (*Arch. f. Gynäk.*, March 17th, 1923, p. 120), it is the standpoint of the Universitäts Frauenklinik at Tübingen to regard Caesarean section as the ideal method of treatment of placenta praevia provided (1) the child be living and viable, (2) there are no signs of manifest infection at the time of admission. Within these limits, and with the exclusion of cases of lateral placenta praevia (with slight bleeding, good uterine contractions, and vertex or breech presentation), for which rupture of the membranes is carried out, all cases—even those which have been examined or have had a vaginal tampon inserted before admission—come to Caesarean operation, the intraperitoneal cervical incision being preferred during the last eight years. Vaginal delivery has been attended with 8.6 per cent. maternal and 54.3 per cent. foetal mortality; for an equal number of Caesarean sections the mortalities—maternal and foetal—were each 6.4 per cent. If the foetus be dead the treatment carried out depends entirely on the acuteness and severity of the haemorrhage; in cases of placenta praevia causing bleeding at a time when viability of the infant is doubtful mild cases are treated expectantly, and more severe haemorrhage as a rule by vaginal delivery, which is accompanied by less risk of damage of the lower uterine segment than is the case towards term. Even with a non-viable foetus dangerous haemorrhage, complete absence of cervical dilatation, and primiparity are conditions which may impel to Caesarean section.

461.

#### Treatment of Fibroids.

L. F. DRIESSEN (*Nederl. Tijdschr. v. Geneesk.*, April 28th, 1923, p. 1760) states that the principles of treatment in fibroids which give rise to serious symptoms are as follows: Operation is required (1) for large fibroids extending above the umbilicus; (2) pedunculated submucous or subserous fibroids; (3) in women under the age of 40; (4) in cases of doubtful diagnosis, especially if malignancy is suspected; (5) in pregnancy. Radiotherapy, on the other hand, is indicated in the following cases: (1) intramural fibroids in women before the climacterium; (2) all cases in which a surgical operation is dangerous owing to visceral disease, diabetes, etc. Prior to 1914 Driessen operated on 111 cases of fibroids, in 19 by supravaginal amputation, and in 92 by total extirpation, with 9 deaths, which were due in 3 cases to cardiac degeneration, in 2 to pneumonia, in 3 to haemorrhage during or after the operation, and in 1 to peritonitis following pyosalpinx. Since 1914, the year in which he commenced radiotherapy, he has treated or seen in consultation

314 cases. In 177 of these, or 56.4 per cent., radiotherapy was employed; in 66, or 21 per cent., an operation was performed; 21, or 6.6 per cent., were curetted only; and 50, or 16 per cent., were treated with ergot only. Fourteen cases which were treated at first by radiotherapy subsequently underwent operation; 2 of these were fatal, but the operation in each case was carried out against Driessen's advice. Since he has adopted radiotherapy Driessen has not had a single death among his patients.

#### 452. Pelvic Varicocele.

G. COTTE and D. JEZDITCH (*Gynéc. et Obstét.*, 1923, vii, 3, p. 205) summarize the clinical features which have been claimed to be characteristic of varix in the venous plexuses of the infundibulo-pelvic and broad ligaments; multiparæ of about 30 to 35 are usually affected, and complain of pain in the loins and lower part of the belly, aggravated by the erect posture, by expulsive efforts, of defæcation, and by sexual excitement; in addition, according to Castaño, congestion of the vulvo-vaginal region leads to increased sexual appetite, but at the same time to dyspareunia. From an analysis of their cases the authors conclude that this characteristic symptomatology is present in a minority of cases only; the sole certain sign by which pelvic varicocele is susceptible of diagnosis consists in palpation of the varix in a vaginal fornix and the observation that its size is augmented when the patient stands up—a finding that is rare, possibly because it is not often sought. In two cases in which the clinical features pointed to pelvic varicocele the authors found at operation fibrocystic ovarian disease. They conclude that the syndrome described by Castaño and others is due to varied forms of pelvic congestion, of which varicocele is an occasional cause. With regard to treatment, by operation, Cotte and Jezditch prefer to make the venous resection in the region of the infundibuliform rather than the broad ligament and to combine it with ligamentary fixation of the uterus, which, if not displaced, shows a pathological degree of motility. In many cases treatment, more or less radical, of coincident morbid adnexal conditions constitutes an important part of the operation, and calls for the exercise of considerable judgement.

### Pathology.

#### 453. The Blood in Malaria.

CH. GARIN and AFFRE (*Lyon Médical*, April, 1923, p. 327) record observations on the blood in a series of cases of malaria. Dealing first with the red corpuscles, they find that these are the first elements to react to the infection. They note poikilocytosis and anisocytosis (inequality of diameter between different corpuscles), the latter particularly in prolonged attacks and in cases of severe anaemia. Specially large corpuscles appear beside very small ones, indicating active regeneration. Haemoglobin was practically normal, although this observation is not in agreement with the views of other investigators. A constant diminution in the number of red cells was found, but it was extremely variable in degree. It yielded rapidly to treatment, particularly at high altitudes, where, in some cases, the normal was exceeded, but the numbers fell again by about a million per cubic millimetre on return to lower levels. In individuals who had spent prolonged periods in malarial regions both the red cell count and the haemoglobin index were found to be below normal, even after two years' residence in a European climate and despite the absence of parasites in the blood. Reviewing the work of different observers, the authors are of opinion that the globular resistance of the red cells is increased in malaria, especially between the attacks. They regard this as a defensive effort against the parasite. Among abnormal forms basophil granular types were found to be frequent (said by Plehn to be diagnostic) and filamentous modifications were never absent, and were more numerous after an attack. On the other hand, nucleated red cells were extremely rare. In regard to the white cells, the authors dispute the generally accepted presence of a leucopenia. On the average, in some thousands of cases, an increase of 800 leucocytes per cubic millimetre accompanied the attack, and often there was even a hyperleucocytosis, though this was relatively small and of short duration. In a comprehensive series of differential counts there was a constant increase of mononuclear cells, more marked in the interval between attacks; there was also a very slight increase in eosinophils, whilst the onset of an attack coincided with an increase of neutrophil polymorphs amounting to almost 1,000 per cubic millimetre—about five times the increase observable in mononuclear white cells. This was detectable in the hours preceding an attack, and fell again during the course of the latter, and the authors consider it as of equal diagnostic value for preventive treatment as the actual presence of the parasite in the blood. Other forms observed were myeloid (7 per cent.), especially

granular myelocytes, rarely myeloblasts. The presence of melanotic leucocytes is described as being rare in primary malaria, but frequent in chronic cases. It is probable, suggest the authors, that malarial blood contains substances antagonistic to the haemolytic action of the parasite—a possible form of immunity. The suggestion is put forward that a study of the reactions of deviation of complement might prove of value from a diagnostic point of view, although so far investigation has been fruitless. In conclusion, the authors note the marked discrepancy in results obtained by the Wassermann reaction as seen in malaria.

#### 464. Influence of Sodium Salicylate upon Arthritis.

H. F. SWIFT and R. H. BOOTS (*Journ. Exper. Med.*, April, 1923, p. 553) record a series of experiments conducted on rabbits with a view to demonstrating the influence of sodium salicylate on an experimentally produced streptococcal infection. The work is of interest in view of the generally accepted theory that rheumatic fever is an infection, although its exact nature is not precisely known. The rabbits were inoculated intravenously with non-haemolytic streptococci and sodium salicylate was administered by a stomach tube; control animals, to whom no salicylate was given, were similarly inoculated. Though it was found that almost as many inflamed joints developed in each case, the rabbits which received salicylate presented a much greater proportion of mildly inflamed joints than did the controls. The evidence indicated, therefore, that salicylates modified the inflammatory reaction in a favourable manner, and the observers suggest two possibilities as to the mode of action. The first is that the drug, though of necessarily weak antibacterial strength, is sufficiently strong to reinforce the normal antibactericidal agencies of the body and cause a more rapid destruction of bacteria in the affected joints. The second possibility is that salicylate, by direct action on the tissues, lowers their power of reaction to the organisms. Certainly, animals to which salicylate had been administered developed fewer immune bodies than the controls. The authors do not consider themselves justified in claiming that there is any conclusive evidence that a non-haemolytic streptococcus is the specific causal agent in rheumatic fever. The acute arthritis developed experimentally was never inhibited nor cured, as in patients suffering from that disease to whom salicylates have been administered; it was of much greater severity and was frequently associated with purulent inflammation of the muscles in the neighbourhood of the affected joints.

#### 465. Glycaemia in Cancer of the Intestinal Tract.

LE NOIR, M. DE FOSSEY, and C. RICHEL (*Bull. et Mém. Soc. Méd. des Hôpitaux de Paris*, May 3rd, 1923, p. 609) measured the fasting glycaemia and the glycaemia provoked by ingestion of 50 grams of glucose on a group of 31 cases of cancer of the intestinal tract—stomach, rectum, and oesophagus. In 5 early cases the fasting glycaemia was normal. In 26 more advanced ones it was normal in 15. As regards the hyperglycaemia provoked by the administration of glucose, the curve obtained was normal in 4 out of the 5 early cases and in 12 out of the 26 more advanced cases. It appears that in early cases there is no disturbance of the sugar in the blood. Later, about half of the cases show hyperglycaemia—either fasting or induced. In the final stages of the disease the hyperglycaemia tends to disappear and the curve becomes normal again. From a diagnostic point of view, then, the study of glycaemia is of no value. From a prognostic standpoint a positive glycaemia indicates that the disease is moderately advanced, while, if the glycaemia be within normal limits, it is probable that the cancer is still in the early stages and should be amenable to surgical interference.

#### 466. Giant-celled Tumour of Achilles Tendon.

R. OLLERENSHAW (*Brit. Journ. of Surgery*, April, 1923, p. 465) reports the case of a patient with bilateral tumours situated over the tendo Achillis. The skin over the tumours was a little darker than normal and in the skin of the right arm there was a patch of xanthelasma. The tumours were removed, and, on microscopical examination, showed, among the tendon fibres, areas where giant cells were present in considerable numbers. Similar tumours arising from tendon sheaths have been described as sarcomata, myeloxanthoma, and by other names. The presence of plaques of xanthelasma in other parts of the body suggested the probability of a xanthic constituent in these tumours, each of which arose from the tendon itself, as there is no tendon sheath in this situation. It appeared from sections that there was a lipid material present in spaces seen in the tumours around which the giant cells were grouped, and that these giant cells were engaged in the removal of this abnormal material. The tumours were probably benign in origin, and there has been no recurrence after three years. A second patch of xanthelasma has, however, appeared on the left arm.

## Medicine.

### 467. Treatment of Convulsions in Childhood.

O. BOSSERT (*Klinische Wochenschrift*, April 16th, 1923, p. 749) records his experience of the treatment of convulsions in children. He recommends first a dose of castor oil. All sources of external irritation should be avoided, and a sedative given; the author specially recommends chloral hydrate (for a child of 4 to 6 months of age he recommends 0.5 gram of chloral hydrate, with mucilage and water up to 25 c.cm., given as an enema). After a quarter of an hour the child usually falls asleep, but if not, then the enema may be repeated in an hour. Magnesium and calcium salts are believed to diminish nervous irritability, and a subcutaneous or intramuscular injection of pure magnesium sulphate dissolved in recently distilled and sterilized water often causes a permanent improvement as regards the convulsions. This injection may be given once daily for several days. In place of magnesium sulphate injections, calcium salts may be given by the mouth. Human breast milk feeding tends to prevent convulsions, and therefore should be advised in the case of children under the age of 6 months. In the whey of animal milk salts are present, the author believes, which tend to cause convulsions. Many children are so sensitive to their influence that even small quantities of animal milk cause convulsions. Hence animal milk should be excluded from the diet at first. But in young children a milk-free diet can only be continued for a few days, hence medical treatment is necessary, so that animal milk may be soon added to the diet. In children over 6 months old a mixed diet may be given. Phosphorated cod-liver oil is of service. In true epilepsy the mixed bromides are recommended. Salt in the diet should be restricted. If bromides fail, a combination of luminal and bromides is suggested. In certain minor forms of epilepsy caffeine has been found useful.

### 468. Treatment of Leprosy.

P. N. ORTIZ (*Bol. de Asoc. med. de Puerto Rico*, March, 1923, p. 27) says that in his experience ethylic ethers are superior to other drugs hitherto employed in the treatment of leprosy. The products at present on the market include the following: crude chaulmoogra oil, soda morrhuate and gynocardate in 3 per cent. strength (Rogers) for intravenous use, antileprol (the commercial name for the original ethylic ethers, which is sold in capsules of 1 gram each for use internally), ethylic ethers and fatty acids with 2 and 2½ per cent. of iodine respectively, and chaulmestrol, the name given to ethylic ethers prepared without iodine. Intramuscular injection, although it gives good results, especially in young and otherwise healthy patients, has the disadvantage of being a slow and painful method, and absorption takes place with difficulty in patients who are in an advanced stage of the disease. The form which responds least to treatment is the purely nervous variety of leprosy. Forty cases were treated by Ortiz in accordance with the method recommended by J. T. McDonald of Hawaii, a maximum dose of 5 grams a week in adults and 3 grams in children being used. In 7 cases the treatment had to be abandoned owing to intolerance; 9 showed considerable improvement, 11 slight improvement, and 11 (8 of whom were of the nervous type) remained *in statu quo*. Ortiz points out that the leprosy bacillus is slow in disappearing from the system, and that only a prolonged treatment is able to destroy it. Some persons who are free from any lesion and are apparently cured may harbour the germ. A nasal discharge, which is found to be repeatedly negative on bacteriological examination, does not exclude the possibility of highly active latent foci.

### 469. Can Salvarsan Create a Positive Wassermann Reaction in the Non-syphilitic?

H. BOAS and A. KISSMEYER (*Ugeskrift for Læger*, March 29th, 1923, p. 221) have investigated the claim made in 1920 by Strickler and others that in certain non-syphilitic persons the injection of arsphenamin may provoke a positive Wassermann reaction. The authors point out that while an injection of salvarsan may sometimes activate the Wassermann reaction in the subjects of syphilis, the provocation of a positive Wassermann reaction in the non-syphilitic by salvarsan is quite another matter, which requires critical investigation before it can be accepted as a dogma. They have come to the conclusion that there is no foundation for this teaching.

They selected 50 non-syphilitic patients, and gave old salvarsan to 7, neo-salvarsan to 6, silver-salvarsan to 26, and neo-silver-salvarsan to 11. The disease from which these patients were suffering was gonorrhoea in 39 cases; the remaining 11 cases were represented by a mixed assortment of skin diseases. From one to five injections of salvarsan were given, and the Wassermann test was carried out once a week. It was invariably negative, whether it was carried out before, during, or after salvarsan treatment.

### 470. Dementia Praecox.

W. S. DAWSON (*Journ. Mental Science*, April, 1923, p. 182) studied in fifty cases the disorders of dementia praecox from the standpoints of (1) general development, skeletal growth, degeneration stigmata, and atavistic signs; (2) myxoedematous changes; (3) sluggish circulation and cyanosis; (4) pulse rate, blood pressure, and oculo-cardiac reflex; (5) dysgenitalism; (6) growth and distribution of hair; (7) obesity; (8) Goetsch's reaction; (9) the pilocarpine test; and (10) the thyroid function test. There was no marked departure from the normal in physical development, and the presence of stigmata and atavistic signs was infrequent; such bodily changes as might be due to hypofunction of the gonads were uncommon; and though gross signs of thyroid disorder were rare, minor signs of hypothyroidism and hyperthyroidism were observed. In all cases reacting strongly to pilocarpine the pulse was reduced in frequency, no case showing an increase. Definite sympathetic hyperexcitability was demonstrated by the Goetsch reaction in one case only, although eighteen others gave a moderate reaction, which was, however, within normal limits. Disorders of the vegetative nervous system appear to be responsible for the chief manifestations of dementia praecox, and the high proportion of vagotonics, many of whom showed evidence of adrenal inadequacy, suggest that the vagotonia is relative rather than absolute, being due to sympathetic adrenal hypofunction. An excess of choline resulting from breakdown of lipoids may also set up vagotonic symptoms. Of the 50 cases 27 were katatonics, 14 simple dementia praecox, 7 paranoid, and 2 were hebephrenics.

### 471. Prophylaxis of Mumps.

A. CHALLAMEL (*Bull. Soc. de Thér.*, April 11th, 1923, p. 97), as the result of his experience, maintains that the duration of the incubation period in mumps is usually twenty days and that the period during which the patient is contagious is very short, being sometimes only a few hours preceding the outbreak of the first symptoms, but usually including the first few days of the disease. He therefore recommends that persons exposed to infection should continue their normal mode of life for nineteen days after the first exposure, but should be isolated for twenty-four hours from the nineteenth to the twentieth day. He considers that this isolation of contacts will be the only effective method of prophylaxis until mumps carriers can be detected by bacteriological examination.

### 472. Is Salicylic Acid a Specific in Rheumatism?

R. EHRSTRÖM and J. WAHLBERG (*Finska Läkarsällskapets Handlingar*, January-February, 1923, p. 15), while admitting the heresy implied by this question, point out that since salicylic acid was introduced in 1876 by Kolbe in the treatment of articular rheumatism, this drug has steadily maintained its reputation for being a specific remedy. But if it were truly a specific, it should appreciably reduce the incidence of rheumatic endocarditis in the cases in which it is given. But does it? To answer this question Wahlberg has searched the records of his hospital from 1842 to the end of 1920. In this period 51,811 patients were treated, and 1,072 of them suffered from heart disease of presumably rheumatic origin. Cases of heart disease due to arterio-sclerosis or syphilis were eliminated, as were also all patients over the age of 40, even when their heart disease was associated with a history of polyarthritis. Cases of renal disease were also eliminated, and thus the 1,072 cases of heart disease must, in the overwhelming majority of cases, have been of rheumatic origin. The frequency of these cases varied considerably from year to year; they represented only 0.3 per cent. of all the cases treated in 1853, and 6 per cent. of all the cases treated in 1911. Between these extremes the incidence of rheumatic heart disease varied considerably. But when the pre-salicylic acid era was compared with the post-salicylic era, it was obvious that the frequency of heart disease associated with polyarthritis had certainly

not diminished with the introduction of salicylic acid treatment of polyarthritis. The authors conclude that the heart disease in such cases is the primary lesion, and the attacks of polyarthritis are mere incidents—short-lived exacerbations of a chronic disease which may have begun many years before the first appearance of arthritis. Salicylic acid has a beneficial, symptomatic effect on these articular exacerbations, just as it has on arthritis of non-rheumatic origin and on the pleurisy of tuberculous origin. But it probably does not touch the root of the rheumatic disease.

#### 473. Trypaflavine in the Treatment of Encephalitis Lethargica.

BUSS (*Deut. med. Woch.*, April 13th, 1923, p. 476) has been giving trypaflavine for the past two years in cases of lethargic encephalitis. His first patient was a servant girl, who suffered from severe headache, cervical rigidity, loss of consciousness, and paralysis of certain muscles of the eyes. On the second day of the disease 5 c.cm. of a 0.5 per cent. solution of trypaflavine were injected intravenously, and this treatment was continued daily for ten days. On the seventh day the patient recovered consciousness. She took, however, seven weeks to recover completely, and lost all the hair of the scalp. Five weeks after discharge she was found to be perfectly well. Since then the author has treated all his cases of epidemic encephalitis with intravenous injections of trypaflavine, repeating the injections daily, and giving first 5 and later 10 grams of a 0.5 per cent. solution for a period of six to eight days. The results in all his nine cases of severe and very severe encephalitis were excellent. Only in one case did this treatment fail, and when a necropsy was performed, the case proved to be one of meningitis with suppuration, and not one of encephalitis. The earlier this treatment is instituted the better the immediate and ultimate results appear to be. But in one case, in which the treatment was not instituted till the sixth day in hospital, rapid recovery was effected after the trypaflavine treatment was instituted, although till then the patient had made no progress. She was discharged as cured three weeks after admission.

#### 474. Fat Diet in the Treatment of Diabetes Mellitus.

L. H. NEWBURGH and P. L. MARSH (*Arch. Intern. Med.*, April, 1923, p. 455) draw attention to the very apparent evils associated with the severe under-nutrition treatment frequently employed, in conjunction with other measures, in cases of diabetes mellitus. They have attempted (as others have done) to construct a diet which would control the diabetic state, and also avoid these evils, by deriving the major portion of the calories of the diet from fat. In the first place they endeavoured to demonstrate that the use of such a large quantity of fat was safe; 190 cases were treated, but for various reasons the results could only be based on 176 of these cases. The diet given contained a large amount of fat, and only a small amount of protein and carbohydrates. It was a diet of 900 calories, derived chiefly from fat. The conclusions which the authors draw from these observations are: (1) That such a diet checked the glycosuria and kept the urine free from sugar; (2) that it was not attended by acidosis; (3) that it maintained the nitrogen balance; (4) that it did not cause a hyperlipidaemia; (5) that it supplied sufficient energy to avoid the evils of fasting and under-nutrition, and permitted an amount of activity compatible with earning a livelihood; (6) that within the limits of their observations it was not attended by downward progress in uncomplicated cases.

#### 475. Klippel-Feil's Syndrome.

VASILESCU and ST. NICULESCU (*Bull. et Mém. Soc. Méd. des Hôpitaux de Bucarest*, January 31st, 1923, p. 13) record a case of this rather rare condition. A soldier, aged 21, was admitted to hospital in September, 1922, suffering from pleurisy. He had had polyarticular rheumatism and malaria, but no other serious illnesses. Apart from the pleurisy he was a healthy, well developed man, with apparently no neck, his chin resting on his manubrium. Head movements were very limited, lateral rotation did not exceed 45 degrees, but movement was not painful and there were no trophic changes. There was no family history of deformity. The Wassermann reaction was negative. A skiagram showed that the bodies of the second to the fifth cervical vertebrae were compressed from above downwards and formed a solid mass; no intervertebral cartilages could be seen except those between the first and second and the fifth and sixth vertebrae. There was no spina bifida. It is stated that this deformity is more common in males than in females (10 to 3). The etiology of Klippel-Feil's syndrome—"neckless men" (Dubrueil-Chambard)—is unknown. Klippel and Feil ascribe it to arrest of development or some injury during foetal life or early infancy. It approximates to the "numerical atrophy" due to spina bifida, which is often found at the level of the segment involved.

## Surgery.

476.

#### Treatment of Flail Ankle.

A. STEINDLER (*Journ. of Bone and Joint Surgery*, April, 1923, p. 284) points out that flail ankle is one of the many difficult problems confronting the orthopaedic surgeon in his treatment of paralysis, and various methods of stabilization of this joint have been advocated and practised in many clinics. Davis performs a subastragaloid section, with backward displacement, by which means a complete fixation of the astragalo-calcaneal joint is accomplished. Hoke, in addition to fixation of the latter joint, also arthrodeses the astragalo-scapoid articulation. Soule advocates fixation of the astragalo-scapoid joint only. The complete fixation of both ankle and subastragaloid joints is carried out chiefly by Whitman's operation of astragalectomy with backward displacement, which usually results in a fibrous fixation of tibia to os calcis. The operation devised by Sir Robert Jones, and known as his "two stage" operation, also aims at fixation of both ankle and subastragaloid joints. It is evident, therefore, that Steindler is not putting forth any fresh idea in advocating panastragaloid arthrodesis, but is simply demonstrating another operative method of stabilizing both ankle and subastragaloid joints. The operation is carried out through a curved incision passing behind and below the outer malleolus. After division of the peroneal tendons and calcaneo-fibular ligament the joint is opened and the foot forcibly adducted, so that the upper surface of the astragalus and the tibio-fibular mortise are exposed to view. The articular cartilage is completely removed from the joint surfaces, and by upward retraction of the astragalus from the inferior joints also. The astragalo-scapoid joint is also dealt with in a similar manner. The cut ends of the peronei are united, the wound closed in layers, and a tissue drain left in for twenty-four hours. Plaster-of-Paris fixation is carried out with the foot in normal alignment and with 20 degrees of plantar flexion. The foot which is suitable for such a method is clearly a complete "dangle" foot associated with no deformity and with moderate knee flexors. The resulting fusion, with rare exceptions, is completely bony, as is well shown by radiograms. A firm and painless gait is the usual end-result.

#### 477. Treatment of the Ill Effects of Lumbar Puncture.

H. C. JACOBÆUS and K. FRUMERIE (*Acta Med. Scand.*, April 10th, 1923, p. 102) suggest that the ill effects of lumbar puncture—headache, vomiting, nausea, and giddiness—are probably due to continuous leakage of the cerebro-spinal fluid through the puncture in the lumbar region, and they record two cases to show how dramatically successful the intraspinal injection of saline solution may prove. This idea came to both authors simultaneously and independently, and they believe that it is of great value in counteracting the often distressing sequels to lumbar puncture. In their first case the patient was almost moribund as the result of spinal decompression from leakage of cerebro-spinal fluid. Two days after the first puncture the operation was repeated, and hardly a drop of cerebro-spinal fluid could be obtained. After the injection of 16 c.cm. of saline solution the pressure, which had been only about 1 cm., rose to 6 cm., and the pulse rate, which had been about 50 to 60, rose to 80. By the time 90 c.cm. of saline solution had been introduced the pressure was 25 cm., and the pulse rate 120; it fell to 96, and the pressure to 18 cm., when about 2 c.cm. of saline solution were withdrawn. The patient rallied even during this injection, and her recovery was so rapid that next day she was as well as ever. The authors supplemented this treatment by raising the foot of the patient's bed, and they suggest that this simple manoeuvre explains why the leakage did not proceed after the second lumbar puncture. Their second case was equally successful.

478.

#### Intussusception.

ALGLAVE (*Bull. et Mém. Soc. de Chir. de Paris*, March 20th, 1923, p. 450) draws attention to certain points which he has noted in connexion with intussusception—first, with regard to the etiology of the condition; secondly, respecting the cause of the early irreducibility met with in certain cases. In the ileo-caecal type it is generally asserted that the free mobility of the gut is necessary for this variety of intussusception to take place, and the fact of this mobility being more marked in the child than the adult is why ileo-caecal intussusception is more often seen in children. He considers that these conditions are not necessary for the production of the ileo-caecal variety, and that it may be found when the ileum and caecum are firmly fixed to the posterior abdominal wall. He records the case of a male, aged 40, where, although the gut was firmly fixed, an ileo-caecal intussusception was found and the ileum was twisted in

a spiral fashion, rendering reduction impossible. He considers that suturing the gut to the posterior abdominal wall will not prevent a recurrence of the condition. Further, he finds that the mobility of the caecum is not more marked in the young child than in the adult. The causation of the early irreducibility of an enteric intussusception he has found to be due to the plecting up of the invaginated bowel, which he likens to an accordion. In one case of the enteric variety where this was marked, at a post-mortem examination the intussusception appeared to measure only 9 or 10 cm., but when it was drawn out it was found to measure 35 cm. The plects may be particularly close round the neck of the intussusception, showing the force with which the condition is induced. Where cases of this nature are met with it may be necessary to carry out a resection of the intussusception immediately.

#### 379. Colostomy in Intussusception.

A. GOTTESLEBEN (*Zentralbl. f. Chir.*, March 17th, 1923, p. 438) describes a method of operation which was employed successfully in the case of a child, aged 16 months, suffering from intussusception, the operation taking place at least thirty-four hours after onset. Reduction was effected without difficulty, after which a Witzel's oblique fistula was made, the tube being passed through a small incision in the anterior longitudinal band of the caecum, and introduced sufficiently far to allow the inner extremity to be guided through the ileo-caecal valve into the ileum. The child was very ill for two days; vomiting was treated by gastric lavage; the lower ileum was irrigated through the tube. On the third day the intestines had recovered their motility, and thereafter the general condition improved rapidly. The tube was removed ten days after operation and the fistula closed spontaneously a fortnight later. The author considers that the establishment of such a fistula reduces the danger of paralytic ileus following the operation, and also that recurrence is prevented by the subsequent adhesions; he advises that the method be adopted not only after successful reduction of an intussusception, for these reasons, but that it be employed also as a palliative measure where reduction cannot be effected, and the general condition of the patient is too poor to allow of resection.

#### 380. Myositis Ossificans.

D. LEWIS (*Journ. Amer. Med. Assoc.*, May 5th, 1923, p. 1281) has observed two cases in which bone developed in incisions of the abdominal wall. In one case a posterior gastro-enterostomy had been performed for duodenal ulcer. The post-operative course was uncomplicated. The patient left the hospital thirteen days after the operation much relieved, the pain and distress following the taking of food having completely disappeared. Three weeks after the operation he noticed some tenderness in the scar, so marked that he could not wear a belt without considerable distress. Seven weeks after the operation a definite mass, measuring a fingerbreadth or more in width, could be felt along the entire length of the scar. This mass was of the consistency of bone, and the x-rays cast a definite shadow. This mass was not removed. The patient was lost sight of, and the final outcome cannot be stated; the mass was, however, decreasing in size. In the second case myositis ossificans developed in the muscles of the lower abdomen following a suprapubic prostatectomy. In four cases the myositis ossificans followed injuries about the elbow, developing most frequently after posterior dislocations. The differential diagnosis is discussed at length. In the etiology of myositis ossificans different factors play a part. No one theory will explain all cases. Myositis ossificans developing in the abdominal wall in clean incised wounds, where there is no possibility of any injury to periosteum or bone, is apparently due to the metaplasia of connective tissue, fascia and muscle in contact with acid secretions becoming converted into bone. It is striking how many cases of myositis ossificans in the abdominal wall have followed operations on the stomach, either a gastro-enterostomy or resection. Myositis ossificans developing after dislocations is apparently due to periosteal stripping and displacement. The ossifying myositis occurring in fractures associated with considerable movement of the fragments, such as the pathological fractures occurring in tabes, demonstrate better than any other lesion the part played by periosteal stripping and displacement in myositis ossificans.

#### 381. Apoplexy following Nitrous Oxide Anaesthesia.

E. CHABROL (*Bull. Soc. de Thé.*, February 14th, 1923, p. 52) records the case of a woman, aged 50, who developed symptoms of cerebro-meningeal haemorrhage after an operation for epithelioma of the breast, in which nitrous oxide was the anaesthetic used. The operation was a difficult one, owing to the presence of numerous metastases, and the patient was kept under the anaesthetic for an hour and a quarter. About

three hours after the operation she came round from the anaesthetic, but almost immediately afterwards sank into a deep sleep. The following day spastic left hemiplegia developed, and, in spite of bleeding and leeching, death took place thirty-two hours after the anaesthetic. Apart from Paget's disease of the nipple, which had preceded the epithelioma of the breast for several years, the patient had always enjoyed good health. A week before the operation the heart, blood pressure, and urine were found to be normal and the Wassermann reaction was negative. A few hours after the anaesthetic 100 c.cm. of urine were obtained and found to contain a trace of albumin. Examination of the blood serum a few hours before death showed 1.15 grams of urea per litre. Commenting on the case, Chabrol remarked that Chevassu and Rathery, at the Congress of Urology at Strasbourg in October, 1921, had emphasized the danger of nitrous oxide anaesthesia in patients with hypertension. In the administration of this anaesthetic the probable duration of the operation and the age of the patient should be taken into consideration. In operations of short duration laughing gas deserved the reputation it enjoyed in dental practice, but in operations likely to last an hour or more cases of this kind should serve as a warning. The age of the patient was of importance and was a more valuable guide than the best blood-pressure apparatus, inasmuch as it indicated the possibility of localized vascular sclerosis, which, as in the present case, was not always revealed by the peripheral blood pressure.

## Obstetrics and Gynaecology.

#### 392. Symptoms of Intracranial Haemorrhage in the Newborn.

ACCORDING TO J. RHENTER and H. EPARVIER (*Journ. de Méd. de Lyon*, April 5th, 1923, p. 209), intracranial haemorrhage is more frequent than is commonly supposed among living newborn children; in addition to the large effusions of blood, characterized clinically by the classic signs of convulsions, general or localized, and of paralysis of a limb or limbs, smaller haemorrhages reveal themselves by less striking signs, but can be diagnosed with certainty if blood be found in the cerebro-spinal fluid after lumbar puncture. Seven cases of the latter category are recorded; in two labour was completed spontaneously, and in two the infants appeared at birth to be healthy and vigorous. The symptoms which aroused suspicion of meningeal haemorrhage and led to lumbar puncture being done appeared within forty-eight hours in all but one child; three had slight convulsive movements, confined in one to the eyelids; two showed rigidity of the neck; one increased tension at the anterior fontanelles; one cyanosis and dyspnoea; one showed bradycardia; four cried almost continuously. Of the seven cases two were fatal, including one of spontaneous delivery in a normal pelvis; in both lumbar puncture gave almost pure blood. In nearly all cases lumbar puncture is the most valuable therapeutic as well as diagnostic procedure; puncture of the fontanelle has been recommended, but trephining should be reserved for cases of grave haemorrhage with signs permitting of precise localization. The paper records one autopsy only at which two tears were found in the tentorium cerebelli; the after-history of the surviving infants is not known.

#### 393. Correction of Deformity in Flat Pelvis.

G. FOSSATI (*Annali di Ostetricia e Ginecologia*, March 31st, 1923, p. 141) writes favourably of the Costa operation of partial symphysectomy and of Rotter's excision of a portion of the sacral promontory. Both procedures have as their object a permanent shortening of the antero-posterior diameter of the inlet in flattened pelvis; and in two cases recorded in the present paper Fossati combined the two operations, as suggested by Giglio. The true conjugate measurements were respectively 7.5 and 7.6 cm. Transperitoneal Caesarean section having been accomplished, thicknesses of the sacral promontory amounting respectively to 1 and 1.3 cm. were excised, and after closure of the peritoneum a crescentic section of tissue was cut off the postero-superior aspect of the pubic symphysis. The combined operation, in common with the components, is applicable only in cases in which the pelvis is flat, and in which this deformity is the sole cause of dystocia. By combining the two excisions of bone a larger total amount can, it is claimed, be added to the diameter of the pelvic inlet (without risk of weakening the pelvic girdle) than is the case with either operation singly. No difficulty in walking followed in either patient. The Rotter and Costa operations have each been restricted to pelvis of 7.5 cm. true conjugate; it is suggested that the combined operation may be carried out in cases of more marked flattening.

**484. The Etiological Significance of Pregnancies and Labours in Cancer.**

S. PÉLLER (*Arch. f. Gynäk.*, March 17th, 1923, p. 59) quotes British, Italian, and other statistics of mortality as showing that there is no direct relation between fertility and incidence of cancer of the genital organs. From analysis of the last ten years' records of the Universitäts Frauenklinik at Vienna he concludes that the incidence of carcinoma is not favoured by the occurrence of numerous abortions or pregnancies; the essential etiological factor is the rate of their occurrence—a small interval between repeated gestations favours and a longer interval is against the occurrence of cancer of the genital tract. The earlier incidence of cancer among those who have aborted is to be ascribed not to the abortions but to the more rapid succession of conceptions and pregnancies among this class.

**485. Death from Obstetrical Shock.**

J. JIMÉNEZ (*La méd. Ibera*, May 12th, 1923, p. 412), who records an illustrative case, states that obstetrical shock, like surgical and traumatic shock, may be due to various causes. Sometimes it is produced by a uterine reflex originating in the cervix as the result of pressure by the foetal head, the mechanism being similar to that which takes place on introduction of a sound or laminaria tent into the cervix. This cause—uterine reflex—is most likely to be found in women of a neurotic temperament, especially if there are pre-existent lesions in the cervix. Another important cause of obstetrical shock is the toxic factor, which comes into play in cases of difficult labour, when an operation or some other form of traumatism has taken place with death of the foetus and infection of the ovum. In the present case, which occurred in a multipara aged 30, neither of these causes was at work, but death was probably due to sudden decompression of the abdomen similar to that which occurs on rapid evacuation of ascites or a distended bladder. The circumstances present in this case were a large uterine cavity with a big foetus and placenta, and a considerable quantity of amniotic fluid, combined with atony of the abdominal wall. The result was that there was a rapid flow of blood to the abdominal cavity and a bulbo-cerebral ischaemia, which was the cause of the fatal shock.

## Pathology.

**486. Eosinophilic Cells.**

A. J. HINKLEMAN (*New York Med. Journ. and Med. Record*, April 18th, 1923, p. 465) investigated the clinical significance of the eosinophilic cells of the blood by studying the numerical relationship of the white cells. While normally such cells are never present in the same sense that lymphocytes and polymorphonuclear leucocytes are, they are always in evidence either during disease or unusual activity of certain tissues, or during direct action upon the blood-making organs of certain toxins chemotactic for this particular cell. In inflammatory processes those tissues which have direct and open connexion with the circulation, and in which infection threatens life (eosinophilic negative tissues—for example, the appendix, peritoneum, pleura), do not liberate positive chemotactic elements to stimulate the blood-making organs to an increased eosinophile production, and the existing eosinophiles, being attracted to the inflamed area, tend to become taken out of the circulation. Those tissues in which the route to the circulation is less direct and open, and in which inflammations are more passive and only indirectly threaten life (eosinophilic positive tissues—for example, the skin, muscles, kidneys), liberate positive chemotactic elements which stimulate the blood-making organs to an increased production of eosinophiles, so that the usual eosinophile count may remain normal or may be increased.

**487. The Pathology of the Angio-neuroses.**

C. KREIBICH (*Klin. Woch.*, February 29th, 1923, p. 337) discusses the pathology of various angio-neurotic phenomena—a subject in which interest has recently been stimulated by the results of the Leriche-Brüning operation of periarterial sympathectomy. Cassirer concluded, on clinical grounds, that the vasomotor-trophic neuroses were irritative, and not paralytic, phenomena, and were of the nature of reflexes. He assumed a trophic influence on the endothelial and connective tissue cells, communicated through vasomotor, not special trophic nerve fibres. The present author thinks that the assumption of trophic influence may be found to be unnecessary. Cell death may be brought about by vasomotor anaemia, due to the vessel wall being so influenced through vasomotor nerve fibres that it is unable to withstand tissue or exudate pressure. Such a vasomotor anaemia differs from an external pressure anaemia, which never causes necrosis

in so short a time. Vasomotor anaemia, however, does not always lead to necrosis—as, for example, in urticaria porcellanea. Necrosis ensues when the vessel wall is suffering from something of the nature of nervous shock or collapse. Slight irritation leads to hyperaemia; stronger, to wheal formation; still stronger, to vessel collapse and tissue death. The same is true of vaso-constriction; spasm leads to various degrees of blanching, and if sufficiently intense, as in severe frost-bite or Raynaud's disease, to gangrene, with inflammation in the neighbourhood. We have therefore to keep in mind a quantitative-motor influence on the vessel wall. Certain phenomena, however, such as the herpes zoster of old people, in which slight anaemia and marked necrosis are observed, are difficult to explain on a quantitative-motor basis. It is possible that further light will come from physico-chemical investigations. It has already been shown that the difference between a wheal and inflammation is that in the latter there is a colloidal change in the endothelial cells; in a wheal there is dilatation, followed by return to the normal—the vessel wall is not damaged, as it is in inflammation. The author finds that the fluid of a wheal is blood plasma; but some observers deny that plasma passage can occur through endothelium by nerve influence without any colloidal alteration in the cells. The Leriche-Brüning operation consists in removing the adventitious coat of the brachial or femoral artery over a length of 8 cm. This part immediately contracts, and peripheral hyperaemia follows. Possibly the vaso-constrictor fibres lie deeper than the dilators. Anglo-spastic conditions have been relieved, possibly by interference with a reflex arc; whether the afferent or efferent track has been interrupted is difficult to say. (Numerous cases are mentioned illustrating the apparent independence of vasomotor manifestations from the site of the disturbance causing them—for example, cutis anserina over one side of the body after a limited burn, etc.). The author has no doubt that the operation works through the nervous system, and argues that the disturbances relieved by it must have been caused through the nervous system. It is possible that the operation may be of use in cases of psoriasis, etc., not curable by other means.

**488. The Rate of Sedimentation of the Erythrocytes in Tuberculosis in Children.**

ELISABETH DEHOFF (*Deut. med. Woch.*, May 4th, 1923, p. 578) has studied the rate of sedimentation of the erythrocytes in the blood in a considerable number of cases and has come to the conclusion that this test is of such enormous clinical importance that those who have tried it can hardly dispense with it. It is of value both in diagnosis and prognosis, and it is a useful guide to specific treatment—more so, in her opinion, than any other guide to the selection and control of cases undergoing specific treatment. The test enables the physician to follow the processes of repair and to distinguish active tuberculosis from certain other diseases. The rate of sedimentation of the erythrocytes is practically normal in simple acute and chronic bronchitis and also in bronchiectasis, provided it is not associated with tuberculosis or pneumonia. The catarrhal phenomena of the exudative diathesis also appear to have no effect on the rate of sedimentation. When this is very rapid even the most cautious specific treatment is contraindicated, and when, in the course of specific treatment, the rate of sedimentation is found to approach the normal, it may be assumed that this treatment is beneficial. For an account of the technique of this reaction the author refers to several papers, among which is Westergren's in *Brun's Beiträge*, 1921, No. 46, page 2.

**489. Does Normal Urine contain Leucocytes?**

E. PFLAUMER (*Zentralbl. f. Chir.*, April 14th, 1923, p. 585) draws attention to the fact that this question does not appear to have been definitely answered. Many textbooks of physiology avoid it altogether. Numerous works dealing with clinical methods speak of occasional leucocytes in normal urine. The author, who has practised microscopy of urine day by day for many years, states as his definite opinion that normal urine contains no leucocytes. This applies to both sexes, provided that in the case of the female the specimen is obtained by catheter. It is not denied that the urine of an apparently healthy individual may contain a few leucocytes, originating from some slight catarrh of any of the numerous glands which communicate with the urinary passages, or possibly of the bladder itself. Such a catarrh may be of no practical significance and may give rise to no symptoms; the leucocytes in the urine, however, are not to be looked upon as a normal constituent. If urine obtained directly from the renal pelvis by ureteral catheterization contains any leucocytes whatever, the kidney is not intact. The author recommends dry stained films for identifying leucocytes when scanty, as in wet preparations they may be confused with small epithelial cells.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

### 492. Cutaneous Lesions due to Tar.

M. J. HUBENY (*Urol. and Cut. Rev.*, April, 1923, p. 210) says that the importance of the industries in the United States connected with the refining and manufacture of coal tar, tar oil, and their numerous products, including creosote, paraffin, vaseline, and gasoline, justifies attention being drawn to the deleterious results liable to follow the constant handling of these substances. The lesions produced on the skin vary considerably. As a rule, the more serious lesions, which are usually situated on the face and forearms, do not develop until after long exposure. Tar warts may exist for a number of years before cancer occurs, but occasionally a carcinoma develops suddenly from a papilloma of only a few months' duration. According to Schamberg and Thibierge, the forearms of those who have been working for a long time with tar products show dark brown discoloured patches with many scattered papillomata or keratomatous projections, grey, yellow, or basaltic in appearance, and resting on a slightly raised base, red in colour and covered with small pustules. There may be erythematous patches without obvious infiltration or squamous pustules. The lesions usually stop below at the wrists and do not extend above the elbows. The face and scrotum may show small keratomatous and verruciform tumours similar to those of the forearms, and extensive comedones due to plugging of the follicular and sebaceous glands. The skin all over the body may show the characters of corneal ichthyosis of moderate intensity. In four of Hubeny's cases the cubital and axillary glands presented a hard, discrete, and painless enlargement. Satisfactory results were obtained by the application of x rays to the skin lesions and enlarged glands.

### 491. Rat-bite Fever.

PELLEGRINI (*Rif. Med.*, April 16th, 1923, p. 363) has collected 29 cases (6 from his own observation) of rat-bite fever, or sodoku, occurring in Italy. In one case the bite was due to a squirrel and in another to a cat; the others were due to rats (*Mus decumanus*). There was no difference in the symptoms in the case of the squirrel and the cat bites. The cause of the fever is the *Spirochaeta morsus muris*. The commonest site of the bite is the hand, especially the fingers of the right hand. Usually the onset of the disease is sudden, without any apparent cause; trauma may precipitate the outburst of the fever. Disinfection or cauterization of the bite at the time does not seem to have any influence on the development of the disease. The usual period of incubation is about fourteen to sixteen days, in severe cases rather shorter. Locally, after apparent healing of the bite, swelling, redness, and itching come on, with all the signs of phlegmonous inflammation; shivering, fever, headache, and signs of general infection then appear. Cutaneous erythema is an important symptom. The fever is intermittent in type and lasts for ten to thirty days or longer (sometimes for months). Exophthalmos, nephritis, jaundice, cardiac and pulmonary symptoms, and purpura have been recorded as complications. The prognosis as regards life is good, but in prolonged cases the disease puts a severe strain on the constitution. Since the introduction of neo-salvarsan good results have followed. Of the author's cases one was fatal—that of a little child who had been bitten several times.

### 492. Typhoid Spondylitis.

J. SABRAZÈS (*Arch. de méd., cir. y esp.*, April 21st, 1923, p. 97) states that this condition was first described by Gibney of New York in 1899. The history and bibliography will be found in the Paris theses of Bonhoure (1912), Chéron and Guyard (1921), and the Bordeaux thesis of Farinaud (1922). Typhoid spine was regarded by Gibney, Quincke, Fichtner, and Painter as the result of periostitis and osteitis, while Osler held it to be a neurosis. Statistics show that it occurs approximately in one out of every 1,800 cases of typhoid fever. It is exceptional before the age of 10 and after 40, the ages of predilection being between 15 and 35. It is most frequent in the male sex (in 8 out of 10 cases, Bonhoure). All forms of typhoid may be followed by this sequel. Spondylo-typhoid, in which the phenomenon appears at the beginning of the disease, is very rare. The upper lumbar, lower dorsal, lumbosacral, and cervical regions are involved in that order of frequency. Severe, moderate, mild, and abortive attacks may be encountered. The abortive attacks

resemble sciatica or neuralgia in some other region. Typhoid spine is usually manifested by pyrexia of an intermittent type and severe dorso-lumbar pain. There is a hyperleucocytosis of moderate degree. Cultures of the blood and cerebro-spinal fluid are negative, but Widal's reaction is positive. In some cases the cerebro-spinal fluid is under hypertension. There is no marked cytological reaction, and excess of albumin is inconstant in the cerebro-spinal fluid. The course of typhoid spondylitis is slow. It may last for months and even years, the average duration being two to three months. It is rarely fatal. The morbid process takes place in the intervertebral discs; the periosteum and ligaments of the affected vertebrae become invested with an inflammatory plastic exudate, which is liable to become organized and undergo calcification and ossification. The vertebral spines and articulations are also affected. In a small number of cases suppuration takes place. The condition must be distinguished from Pott's disease, in which the lesions do not usually affect several vertebrae at once, while there is a rarefaction of bone not present in typhoid spondylitis. The vertebral manifestations of syphilis are differentiated by the cytological, chemical, and biological changes in the cerebro-spinal fluid. In rhizomelic spondylitis the intervertebral discs are unaffected. In traumatic spondylitis the history is distinctive. As regards treatment, good results have been obtained by vaccine therapy (Weil, Dufour, Debray and Guyard, Sicard and Robineau, Vincent and Muratet), auto-vaccines being employed when possible. Subsequently massage, Swedish exercises, and tonics are indicated.

### 493. Quinidine in Heart Disease.

M. ARJEFF (*Deut. med. Woch.*, May 4th, 1923, p. 576) has given quinidine in 43 cases of heart disease, and in 25 normal rhythm was restored. In 63.7 per cent. of the patients between the ages of 25 and 40 this result was achieved, whereas among patients between the ages of 41 and 70 normal rhythm was restored in only 56.7 per cent. Among the 25 cases in which the normal rhythm was restored there were 13 with signs of valvular disease and 10 in which arterio-sclerosis was the most prominent morbid condition. Among the 18 cases in which the drug failed to restore normal rhythm there were 8 of valvular disease of the heart and 9 of arterio-sclerosis. These figures suggest that neither the age of the patient nor the nature of the heart disease greatly affects the action of quinidine. The dosage adopted by the author was 0.2 gram on the morning of the first day, two doses of 0.2 gram on the second day, two doses of 0.4 gram during the next few days, and finally three doses of 0.4 gram every day. The author continues the exhibition of quinidine even when it provokes tinnitus and headache, and appears to have done so with impunity.

### 494. Neuroses Following Encephalitis Lethargica.

J. HÄGELSTAM (*Finska Läkarsällskapets Handlingar*, January-February, 1923, p. 70) has been struck by the frequency and variety of the neuroses following epidemic encephalitis, 90 cases of which were treated in his hospital in Helsingfors. One of his patients was a clergyman, aged 35, who, a year and a half after an apparently uneventful recovery from an attack of encephalitis, began to find his voice failing him. Sometimes, but not always, he could make his voice heard from the pulpit, and his only symptoms were excessive salivation and a feeling of tiredness in the jaws. The case was suggestive of an abortive form of myasthenia gravis, and the author is inclined to think that in the future many a case now regarded as an isolated neurosis may be linked up with some previous organic lesion. In five of his cases the vegetative nervous system was involved, as shown by excessive perspiration, salivation, and seborrhoea. One of his patients was a boy, aged 10, who showed a remarkable succession of neuroses which began a fortnight after he had apparently recovered from a typical attack of encephalitis. First there was an excessive discharge of mucus from the throat. This was banished by tonsillectomy. He then had attacks of sneezing, unaccompanied by any discharge from the nose. After several weeks this phenomenon gave place to a curious laryngeal cough, which lasted throughout the summer, and then gave place to attacks reminiscent of asthma. They were accompanied by salivation and attacks of shivering, with groaning and crying, and complaints of great tiredness. During two months of disciplinary treatment in hospital these attacks gradually became less and almost ceased, but a relapse occurred on his return home.

**495. The Action of Normal Serum on Diphtheritic Infection.**

H. L. RATNÖFF (*Klinische Wochenschrift*, March 5th, 1923, p. 440), in view of Bingel's contention that normal serum is as effective as antitoxin in the treatment of diphtheria, carried out investigations on guinea-pigs to determine whether the specific antitoxic action of immune serum was strengthened by simultaneous administration of normal serum—in other words, whether the dose of antitoxin which by itself was not sufficient could save the experimental animal when normal serum was injected at the same time. The normal serum of horses and guinea-pigs was employed. It was found that neither had any protective action. The experiments furnished no proof that any other constituents of the serum than the antitoxin were responsible for its curative effects. Although these experiments are not necessarily applicable to human pathology, they indicate that clinical results should be subjected to a more stringent criticism. More conclusive proofs of the equal value of normal and immune serum in the treatment of diphtheria are required than are at present available.

**Surgery.****496. The Early Diagnosis of Renal Tuberculosis.**

A. HÜBNER (*Deut. med. Woch.*, May 4th, 1923, p. 574) bases the following views on an experience of 58 cases of renal tuberculosis coming to operation and 109 cases examined under polyclinic conditions. The value of demonstrating the tubercle bacillus by direct microscopic examination or by animal inoculation is, he believes, much overrated. The kidneys may transmit tubercle bacilli from some distant focus without there being tuberculous disease of the kidneys, and, on the other hand, even in definite cases of renal tuberculosis animal inoculation may prove negative. Catheterization of the ureters is often superfluous, but palpation of the thickened ureters through the abdominal wall, rectum, or vagina may yield important information at an early stage—at a stage when the bladder is not yet involved. It is, however, secondary disease of the bladder which the author considers most helpful in detecting early disease of the kidneys, for the tuberculosis soon spreads from kidney to bladder, giving rise to pyuria and other conditions. While he is no enthusiast with regard to catheterization of the ureters, he puts cystoscopy at the forefront of diagnostic methods, and in the overwhelming majority of his cases he has been able by cystoscopy to diagnose renal tuberculosis without the aid of the microscope.

**497. Prostatectomy.**

H. H. YOUNG (*Surg., Gynec., and Obstet.*, May, 1923, p. 589) states that in reducing the mortality of prostatectomy most has been accomplished by careful pre-operative treatment. Preliminary urethral or suprapubic drainage, together with forced fluids by the mouth, subcutaneously, or by intravenous injection, he considers to be essential in cases with evidence of renal impairment. He determines the renal function at intervals during treatment by using phenolsulphonephthalein, which is eliminated more rapidly and in greater quantity by a healthy than by a diseased kidney. In 551 cases of prostatic hypertrophy in which he used the phthalein test, first on admission to hospital and again before operation, renal function improved in 99 per cent. of the cases so much after the pre-operative treatment that the drug was being excreted at the time of operation to the extent of 20 per cent. or more. With a very low phthalein excretion on admission, he estimates the blood urea as an additional test, and finds that the blood urea drops almost to normal (0.3 gram to 0.5 gram per litre) and the phthalein excretion rises considerably in most cases during the treatment. Renal impairment is most common and most pronounced in patients never catheterized who have a large amount of residual urine, whereas it is less marked in cases with large amounts intermittently catheterized. While marked renal impairment is not often found with residual urine of less than 400 c.cm., the author finds it occasionally with small residuals of 100 c.cm. or less, and thinks this is probably due to frequent and prolonged urination, during which the ureters are closed and pelvic distension occurs. The onset of infection may greatly accelerate the renal impairment; severe cystitis, especially if associated with vesical calculus, increases vesical spasm and consequent back pressure. The lower the phthalein test at operation the greater is the mortality, and the author continues the above treatment, if possible, until the phthalein test is 30 to 40 per cent. Cases with a mild pre-operative cystitis are less subject to post-operative fever and toxæmia than the previously sterile cases; but whether or not this is the case the danger from a virulent organism—especially a coccus

infection—issuing that, besides cleansing the external genitalia, he irrigates the anterior urethra, before any instrumentation, with a 1 per cent. solution of merxyl, which is non-irritating and acts in the presence of albumin, pus, and urine. The author considers that almost every case can be brought into condition for perineal prostatectomy without a first stage suprapubic drainage. After a detailed description of the technique of his perineal operation, which he believes allows of more complete removal and better control of hæmorrhage than the suprapubic operation, the author lays stress on the importance of the administration of fluid by the mouth, subcutaneously, and in grave cases intravenously, in the after-treatment of all cases. In very feeble cases blood transfusion is stated to be invaluable. As regards post-operative incontinence of urine, the author considers that this is the result of using the median perineal incision passing through the external sphincter and triangular ligament, instead of an inverted U-shaped perineal incision which allows of the bulb, transverse perineal muscles, triangular ligament, and external sphincter being seen in turn, carefully avoided, and the urethra opened far back near the apex of the prostate, well behind all sphincteric fibres. He discusses post-operative complications in detail, and advises removal of drainage tubes and gauze from the perineal wound in twenty-four to thirty-six hours after operation; four or five days later the penile urethra is irrigated in order to open up the membranous portion, and if normal urination has not been re-established within three weeks an instrument is passed as far as the membranous urethra, no attempt being made to enter the bladder. Closure of the fistula, in the author's experience, usually occurs spontaneously within three weeks of operation.

**498. The Differential Diagnosis of Gall Stones and Gastro-Intestinal Disease.**

E. MEULENGRACHT (*Ugeskrift for Læger*, May 10th, 1923, p. 325) has questioned 128 patients who had been operated on for gall stones in the period 1913 to 1922, as to the date when their gall stones were first diagnosed. Only in 31 cases had they been diagnosed early in the disease, and in as many as 63 cases the original diagnosis had been some gastro-intestinal disease. In most of these 63 cases the duration of this mistake was a matter of several years. The most common mistake was the diagnosis of "gastric catarrh." The questions addressed to these ex-patients elicited the facts that in none had dyspepsia occurred by itself, without a history of biliary colic; that in 75 cases there had been dyspepsia in the intervals between the attacks of pain; and that 53 patients had felt perfectly well during these intervals. The most common symptom was a sense of distension, discomfort, and pressure immediately after meals.

**499. Bone-graft Fixation of Vertebrae in Spinal Caries.**

R. STRÄTER (*Deut. Zeit. f. Chir.*, March 5th, 1923, p. 313) has found in his experience that this operation, first introduced by Albee and by Henle, is a useful adjunct in the treatment of spinal caries, and is an improvement on the older methods of fixation by apparatus. He uses a graft from the patient's tibia, including periosteum and endosteum. If necessary the graft may be bent, for better apposition, as the fracture unites by bone. Some experimenters have found that grafts implanted in the spines of dogs show a tendency to undergo segmentation, corresponding to the level of the intervertebral discs, and the author has noticed this in radiograms of some of his cases; in course of time, however, he finds the clear zones disappear. He makes this an indication for keeping the patient in the dorsal recumbent position for two to three months; and for further six to nine months a plaster corset is worn. He does not agree with Albee that the operation has any influence in diminishing deformity which is already present. On the contrary, he finds that if there is marked deformity, it tends to increase after the operation, in course of time. It is frequently noticed that patients who, up to the time of operation, complained of pain on the slightest movement, experience complete relief of this symptom soon after operation. The general treatment by fresh air, sunlight, etc., must be continued; it is sometimes difficult to impress this upon the patient. Of 33 cases treated by the operation in question 18 are looked upon by the author as cured, the patients being quite well, and more than a year having elapsed since operation. Four cases operated upon within the last twelve months are improved. Two cases are in a serious condition; seven have died (one of influenza). In one case paraplegia ensued after operation, but cleared up within fourteen days. The author considers that these figures alone establish the superiority of operative fixation over methods of fixation by external apparatus. It is also to be noted that the operative method is much cheaper, financially, than long continued fixation by apparatus, particularly in the case of growing patients. In no case did any permanent harm result from operation.

## 500. Treatment of Gonorrhoea.

G. H. WOOD (*Journ. R.A.M.C.*, May, 1923, p. 367) advocates intravenous injections of acriflavine in the treatment of gonorrhoea, not so much as a method of treatment in itself as an aid to existing methods, in that it rapidly relieves the discomfort of a profuse, acute urethritis, and has a remarkable effect in clearing up an intractable case when other methods have failed. A freshly prepared sterile solution of acriflavine, 1 in 1,000 in normal saline, slightly above blood heat, is used, and is introduced into a vein at the rate of about 50 c.cm. a minute. The first injection of 250 c.cm. is given as early as possible, and after this 300 c.cm. are given at intervals of about five days. The author finds that more than three or four injections are rarely necessary, and that as a rule there is no reaction following the injection. The patient's face often assumes a slight yellowish colour towards the end of the injection, but this soon passes off. Twenty-four cases are quoted, which were discharged from hospital apparently cured after the usual tests had been carried out. Of these, twelve were acute cases placed under treatment within a few days of infection; they had an average period in hospital of thirty-four days.

## Obstetrics and Gynaecology.

## 501. Cancer of the Cervix Complicating Pregnancy.

SCHWEITZER (*Zentralbl. f. Gynäk.*, April 28th, 1923, p. 657) states from his own statistics that cancer of the cervix only occurs in 0.05 per cent. of pregnancies, the reason of this being that cancer usually occurs at a later age; the average age, however, of his cases was 35½ years, which is, of course, very early for cancer to develop. It would seem that many pregnancies following one another in quick succession have something to do with the development of cancer at a subsequent pregnancy. The symptoms are similar to those of cervical cancer in the non-pregnant, but the bleedings often occur at what would have been a menstrual period, and are taken for such, although usually they are smaller in amount. Loss of weight during pregnancy is considered a valuable additional symptom. Early carcinoma has, in the author's opinion, no effect upon pregnancy, but advanced carcinoma may give rise to abortion (von Franke states in 30 to 40 per cent. of cases) due to the action of the bacteria arising from the cancer on the foetal membranes and endometrium. At labour carcinoma, if supravaginal or circular around the cervix, often causes dystocia by inhibiting dilatation, and if operation is not performed rupture of the uterus results, although in some cases the cervix ruptures and allows the child to be born. Infection due to streptococci causing septicaemia is the great danger in the puerperium. Regarding the effects of pregnancy on cancer opinion differs greatly, but the author considers that, although the growth increases more rapidly, the malignancy is not increased; the trauma of birth, however, causes a greater growth during the puerperium, when the prognosis—which is always grave—is much worse than during pregnancy. The author recommends the radical operation for operable cases, especially during the first half of pregnancy, when operation seems to give the best results, but in the second half, when the results are not so good, he inclines to radiotherapy for the child's sake, although if the case were definitely operable he would advise operative methods. Spontaneous birth has occurred in several cases through cervices treated by radiotherapy. The author finds that 82 per cent. of his cases were operable and 43 per cent. were absolutely cured, no recurrence being noted for over nine years in each case. All the cured cases were treated during the first half of pregnancy. In inoperable cases palliative treatment is advised, combined with Caesarean section and supravaginal hysterectomy at term to prevent puerperal septicaemia.

## 502. Disturbances of Menstruation in Acquired Tuberculosis.

M. STANTCH (*Rev. Méd. de l'Est*, April 1st, 1923, p. 233) suggests that acute tuberculosis acts as an atypical septicaemia in arresting menstruation by inhibition of the ovarian stimulus. In pneumonia, general peritonitis, and similar conditions the menstrual function is first deranged. There are, however, cases in which the bacillary septicaemia, instead of producing a sudden amenorrhoea, induces an overactivity of the ovary. Menstruation commences with flooding, an excessive flow lasting for days or weeks; the lessened coagulability of the blood is an important factor. The gravity of the patient's general condition accounts for the occurrence of epistaxis, haemoptysis, gastro-intestinal haemorrhages, vomiting, diarrhoea, sweatings, etc. The septicaemic state may produce these symptoms, but menstrual disturbances play an important part. In acute pulmonary tuberculosis the intoxication stimulates the

ovarian function and excessive or prolonged menstruation reacts unfavourably on the pulmonary infection. This vicious circle lasts for two or three months, but the resulting exhaustion induces amenorrhoea before the fatal termination. In these cases the pulmonary physical signs become more marked during the menstrual periods, and vicarious haemorrhages are not uncommon. In the fibrotic type of chronic pulmonary tuberculosis normal menstruation is usual, as the slight degree of toxæmia causes no systemic disturbance. In progressive pulmonary lesions, on the contrary, menstruation may be deficient or irregular, and during the periods pulmonary symptoms are definitely aggravated, and demand absolute rest and careful observation and hygienic measures. In the period of advanced ulceration and cavitation severe toxic absorption produces amenorrhoea. Stanitch compares the condition of patients who carefully observe hygienic and dietetic directions with that of patients who insist on following their ordinary occupations, and concludes with the statement that in chronic surgical tuberculous cases menstruation appears late (from the age of 16 to 20); it is regular, scanty, and of short duration. Menstruation rarely aggravates the tuberculous lesions in these cases.

## 503. Analgesia during Labour.

G. ROSSIER (*Le Scalpel*, April 28th, 1923, p. 460), at the Lausanne maternity hospital, has endeavoured to diminish the pains of childbirth by administering pastilles containing 0.0032 gram of heroin, 0.0018 gram of dial (diallyl barbituric acid), and 0.5 gram of chlorotone. The first is given shortly after dilatation of the os has commenced, and four or five are given in all, about thirty drops of chloroform being given by inhalation during the passage of the head through the vulva. Failures numbered 12 out of 60—about the same proportion as is given in German reports of scopolamine-morphine injections; but no untoward effects on the infant were noted. In 45 cases equally satisfactory results were found to attend the administration of pastilles containing 0.015 gram of dionine (ethyl-morphine hydrochloride), 0.0078 gram of dial, and 0.5 gram of chlorotone.

## Pathology.

## 504. Culture of the Seminal Fluid in Chronic Gonorrhoea.

THE cure of gonorrhoea is very difficult to control; even after the disappearance of all symptoms and the cessation of the morning urethral discharge infection may still be present, as is shown by its transmission during coitus. According to C. MASSIAS (*Gaz. Heb. des Sci. Méd. de Bordeaux*, April 29th, 1923, p. 198), the gonococcus in these cases lodges, not in the urethra or in the neighbouring glandular structures, but in the seminal passages. This is shown by the fact that positive cultures can be obtained from the semen even in the absence of all clinical infection of the prostate, seminal vessels, bladder, and epididymis. The cultures must be taken with the greatest precautions as to asepsis, and the fluid inoculated as soon as possible after emission on to ascitic agar. Having isolated the organism, the author proceeds to the preparation of an autogenous vaccine. If the gonococcus be obtained in pure culture, a vaccine is made of a strength of 1,000 to 2,000 million organisms per cubic centimetre. In the case, however, of a mixed infection a polyvalent vaccine is prepared containing 5,000 to 6,000 million organisms. The first dose should be a quarter of the maximum; the second dose, given four to six days later, should be half of the maximum; the third dose three-quarters of the maximum; and the fourth dose, consisting of a full cubic centimetre, should be repeated five or six times. The results obtained appear to be best in the case of gonococcal or staphylococcal infections.

## 505. The Blood Picture during an Attack of Tertian Malaria.

M. WOENS DROEGT and C. VAN DAM (*Nederl. Tijdschr. v. Geneesk.*, 1923, i, p. 2002), of Amsterdam, examined the blood of four patients suffering from tertian malaria to determine the changes in the number and relation between the different varieties of leucocytes during and immediately after the paroxysm. An enumeration of the parasites was also made to determine their relation to the course of the fever and the leucocyte picture. The following method was employed: The leucocytes were examined at first every hour and then every half-hour for a few hours before the expected attack, and a large number of film preparations were made of the blood of each patient and the varieties of parasites and leucocytes studied. The results were as follows: In tertian malaria, as seen in Holland, there is a leucopenia before and during the onset of the typical paroxysm. The leucopenia begins some hours before the febrile attack and is most pronounced during

the rise of temperature. After the fever has subsided the leucocyte count returns to normal. The falling line of the leucocyte curve coincides with the division of the malarial parasites. An hour before the beginning of the fever young parasites have, as a rule, penetrated the chromocytes. The division is complete before the fever has reached its acme. There is a constant relation between the male and the much more numerous female gametes. The duration of the division of tertian parasites is probably between six and eight hours. According to Schilling's leucocyte formula it occurs simultaneously with the diminution in the number of leucocytes per cubic millimetre. There is thus at the beginning of the febrile attack a displacement to the left. Towards the end of the febrile attack the displacement to the left diminishes and a monocytosis occurs.

#### 506. A Bacteriolytic Principle (not Bacteriophage) in the Intestine of Cholera Patients.

WHILE attempting to isolate a bacteriophage virulent for the cholera vibrio, F. D'HERELLE (*C. R. Soc. de Biologie*, March 24th, 1923, p. 723) succeeded in demonstrating the presence in the stools of patients suffering from cholera of a bacteriolytic principle which appeared to be quite distinct from the bacteriophage. It was found in the faeces from three to four days after the commencement of the illness, and persisted till death. To demonstrate it, 2 c.cm. of the liquid or semi-liquid dejections were emulsified in 20 c.cm. of bouillon, incubated for twelve hours at 37° C., and filtered first through kieselguhr, and then through a candle. In the non-diluted filtrate an agar culture of cholera vibrios was rubbed up in an amount sufficient to give an emulsion of about 100 million per cubic centimetre. After incubation for twelve to eighteen hours at 37° C. the organisms were found to be dissolved, and the fluid was quite limpid. There are about this principle certain properties which distinguish it from the bacteriophage. For instance, the degree of lysis which occurs is in proportion to the quantity of filtrate employed. With the pure filtrate 100 million vibrios are dissolved in twelve to eighteen hours. The filtrate diluted by one-half is only capable of dissolving 20 to 25 million organisms, while if it be diluted 1 in 10 it ceases to have any lytic action whatever. Again, there is no regeneration of the principle in culture. The filtrate of the lysed vibrios is absolutely inactive. Nor in an agar culture are there the characteristic plaques of the bacteriophage. The author concludes that this principle is of the nature of a diastatic ferment, and is produced by the body in response to the stimulation of the proteins of the cholera vibrio.

## Radiology and Electrology.

#### 507. X-Ray Diagnosis of Duodenal Ulcer.

A. AKERLUND (*Acta Radiologica*, vol. ii, Fasc. 1, p. 14) recommends, with regard to the technique for the examination of the duodenum, an intimate co-operation between fluoroscopy and roentgenography; he describes a few simple arrangements for the exact adjustment of small plates and for the taking of small serial pictures of the duodenum in different positions of the body. The pictures are adjusted under fluoroscopic control in the most suitable directions of projection. The author especially recommends examination in the upright position. The changes in the form of the bulb constitute the central point in the direct x-ray diagnosis of the duodenal ulcer. The author distinguishes four kinds of ulcer deformities in the bulb—namely, (1) niche, (2) defect, (3) retraction, and (4) diverticulum. According to the author the bulbar niche is by no means rare; out of the material of about 100 positive cases of duodenal ulcer, collected during the course of two years at a hospital, he observed the niche symptom in the bulb in rather more than 60 per cent. The bulbar niche is most often localized to the lesser curvature side, which is retracted. As a rule a local, circular, and often spastic constriction (defect) occurs in the niche plane from the greater curvature side. The bulbar deformity arising here, which may be called a miniature picture of the ulcer deformity of the stomach, constitutes, in the author's opinion, the most typical ulcer deformity in the bulb, and has been confirmed by him in more than 50 per cent. of his cases. As to the cause of the "paradoxical" four hours' retention by uncomplicated duodenal ulcers with initial hypermotility, and probably also the origin of the typical hunger pains, the author ascribes a certain importance to the spastic, circular, bulbar constriction in the ulcer plane, which usually appears more marked during the later stages of digestion. The spastic shortening (retraction) of the longitudinal muscles—particularly strongly developed in the medial bulbar region—which may result in a pyloric insufficiency directly observable in the x-ray picture, offers a mechanical explanation of the initial hypermotility.

1042 D

#### 508. X-Ray Treatment in Erythraemia (Polycythaemia).

M. KAUFMANN (*Klinische Wochenschrift*, April 16th, 1923, p. 770) records a case showing the good effects of x-ray treatment in erythraemia (polycythaemia). The patient was a female, aged 33, who from childhood had had a red complexion, which had gradually become more intense until the colour of the face was "copper red." She complained of headache, vertigo, and burning in the eyes. The red corpuscles were 8 million per cubic millimetre. The liver and spleen were enlarged, and the heart was dilated to the right. After x-ray treatment of twenty-seven regions of the limbs and trunk, on five occasions during four months, great improvement followed. Her complexion became paler, and the red corpuscles diminished to 6 million per cubic millimetre. The improvement continued, and a year and six months later she appeared quite healthy; the liver, spleen, and heart were normal, and the red corpuscles numbered only 5 million per cubic millimetre.

#### 509. Radiotherapy for Carcinoma of the Cervix.

W. S. FLATAU (*Zentralbl. f. Gynäk.*, May 12th, 1923, p. 737) emphatically recommends radiotherapy for cancer of the cervix, and gives statistics from his own clinic at Nürnberg of 310 cases, which he has treated during the last ten years. Of these 310 cases 24 per cent. are still alive, the remainder having died or been lost sight of. The author states that the number of cures is noteworthy, for in the early days the apparatus and dosage were defective. He then subdivides his 310 cases: 101 cases were operable—his definition of operability being that the disease was confined to the cervix, no thickening nor glands were felt in the parametrium, and the uterus was mobile; the other 209 cases not conforming to these conditions were counted as inoperable. Among the operable cases 50 per cent., and among the inoperable 9.5 per cent., are still alive; of the latter the condition even when rapidly advancing was improved in most cases, and the 9.5 per cent. cured could not have been cured by any operative procedure. During the last three years (1920-22) the author has treated 68 cases with what he calls his standard method of treatment, which consists of 50 mg. of radium placed in the cervical canal for forty-eight hours and 50 mg. placed against the growth in the vagina for twenty-four hours, with which is combined, either before or after, cross-raying of the pelvis from back to front and side to side. Of these cases 80 per cent. of the 22 operable cases and 22 per cent. of the 46 inoperable cases are still alive and well. This, says the author, compares very favourably with other statistics, both operative and radiotherapeutic, in which recurrence during the first year amounts often to nearly 90 per cent. Radiotherapy is now, in the author's opinion, practically a safe method of treatment, no immediate mortality occurring, and with the improved technique now adopted fistulae rarely, if ever, occur, and skin disturbances and burns, especially if only one application is required, are hardly ever seen. He concludes by saying that radiotherapy for cancer of the cervix can achieve successes which operation could never attain.

#### 510. Treatment of Vascular Naevi with Radium.

R. H. RULISON and S. MCLEAN (*Amer. Journ. Dis. Children*, May, 1923, p. 359) discuss the radium treatment of vascular naevi, especially the type of raised capillary cavernous haemangiomas. Tubes of 25 and 50 mg. without filtration, other than the silver capsule containing the glass tube of radium, were used, the dosage being regulated by varying the distance between the tube and the skin from one-eighth to half an inch. An interval of at least three weeks separated each application, the number of which averaged fifteen, with an average dosage of 40 milligram hours. The younger the patient the better and quicker are the results. Flat naevi are more refractory than the raised, the port-wine mark being especially obstinate, but the treatment gives results in early infancy which cannot be obtained by any other methods in dealing with raised vascular naevi on the face. Among its disadvantages are the expense, lengthiness and possibility of ulcer formation and tardy healing following over-treatment, or of a resulting telangiectasia and atrophic skin with later keratosis and epithelioma. The advantages, however, outweigh the disadvantages, in the painlessness and the fact that, by carefully watching the gradual changes after each treatment, the lesion can be made to disappear without damage to the overlying skin. Ulcerations and haemorrhagic areas heal rapidly without scarring, or, when this is unavoidable, the scar is smooth and comparatively inconspicuous. It is the fact that radium exerts a definite, specific, selective action on the abnormal endothelial cells lining the blood vessels unattainable by any other form of treatment which affords the greatest reason for its use in these cases. All angiomas, however, do not respond equally to radium therapy, and treatment by carbon dioxide snow, electrolysis, or surgery gives good results in some forms.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

### 511. Tumour of the Upper Cervical Cord.

I. ABRAHAMSON and M. GROSSMAN (*Journ. Nerv. and Mental Dis.*, April, 1923, p. 342) give notes of eight cases of tumour of the upper cervical cord. Diagnostic spinal puncture in such cases is dangerous, since death may immediately follow withdrawal of the fluid, or acute swelling or haemorrhage may occur in the tumour, causing tetraplegia. The initial sign of a cervical cord tumour may be sphincter, sensory, motor, or respiratory disturbance. Urination and defaecation are at first delayed, interrupted, and difficult; retention and incontinence follow, and the sexual mechanism may be affected. A sphincter lesion with cervical root pains, with or without motor signs, suggests a cervical cord tumour. Besides sensory and motor consequences, respiratory disturbances, from diaphragmatic paresis, may occur early or late when the tumour affects the phrenic nerve origin in the second and third cervical roots, and among disturbances of the uncontrolled autonomic system caused by pressure may be bradycardia from vagal irritation, and Stokes-Adams syndrome culminating in convulsive seizures. Irritation of the cilio-spinal arc may dilate the pupil, widen the palpebral fissure, and cause exophthalmos on the same side as the tumour, followed later by paralysis, as manifested by miosis and enophthalmos, and irritation of the vasomotor and secretory nerves of the face may produce heat, redness, hyperhidrosis, paralysis-cold, cyanosis, and anhidrosis. Tumours in the uppermost segments lying within the foramen magnum may extend their pressure into the cranial cavity and cause papilloedema, while pressure on the posterior aspect of the cord may cause marked astereognosis, vibratory sense disturbance, and ataxia, especially in the upper extremities. No single sign is essentially diagnostic, deduction being made from suggestive signs to corroborative, interpreting in terms of tumour qualities the pressure exerted by a foreign body in an inextensible canal on contents of varying mobility and fixation.

### 512. The Auricular Sign in Meningitis.

B. MENDEL (*Klinische Wochenschrift*, April 23rd, 1923, p. 782) attaches great importance to hyperaesthesia of the area supplied by Arnold's nerve, as a symptom of meningitis, from a diagnostic point of view. It is known that a continuous painful impression will set up a state of increased irritability in the spinal segment concerned. This culminates eventually in an overflow of irritability ("irradiation") from the cells of the spinal ganglia into other nerve channels, which also are brought into a state of morbid irritability. This latter may become evident of itself; or it may become manifest on the application of some slight stimulus which would normally cause no reaction. The meningeal branch of the vagus arises from the jugular ganglion of the vagus, and the auricular branch arises from the same ganglion, and is distributed to the posterior wall of the external auditory meatus. The jugular ganglion and the ganglion nodosum correspond to posterior spinal ganglia, and it would be expected therefore that prolonged meningeal irritation would irradiate to the auricular branch and set up hyperaesthesia at the back of the ear. In practice this is found to be the case. Slight tapping or pressure with the finger on the posterior aspect of the external auditory meatus produces facial spasm, and sometimes cries, indicative of pain, in patients suffering from meningitis. The sign appears early, when other symptoms, such as stiff neck and Kernig's sign, are absent or indefinite. Five cases of meningitis (two tuberculous, two epidemic, and one pneumococcal) all gave the sign. A large number of patients with dental and accessory sinus disease, with earache, did not give it in any instance. The author considers that it affords an extremely simple means of giving an early opinion as to the presence or absence of meningitis.

### 513. Typhoid Fever in Large Towns.

A. LOIR and H. LEGAGNEUX (*Paris méd.*, April 14th, 1923, p. 359) remark that twenty years ago about 300 persons died annually at Havre from typhoid fever, but since then not more than twenty deaths a year have been due to this cause. This great fall in typhoid mortality is due to supervision of the drinking water. At the present time other factors than drinking water are more frequently the cause of typhoid fever in large towns—namely, milk, mussels, oysters, radishes, and flies. In 1913 an epidemic at Havre was due to milk

supplied by a farmer who had a mild attack of typhoid; it was found that the linen through which the milk was strained was washed with the same brush as that used for the patient's body linen. From 1910 to 1921 cases of typhoid were always more numerous at Havre during the months in which most oysters were eaten (October to December). Salads and vegetables eaten raw, such as radishes, may give rise to epidemics as the result of manuring, especially as the typhoid bacillus keeps alive for a long period in damp soil. The likelihood of an epidemic being due to a carrier should always be considered when the cases notified are agglomerated within a small area in which the inhabitants are likely to have the same provider, especially in the case of sweets, creams, and ices. During the epidemic of typhoid at Havre in 1921 the authors were impressed by the much larger number of cases occurring among women and children who had not been inoculated, as compared with those among men aged from 25 to 40, most of whom had been inoculated in the army. Of the 45 male cases 37 were under 20, and of the remainder only one, who had an attack of paratyphoid B fever, had been inoculated.

### 514. Intravenous Therapy of Rheumatoid Arthritis.

H. LAURIE (*Med. Journ. Australia*, March 24th, 1923, p. 303) records his experience in 56 cases of non-suppurative infective arthritis treated by intravenous injections of *B. coli communis* stock vaccine. With an initial dose of not more than 25 million, increasing up to a maximum of 1,200 million, intravenously, the typical reaction consists in a sharp rigor half an hour to one hour after injection, with a return to normal every twenty-four hours. Contrasted with treatment by subcutaneous injections of autogenous vaccines the intravenous injection of *B. coli* vaccine gives better results, pain being relieved much more rapidly and the stay in hospital shortened, being usually only a few days, with detention for one night for those who return for subsequent weekly injections. In the acute cases recovery is rapid, and relief from all disability follows injections varying in number from one to seven. Of eleven subacute cases eight cleared up entirely, the other three becoming free from pain, but with some remaining stiffness and limitation of movement. Of the chronic cases all were improved as far as pain, stiffness, and range of movement were concerned, but the bony changes and deformities were uninfluenced, and in very chronic cases with fibrous ankylosis and bony deformities there was improvement in all but one. Little or no result followed the treatment in uncomplicated osteo-arthritis, but gonorrhoeal cases were very amenable, the improvement being much more rapid than when treated by gonococcal vaccine subcutaneously.

### 515. The Abortive Treatment of Syphilis.

C. TATAME (*Ann. de Derm. et de Syph.*, April, 1923, p. 243) discusses the abortive treatment of syphilis, and emphasizes that the disease is a general, not a local, infection, and that the virus is found in the blood even before the local reaction manifests itself. The chancre is to be regarded as a local manifestation of a general reaction. It is during the primary period (from the time of the initial infection to the appearance of a positive Wassermann reaction) that successful cure is pre-eminently possible. During this period the organism is still free and not yet fixed to cellular elements, and is therefore the more easily destroyed. While recognizing the wide diversity of opinion existing in connexion with the pathology and therapeutics of syphilis, he is nevertheless convinced that abortive treatment is possible if the disease be attacked early in the primary phase, and that cure is also possible even later when a positive Wassermann reaction has developed. He considers a factor of great importance bearing on the prognosis of "abortive" cure to be the extent to which the inguinal glands are affected—where the involvement is slight the outlook is favourable. That some of his cases later contracted a second infection of the disease he regards as convincing proof of successful cure, other indications being a negative serum reaction and the absence of signs of disease in the patient's wife and children. In 24 cases of primary syphilis with a negative serum reaction he had 100 per cent. of cures, and out of 50 cases where the reaction was positive he was successful in 60 per cent. He is convinced of the importance of excision or destruction of the chancre itself by the thermocautery, by which means the removal of a dangerous nest of the organisms is effected. His practice in abortive treatment is to use neo-salvarsan in doses of 0.45 gram, rising progressively to 0.9 gram by a series

of injections at five-day intervals, with a total of 4 to 6 grams, alternating with eight injections of mercury salicylate. In conclusion, he summarizes the following points as being absolutely necessary if an abortive cure by a single treatment is to be successful: early diagnosis, the institution of treatment at the soonest possible moment, the selection of cases with a negative serum reaction, excision of the chancre, and examination of the cerebro-spinal fluid as well as the blood. Cases should, in his opinion, be kept under observation for a period of three years.

#### 516. Prophylaxis of Tuberculosis in the Newborn.

R. DEBRÉ (*Gynéc. et Obstét.*, 1923, vii, 3, p. 199) remarks that the child of a tuberculous mother is usually healthy at birth, and that the hereditary dystrophy which has been described in such infants is almost invariably due to an early overlooked post-natal infection. The occasional presence of tubercle bacilli in the milk of tuberculous mothers is of little importance, but the possibility of the infants' inhaling or ingesting particles containing virulent bacilli coughed or spat up by the mother is fraught with much danger. Five cases are related in which an infant succumbed to tuberculosis from one to five months after birth in spite of having been totally separated from the mother after her discharge from the lying-in home. Debré advocates absolute separation of the tuberculous mother from her infant; in conjunction with L. Bernard and Couvelaire arrangements have been made in certain Paris pre-natal clinics for the preparation of tuberculous pregnant women for this drastic step, and some infants are ultimately "boarded out" in families other than their own.

#### 517. Desensitization by Repeated Cuti-inoculations.

P. VALLERY-RADOT (*Bull. et Mém. Soc. Méd. des Hôpitaux de Paris*, March 29th, 1923, p. 460) reports the case of a dentist who was in the habit of developing a severe attack of asthma whenever he was exposed to the emanations of horses. Experimentally it was found that the application of horsehair to the skin determined not only a local reaction, but also general disturbances of the nature of a haemoclastic crisis, and sometimes an asthmatical attack. An attempt to desensitize him was made by practising cuti-inoculations almost daily over a period of two months with horsehair, sterilized by heat at 212° F. on three occasions. The result was quite successful and the crises disappeared completely. Four months later, however, the anaphylactic state returned, and the asthmatic crises reappeared. A few months after this new sensitization the patient suffered from an attack of eczema. The effect of this trouble was to desensitize him again—this time permanently. Other cases are mentioned in which the repeated introduction of protein poisons by the cutaneous route was successful in desensitizing patients suffering from anaphylaxis.

## Surgery.

#### 518. Radical Operations on the Stomach.

W. J. MAYO (*Surg., Gyn., and Obstet.*, April, 1923, p. 447) says that radical operations for cancer of the stomach have attracted the attention of surgeons for forty years, and for the last ten years have been resorted to with increasing frequency in cases of benign lesions of the stomach. Gastro-enterostomy, he says, will cure 90 per cent. of duodenal ulcers, but it will fail in some cases, and in these a partial gastrectomy is the operation of choice. The field for gastrectomy is much wider in gastric ulcers. The mortality for this operation for ulcer of the stomach should not be more than approximately 4 per cent. The lesser curvature is the most important portion of the stomach, and is the key to the lock which interferes with the liberation of the stomach. The success of removal depends on early ligation of the gastric artery as close as necessary to the coeliac axis. The author favours the restoration of the lumen by anastomosing the end of the duodenum to the narrowed end of the stomach after the Billroth I method. If it cannot be done, one of the other methods must be employed. Where total gastrectomy is performed he finds that the anastomosis of the jejunum to the oesophagus is best effected by Moynihan's technique, beginning the union posteriorly by peritoneal-muscular sutures as the stomach is gradually cut free from the oesophagus. Complete gastrectomy has given only one five-year cure, and after the complete operation patients present a peculiar type of anaemia, showing that the stomach has some immediate relation to the health of the red blood cell. The Billroth II method, when done in two stages—a gastro-enterostomy being the primary operation—is without a rival, and has an established position in gastric

surgery. The tendency of the stomach to drop to the left after the Billroth I operation has been overcome by suturing the stomach to the suspensory ligament of the liver. Proper mobilization of the lesser curvature is, in the author's opinion, the most important single step in radical operation of the stomach.

519.

#### The Treatment of Coxa Plana.

H. WALDENSTRÖM (*Acta Chirurgica Scandinavica*, April 11th, 1923, p. 577), who claims to have described the Legg-Calvé-Perthes hip-disease in the same year (1909) as Legg, has carefully followed 40 cases, in 20 of which the disease had ceased to be active. Ten of these 20 patients had passed the age of 20 and the author was thus able to form a fairly definite opinion with regard to prognosis and the effects of treatment. He has come to the conclusion that there is no inflammatory element in the disease, and that the term "osteochondritis" is therefore misleading. As early as 1909 he held that no intervention should be attempted, anticipating that the prognosis was as good without as with treatment. This opinion he still holds, but he modifies it so far as to interdict gymnastics and jumping on one leg, as well as taking long walks during the first three to five years of the disease. When, however, pain and contractures are troublesome, it may be necessary to prescribe extension with rest in bed for four to six weeks, and in some cases this treatment may have to be repeated. Of the 40 patients 35 were boys and only 5 were girls. The disease was bilateral in 5 cases.

520.

#### Intracardiac Injection of Adrenaline in Acute Cardiac Failure.

J. EXALTO (*Nederl. Tijdschr. v. Geneesk.*, March 17th, 1923, p. 1098), who reports a successful case, states that he has found nine other examples on record of recovery after intracardiac injection of adrenaline for acute cardiac failure during anaesthesia, published respectively by Volkmann, Zuntz, von Tappeiner, Henschen (two cases), Frenzel, Guthmann (two cases), and Blieding. The anaesthetics used were chloroform, ether, or a combination of the two. Six minutes was the longest and two minutes the shortest interval between the stoppage of the heart's action and the injection. As a general rule, therefore, one should not wait longer than four or five minutes before employing the method. The dangers of intracardiac injection are stated to be as follows: (1) Wounding the internal mammary artery. This can be avoided by inserting the needle two fingerbreadths to the left of the sternum. (2) Wounding the pleura. Esch reports the case of a patient who lived seven hours after injection of adrenaline, but died of pneumothorax due to the injection. (3) Injury to the coronary vessels. Erkes reports a case where death occurred immediately after the injection, owing to haemopericardium probably due to this cause. (4) Injury to important nerve centres in the heart muscle. It is better to inject the adrenaline directly into the ventricle than into the pericardium or heart muscle. Aspiration of blood with the syringe as well as the sudden cessation of resistance or perforation of the heart muscle shows that the ventricular cavity has been reached. The largest dose in successful cases in adults has been 2 c.cm. of the 1 in 1,000 solution of adrenaline. In infants successful results have been obtained with 0.2 mg. The interval between injection and the resumption of cardiac activity has varied between a few seconds and three minutes. In Exalto's case the heart started beating again almost immediately after the injection, and spontaneous respiration quickly followed, whereas in other cases respiration was slower in starting and sometimes had to be aided artificially. Exalto's case was in an infant aged six months, on whom he operated for an extensive naevus on the arm with Paquelin's cautery under anaesthesia with ethyl chloride and ether. At the end of the operation the pulse suddenly became imperceptible and the child stopped breathing. As artificial respiration and indirect cardiac massage for four minutes had no effect, 0.7 c.cm. of the 1 in 1,000 solution of adrenaline was injected and the child immediately recovered.

521.

#### Post-traumatic Cutaneous Epithelioma.

P. HICKEL and CH. OBERLING (*Bull. Soc. Française de Derm. et de Syph.*, March, 1923, p. 15) observe that many cases of malignant tumour following injury have been reported; most frequently they are sarcomata, much more rarely epitheliomata. Such tumours usually develop at a late period, sometimes many years after the receipt of the injury. It is well known that cancer may arise in old scars or burns and in tissues irritated by chronic inflammation. The development of cancer as the direct effect of a single injury has been rarely observed, but this question has come to the front on account of many soldiers attributing the development of cancer to an old wound received in the war. An official report on the direct connexion between a single

injury and cancer was definitely adverse to this view. The authors therefore think the two following cases, where the connexion seemed evident, of interest: (1) A man, aged 45, injured his hand with a piece of wood, a splinter penetrating the dorsal aspect of the base of the right thumb; the skin had previously been quite healthy; the wound bled slightly and healed spontaneously. In fifteen days a small tumour (the size of a pea) was found at the site of the wound; it was cauterized, but rapidly increased in volume, and in six or seven weeks it measured 3 cm. by 2.5 cm., and 1 cm. in thickness; it was excised, and the patient has had no recurrence. Histological examination showed that it was a typical epithelioma. (2) A young man, aged 22, received a slight burn on the lower lip in 1919, which healed, leaving only a small scar. In 1921 a small fissure appeared in the scar, painful only when touched by an acid. On admission to hospital there was a tumour as large as a haricot bean, with soft base and no evidence of infection of lymph nodes. A section showed a typical epitheliomatous structure in the centre of the tumour. The authors consider that the connexion between a single trivial injury and the development of epithelioma is clear in each case, and they think that the more rapid evolution of the tumour in the first case was probably due to its occurrence in a middle-aged man.

#### 522. Injuries of the Semilunar Cartilages.

GUIXIN (*Arch. Méd. Belges*, March, 1923, p. 238) discusses the mode of production of lesions of the semilunar cartilages of the knee-joint. He regards the cartilages not as moving to and fro during movements of the joint, but as fixed on the head of the tibia. The anterior horn of the internal cartilage is only held by a small and weak ligament to the anterior part of the head of the tibia; the posterior horn is more securely fixed. The external cartilage is well fixed in position. Both cartilages are securely attached to the capsule of the joint, which also gives them their blood supply; the coronary ligament fixes the cartilages firmly to the head of the tibia. Injuries of the cartilages are often produced by a sudden movement of extension whereby the vasti pull upon the capsule; this may produce a false luxation, or separation of the cartilage from the capsule. In these cases no lesion of the cartilage is found at operation, but careful suture of the capsule produces a cure. When true luxation occurs the cartilage becomes pinched between the femur and the tibia and leads to locking of the joint, or, if the attachments of the cartilage resist, the meniscus itself may be fractured. He also describes a condition of hypermobility of the cartilage due to frequent distension of the capsule with fluid. The chief symptoms of these injuries are pain and locking of the knee-joint, the knee being flexed on the thigh and all movement being impossible. The cartilage can sometimes be palpated between the ends of the bones. Surgical treatment may not be necessary in the early stages, except when the diagnosis of rupture of the cartilage is certain. In luxation, when the pain persists and there is repeated swelling of the joint and lockings, it will be advisable to operate. The operation is not absolutely devoid of risk. The best incision is a vertical or slightly curved one which gives ample room to explore the joint and does little damage. In cases of true dislocation the cartilage should be completely removed, or, if fractured, all the pieces must be excised. The capsule is closed, and the day following operation active and passive movements are instituted. Walking is not allowed for eight or ten days.

#### 523. The "Cuff" Method in Gastric Operations.

C. HÜRHAMMER (*Zentralbl. f. Chir.*, April 21st, 1923, p. 633) has applied with success this method, performed experimentally on animals by Goepel, to operations on the cardiac end of the stomach in the human subject. The method finds its field in cases where a hollow viscus with little or no serous covering is to be united to a portion which has such a covering; and the principle consists in preparing a cuff of the serous and muscular layers of the latter, the mucosa being divided some distance (3 to 4 cm.) from the level of section of the first-named layers. The sero-muscular cuff is then used to cover the union of the mucosa to the non-serous viscus. In this way the author has in one case succeeded in uniting the oesophagus to the duodenum after almost total resection of the stomach. The patient (a man of 70) lived three months. In a second case, with carcinoma of the lesser curvature near the cardiac orifice, the oesophagus was successfully implanted into the remaining prepyloric portion of the stomach. The patient was quite well a year after operation. If the pyloric end could not be approximated to the oesophagus, the alternative would be to implant the oesophagus into the jejunum (using a cuff of the latter to cover the union), followed by lateral or end-to-side anastomosis of the proximal end of the jejunum. The author considers that the method is a most valuable contribution to the technique of operations in such cases as those alluded to above.

## Obstetrics and Gynaecology.

524.

#### Sarcoma of the Uterus.

J. C. MASSON (*Amer. Journ. Obstet. and Gyn.*, April, 1923, p. 345), from a series of 50 cases of uterine sarcoma treated by him between 1906 and 1920, considers that sarcoma forms less than 1 per cent. of all uterine tumours and its frequency compared to carcinoma is 1 to 50. The author finds that the commonest variety of sarcoma is the spindle-celled type, which develops in a fibromyoma; this is less malignant than the sarcoma of the mucosa, which is not encapsulated, the most malignant type being the small round-celled sarcoma. The mucosal sarcoma occurs as a polypoid growth, and the author urges that all so-called polypoid endometritis should be examined very carefully microscopically as the diagnosis is difficult. The same difficulty is experienced in differentiating degenerating fibroids and polypi from sarcoma. Sarcoma of the uterus occurs usually between the ages of 40 and 50 and grows much more rapidly than carcinoma, but metastases occur much later—in fact, metastases are of rare occurrence except in the small round-celled type, when the lungs often become involved. The clinical features are not constant, and in the encapsulated slow-growing tumours are similar to those of fibroids and impossible to diagnose from them. Pain between and during the periods is a common symptom and is accompanied by cachexia, haemorrhages, and foul vaginal discharge. The uterus is enlarged and is observed to grow rapidly. As regards treatment the author favours the modified Wertheim hysterectomy in favourable cases, followed by deep x-ray therapy. For advanced cases radium is given in full doses with repeated doses of x-rays. Sarcoma seems to be more susceptible to radio-active substances than cancer, and in Germany that method of treatment is chiefly relied upon; but radium is not without its dangers, as the author has found a pelvic abscess follow its administration in two of his cases. If sarcoma is only discovered after a myomectomy has been performed the author believes that the patient should be subjected to a pan-hysterectomy, although in many cases the myomectomy will have cured the condition, if the tumour was still encapsulated. The author's immediate mortality in his operable cases was 4 per cent., and 76.59 per cent. were found to be well several years after operation. In the other 20 per cent. local recurrence was the chief cause of death.

#### 525. Pre-natal Antisymphilitic Treatment and Infant Mortality.

A. COUVELAIRE (*Bull. Soc. d'Obstét. et de Gyn. de Paris*, 1923, i, p. 34) publishes the following statistics from the Baudelocque Clinic. Cases of untreated maternal syphilis between 1919 and 1921 numbered 180. Of 37 cases of syphilis contracted during pregnancy a living infant was born in 22 per cent. only; the infant was living at birth in 36 per cent. of cases in which syphilitic infection occurred shortly before conception; 41 mothers with old-standing syphilis gave birth to 73 per cent. of living children. Subsequent observations showed that at the end of twelve months all the living infants of the first-named group of mothers had died, and one only of the infants of the second group was certainly found to be surviving. During the same period 125 pregnant women received antisymphilitic treatment; stillbirths amounted to 34 per cent. among those infected during pregnancy; 8 per cent. among those treated during pregnancy for syphilis contracted shortly before; none among those recently infected women whose treatment took place before and during pregnancy; and none among the adequately treated long-standing cases. In the treated cases infants surviving greatly outnumbered those deceased at the end of twelve months. Treatment consisted exclusively in injections of sulpharsenol, chosen partly on account of its efficacy and partly because injections by the physician are more certain of administration than medicaments taken at the discretion of the mother.

526.

#### Purpura during Gestation.

ACCORDING to G. C. MOSHER (*Surg., Gynec., and Obstet.*, April, 1923, p. 503), purpura haemorrhagica, although a rare complication of pregnancy—fewer than 40 cases having been reported in the literature—is one of grave import. The outcome is generally less serious if an early abortion occurs, but it is rare for a patient to go to term and recover. In half the cases the foetus perishes in utero or dies within a few days following birth. As in non-pregnant women, haemorrhagic purpura is characterized by haemorrhages from mucous membranes, petechiae and ecchymoses, and prolonged bleeding but normal coagulation time; the platelet count shows very striking reduction. Pregnant subjects are particularly prone to metrorrhagia, which, in common with other haemorrhages, do not usually occur until the sixth or

seventh month. No drug treatment is of avail; apparently the only remedy is to make a transfusion of blood, which may have to be repeated, so as to keep the platelet count over 110,000. A case is related by the author in which the patient recovered after repeated transfusions and the induction of abortion during the seventh month. This case is peculiar as the child—in contrast with the usual findings—manifested extensive subcutaneous ecchymoses during the ten hours which elapsed between its birth and death.

#### 527. Caesarean Section Statistics.

W. BENTHIN (*Deut. med. Woch.*, May 4th, 1923, p. 572) has analysed the 62 cases of Caesarean section performed by himself since 1898 and has found that there were only 5 immediate operative deaths among the mothers. The total mortality was, however, twice this figure—that is, 16 per cent. The post-operative morbidity was 14 per cent., and there were 4 cases of parametritis. Only one mother was lost on account of haemorrhage, which in this case was due to atony of the uterus. This atony did not culminate till after the operation, which could not therefore be held entirely responsible for the death. With regard to subsequent rupture of the uterus, this accident has become very rare since the opening in the uterus was carried further down, and, provided the wound heals by first intention, the chances of a subsequent rupture are small, but not yet quite negligible. The risk of post-operative adhesions is also small, as proved by the findings in repeated Caesarean sections on the same patient. The author refers to the eventful career of a patient on whom Caesarean section was first performed in 1910. In 1912 and again in 1917 she was successfully delivered by version and extraction. In 1913 labour was completed spontaneously, and in 1920 by perforation of the following head. In 1921 Caesarean section was performed for the second time, and the scar of the first operation was found to have held satisfactorily. Cases such as these—and the author refers to several—indicate that the risks of the operation scar giving trouble at subsequent confinements have been exaggerated. Among 14 cases of Caesarean section for eclampsia, there were only two fatalities among the mothers (fatal peritonitis and sepsis) and only four of the fifteen infants born to these fourteen mothers died. Three of these deaths had occurred before the operation. These figures are eloquent testimony to the effectiveness of Caesarean section in cases of eclampsia.

## Pathology.

#### 528. The Sero-diagnosis of Typhoid Infections by the Globulin Reaction.

STARTING from the known fact of the close relation which exists between the globulin and the antibody content of a serum, H. DIACONO (*C. R. Soc. Biologie*, April 14th, 1923, p. 869) wished to see whether it would be possible to develop a more sensitive test for the presence of agglutinins in the serum of an organism immunized to typhoid than the usual Widal reaction. The serum to be tested was diluted with 30 parts of distilled water, and submitted to a current of carbon dioxide for half an hour, in order to precipitate the globulins which it contained. It was then centrifuged, and the clot suspended in a volume of physiological salt solution corresponding to one-tenth of the original amount of serum. Altogether 18 serums were treated in this way—10 positive and 8 negative. Parallel tests were then put up against *B. typhosus* and *B. paratyphosus* A and B, using the serum for one series and the globulin suspension for the other. Reading after three hours at 37° C., the results showed that the titre of the globulin suspension was, on an average, about ten times as high as that of the original serum. Apart from showing the essential part played by the globulins in the mechanism of agglutination, this serves to demonstrate the greater sensitivity of the globulin reaction. The author proposes to employ this reaction in the early diagnosis of cases of typhoid fever, hoping that the presence of agglutinins in the serum may be demonstrated at an earlier date than is at present possible.

#### 529. The Etiology of Epidemic Encephalitis.

A. SCHNABEL (*Klinische Wochenschrift*, March 5th, 1923, p. 429) discusses the relationship between herpes febrilis and epidemic encephalitis. Doerr and the author succeeded in isolating from the cerebro-spinal fluid of an encephalitis patient a virus which was closely allied to or identical with the virus of herpes, and therefore maintained the identity of the herpes and encephalitis virus. Levaditi and Harvier by local infection of a rabbit's eye with portions of the brain

of a rabbit which had had encephalitis produced a kerato-conjunctivitis similar to that which Salmann, Blanc and Caminopetros, and Doerr and Schnabel had produced with the brain of a rabbit infected with herpes. Doerr and Voelting showed that rabbits whose corneas had been infected with herpes developed constitutional disturbance, spasms, and paralyses which usually ended fatally. It is of epidemiological interest that patients with herpes febrilis as well as healthy persons who had recently had herpes showed the virus of herpes in their saliva, just as the virus of epidemic encephalitis had been found in the saliva by Loewe, Hirschfeld and Strauss, Netter, and others. Subsequently it was found that rabbits who had had a herpetic affection of the eye did not react either to a corneal or subdural application of a virulent encephalitic brain, and conversely encephalitic keratitis protected against corneal or subdural inoculation of herpes. The hypothesis of the identity of the virus of herpes febrilis and epidemic encephalitis was thus confirmed. The fact that herpes febrilis in the ordinary form of vesicles on the skin is not often seen in epidemic encephalitis cannot be regarded as an objection to the hypothesis of the identity of the two viruses, as it is probable that the herpetic eruption may develop on the mucous membranes, especially in the nasopharynx. F. STERN (*Ibid.*, p. 433), who agrees with Schnabel as to the relation between the virus of epidemic encephalitis and herpes febrilis, thinks it possible that the virus of epidemic encephalitis is an ordinary saprophyte of the mouth and throat, and that it becomes activated and neurotropic under the influence of certain factors, especially influenza and possibly alcohol. The constitution of the patient is also of importance. Stern has found that physical infantilism is fairly frequent, and regards it as a sign of diminished resistance.

#### 530. The Distribution of the Bacteriophage in Different Media.

P. HAUDUROY (*C. R. Soc. de Biologie*, April 28th, 1923, p. 1084) records experiments he has made to determine to some extent the distribution of the bacteriophage. Search was made in water, earth, and the faeces of normal and of sick individuals. The technique of isolation was as follows: After an incubation of twelve to twenty-four hours in ordinary bouillon of the substance to be examined the culture was filtered on a Chamberland L3 candle, and 1 or 2 c.cm. of the filtrate added to a tube containing 8 c.cm. of sterile broth. This was inoculated with 2 drops of a bacterial emulsion, and left at room temperature for twenty-four hours. At the end of this time the controls were turbid, while the experimental tubes were either clear or turbid, depending on whether or not a lytic principle was present in the filtrate. In this work three organisms were used—namely, *B. dysenteriae* Shiga, *B. coli*, and *B. typhosus*, all of which were susceptible to lysis. In ten attempts the lytic principle was found eight times in earth, and three out of five times in water. Working with the stools of typhoid patients, the author tested the action of the filtrate on the infecting organism isolated from the patient by blood culture. In the case of nine patients he was able to demonstrate a correlation between the presence of the bacteriophage and the amelioration of the general condition. The lytic principle was never found when the patient's temperature was raised, and the author concludes that the bacteriophage probably plays a considerable part in the development of immunity.

#### 531. The Intrapulmonary Digestion of Fat.

IF an injection of a fatty emulsion be made into the veins of a dog a considerable proportion of the fat is arrested by the lungs, where it undergoes a process of digestion. H. ROGER, L. BINET, and J. VERNE (*C. R. Soc. de Biologie*, May 5th, 1923, p. 1140) have studied histologically pieces of lung tissue removed from dogs which had been submitted to an injection of olive oil. In portions taken out five minutes after the introduction of the fatty matter one finds that the fat is brought to a standstill in the ultimate ramifications of the pulmonary artery and in the alveolar capillaries. Examination of sections made from pieces of lung tissue removed at variable periods subsequently shows that this fat undergoes alterations; the globules are eaten away and come to assume a scalloped condition, while the staining reactions are modified so that osmic acid colours them grey rather than black, and Sudan yellow rather than red. Gradually the globules of fat get smaller and smaller, but, even when much reduced in size, they still remain adherent to the vascular endothelium and are not carried away by the blood current. This intravascular digestion seems to occur best in the most fully ventilated portions of the lung. In areas of consolidation the process is much slower; it seems to depend upon a phagocytic action of the endothelium instead of a ferment action as in the case of normal lung.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

### 532. Treatment of Diabetes with Insulin.

SUCCESSFUL treatment of diabetes with insulin, says E. P. JOSLIN (*Journ. Amer. Med. Assoc.*, June 2nd, 1923, p. 1581), depends on the utilization of all those measures that have proved of the greatest value in the treatment of diabetes without insulin. These are as follows: adherence to a diet which will keep the urine sugar-free, avoidance of over-nutrition or extreme undernutrition, and a method of life compatible with the strength such a diet affords. A knowledge of the fundamental principles of the diet and of the values of a few foods is essential, otherwise the insulin will be squandered and the patient placed in jeopardy. Insulin, the author insists, does not cure diabetes; it does not allow a diabetic to eat anything he desires; but hitherto nothing has been discovered as valuable for the diabetic as insulin. Diabetes, however, though subdued, is not yet conquered. Intelligent patients, Joslin suggests, can be taught the use of the diet and insulin in a week, and in two weeks the average patient can become free of acid and sugar, and learn what is requisite either in hospital or, with a nurse trained in the care of diabetics, in his own home. Insulin can be discontinued in a small fraction of cases. Those patients may be able to omit it who receive it temporarily because of an exacerbation caused by complications, or whose diabetes is of recent onset, though perhaps the latter should receive it intermittently as a prophylactic against increasing severity. R. H. MAJOR (*Ibid.*, p. 1597) reports on the successful use of insulin in cases of severe juvenile diabetes, in the treatment of diabetic coma, and in lowering the blood sugar in cases of diabetes. The study of the urinary output has shown that usually a polyuria of from 3,500 to 5,500 c.cm. in twenty-four hours is present with an absence of glycosuria. Such large amounts of urine, however, were coincident with high values for blood sugar, although the ratio between the two was not constant. In only one patient was sodium bicarbonate used; it had no apparent effect on the acidosis. In two patients the author has seen symptoms of collapse accompanied by profuse sweating and a sense of great oppression and fear three hours after the injection of 15 units of insulin. One of these patients was given 20 grams of glucose by mouth and recovered promptly. The second patient recovered quite suddenly from his collapse without treatment. This attack occurred during the night, and the blood sugar the following morning at 8 o'clock was 50 mg. per 100 c.cm. Both patients had a hypoglycaemia when studied soon after these symptoms. This experience emphasizes that caution must be exercised in the use of insulin.

### 533. Oral Administration of Vaccine in Enteric and other Intestinal Infections.

J. H. HARVEY PIRIE and A. J. ORENSTEIN (*Med. Journ. of South Africa*, April, 1923, p. 224) discuss the subject of the administration of vaccine by the mouth in affections of, or diseases acquired through, the alimentary tract. They regard it as reasonably certain that protection against such diseases can be successfully obtained by this route. In support of this contention Besredka is quoted as holding the view that in typhoid fever and dysentery immunity is the peculiar property of the cells of the intestinal mucosa, and that any immune bodies found in the blood are accidental, not essential, and merely evidence that infection has occurred. Besredka also maintains that the value of subcutaneous protective inoculation is solely due to its action on the intestinal mucosa. Further, Nicolle and Conseil, working on volunteer subjects, are cited as having demonstrated the success of the oral administration of vaccine in experimentally produced bacillary dysentery and Malta fever. It is contended that like results could be obtained in typhoid, paratyphoid, and cholera. Attention is drawn to the absence of any appreciable agglutinin formation in the cases of these observers, who also found it impossible to infect native Tunisians with dysentery, probably owing to immunity acquired through the frequent drinking of infected water, and the authors advise imitating nature in this respect by administering frequent small doses of vaccine. As evidence of the value of oral vaccination the authors publish an account of an epidemic of enteric fever occurring among natives in a gold mine in which the method was tested. Seven strains of *B. typhosus* were employed in the preparation of the vaccine, which was administered in liquid form

on three successive days in doses of 40 million in conjunction with 3-grain keratin-coated ox-bile pills. Although the treatment was commenced a little later than half-way through the epidemic, which might possibly have already commenced to decline, nevertheless the course of events subsequent to its inception was such that the authors feel justified in presuming its efficiency. Twenty cases were admitted to hospital after vaccination had been initiated; of these, 16 had been vaccinated and 4 not. Among the 16 vaccinated the mortality was 5; among the unvaccinated it was 3. It is thought probable that the former were in the stage of incubation when vaccinated, as the fatal cases among them died on the second, fourth, sixth, twelfth, and eighteenth days after admission. It should also be noted that of 3,600 natives in the camp 1,500 received two doses only of vaccine.

### 534. Suffocation of Infants by Bed Straps.

J. FOG (*Ugeskrift for Læger*, May 3rd, 1923, p. 305) notes that within the last few years two fatalities have occurred in infants who were suffocated by the straps with which they were kept in bed. The age of both infants was a year and nine months. The straps or reins generally used by mothers in Denmark consist of a loose belt with two limbs, one running over each shoulder. Connected to the belt is another strap which is secured to the side of the bed. Provided these straps are made of inelastic material, and the bands passing from one side of the belt to the other over the shoulders are as short as possible, there is little chance of a fatal accident. Considering how common the use of these straps is, the chances of their causing fatal suffocation may be regarded as negligible. In one of the cases referred to the mother found her infant lying on his stomach in bed with his feet dangling over its side. His face was buried in the pillow, and his throat was resting on the tightly drawn strap connecting the belt with the side of the bed which was nearest the wall. The necropsy showed two narrow transverse furrows running across the neck. There were no other signs of injury, and neither the thyroid nor the cricoid cartilage had been fractured. There were no haemorrhages, and no foreign bodies could be found in the mouth, throat, or respiratory tract.

### 535. A Vaccine for Typhus Fever.

P. MODINOS (*Paris méd.*, May 12th, 1923, p. 425) states that typhus fever has long been endemic in Egypt, where during the last fifteen years there have been 148,150 cases, with 42,594 deaths. During the period 1916-20 there were 94,057 cases, with 25,232 deaths, or a mortality of 27 per cent. He has recently treated 12 cases at the European Hospital at Alexandria with a vaccine derived from cultures of *Proteus X 19* which contained 3,000 million organisms per cubic centimetre. The first dose consisted of one-tenth of a cubic centimetre, and the dose was increased by one-tenth of a centimetre daily until half a gram was reached. No reaction followed the injection, which was made subcutaneously in the subclavicular region or on the outer surface of the arm. Although the temperature did not fall until after the third or fourth injection the patient's general condition improved immediately after the first. Not only did no deaths occur, but the duration of the disease was shortened and no complications ensued.

### 536. Bromodermia and Iododermia.

F. PARKES WEBER (*Brit. Journ. Derm. and Syph.*, May, 1923, p. 169) calls attention to the mycotic type of bromodermia and iododermia, and a facial, pharyngeal, and intraoral oedema and swelling of the salivary and thyroid glands in iodide idiosyncrasy. It is pointed out that such idiosyncrasy may cause a mycotic iododermia, developing in a non-syphilitic patient under treatment with iodides, to be mistaken for a syphilitic condition, with the consequent further pushing of the drug and grave results. Chronic nephritis, alcoholism, cachexia, and senility may partly account for such idiosyncrasy. The eruption sometimes becomes worse after the drug has been stopped, thus confusing diagnosis with mycosis fungoides or sarcoma. Bromism in breast-fed infants whose mothers are taking bromide sometimes manifests itself by a severe "nodose" form of eruption. Facial, especially orbital, oedema following iodides may occur even after small doses, and is often accompanied by sublingual oedema with occasionally swelling of the salivary glands simulating mumps. Thyroid enlargement, and even acute swelling and symptoms suggestive of Graves's disease, are recorded as following iodide administration, or the outward application of iodine.

## Surgery.

## 537. Gastric Surgery.

CHARRIER and CHARBOUND (*Journ. de Méd. de Bordeaux*, May 10th, 1923, p. 303) emphasize the good results that may be obtained by gastrectomy in cases of gastric ulcer and gastric carcinoma. In thirteen cases of gastrectomy for malignant growths which they record there were three deaths. They urge that gastrectomy should be more often performed for these conditions, as it is not such a severe operation as many believe it to be. A gastro-enterostomy is often done, they suggest, not because it will cure the condition but because it is regarded as a less serious operation. In carcinoma of the stomach gastrectomy is the only operation which can hold out any prospect of cure for the patient; deep therapy up to the present has not been able to take the place of operation. The best results follow the more extensive operations on the stomach; though the mortality after gastrectomy is higher than that following gastro-enterostomy the results appear to justify the increased risk. The authors record cases of malignancy operated upon up to two years previously showing good results without evidence of recurrence. Further, these cases take on a new lease of life, with increased hope, after the radical operation has been performed. In cases of ulceration the pyloric ulcer is best treated by gastro-enterostomy with or without pyloric exclusion, and operations such as pylorotomy are unnecessary. An ulcer on the lesser curvature may be treated by local excision or the cauter, combined with a gastro-enterostomy. Where there is an old callous ulcer, adherent to surrounding organs and liable to undergo malignant change, gastrectomy is the best operation. If every case of ulcer or carcinoma were regarded individually the general results, the authors assert, would show an undoubted improvement.

## 538. Treatment of Scleroderma by Periarterial Sympathectomy.

W. HORN (*Zentralbl. f. Chir.*, May 26th, 1923, p. 831) reports a case of scleroderma treated successfully by the operation of periarterial sympathectomy. The patient was a female, aged 23. Three years ago she noticed a circumscribed patch of hardness in the skin of the left forearm; within a year this spread over the whole of the left arm. Six months ago the same condition appeared at the right forearm. Various methods of treatment had been tried without avail. The skin of the left forearm and upper arm was bluish-red; the normal furrows and fine markings were absent; the skin was of board-like hardness to the touch, without elasticity, and could not be raised in folds. The changes were most marked along the ulnar border and on the back of the hand. Sensation was normal. The right forearm showed the same appearances in lesser degree. On January 24th, 1923, the brachial artery was exposed at its upper part; this was done with some difficulty, the connective tissues round the vessels being thickened and firm. The adventitious coat was removed for a distance of 8 to 10 cm.; the artery was observed to contract during this process. Healing was uneventful. The left pulse was not palpable till three hours after operation. The arm was warmer to palpation than before operation. Two weeks later the skin began to lose its hardness, and slowly regained its elasticity, so that it could be raised in folds. The upper arm became normal; improvement continued more slowly in the forearm and hand; there is still a narrow strip along the ulna where the skin is thickened, and this has remained stationary for some time. The author suggests that some sympathetic fibres to the forearm run in the adventitia of anastomotic vessels which leave the main artery above the seat of operation. He intends to operate next upon the right brachial artery of the same patient, with a view to restoring the skin of the right forearm to its normal condition.

## 539. Differential Diagnosis of Purulent Labyrinthitis and Cerebellar Abscess.

RIMINI (*Arch. Internat. de Laryngol., Otol. et Rhinol.*, February, 1923, p. 129) notes the difficulty in differentiating between these two conditions, and relates a case illustrating this. A woman, aged 36, was admitted to hospital with a history of a discharging left ear since childhood and much pain in the ear for the past month, with attacks of pyrexia and rigors lasting about two days. On examination there was a large polypus in the meatus, a marked loss of hearing on the affected side, some vertigo and symptoms of a fistula into the horizontal canal. After extraction of the polypus the patient became completely deaf on the left side and a radical mastoid operation was performed. The temperature rose and there was vomiting and nystagmus to the right. After a few days the temperature gradually subsided and the vomiting ceased, but the patient suffered from very bad headaches. Nearly

three weeks after the operation the pulse rate dropped to 70, 60, and finally to 50, while the temperature also fell below normal. On this a diagnosis of cerebellar abscess was made, but the patient died suddenly before operation. Autopsy revealed an abscess in the left lobe of the cerebellum. The author discusses the various symptoms separately: (1) The slowing of the pulse is symptomatic of intracranial pressure, and therefore indicates cerebellar abscess; rising pressure affects the vagus nucleus and later the respiratory centre. (2) Headache is usually present in cases of abscess, but may accompany any form of otitic lesion; if localized in the occipital region and exaggerated by percussion it points to abscess. (3) Vomiting, vertigo, and nystagmus are common to both conditions, but in purulent labyrinthitis are accompanied by complete cochlear deafness. These three symptoms tend to disappear as the inflammatory processes destroy the labyrinthine end-organ, but in cases of abscess tend to increase as the pus accumulates. In the case of nystagmus there are three further points of note: (a) Nystagmus to the affected side points to either lesion if persisting after vestibulotomy to abscess. (b) Rotatory nystagmus to the affected side with an apparently inexcitable labyrinth indicates cerebellar lesion. (c) Nystagmus towards the healthy side indicates either lesion. If vestibulotomy reverses or augments the nystagmus cerebellar lesion is diagnosed, but if the nystagmus is reduced the lesion is in the labyrinth. Bárány's caloric and rotatory tests, especially the past-pointing ones, are used to estimate the state of the labyrinth. Lumbar puncture shows an increase of tension and of leucocyte content in most cases of abscess, but not often in labyrinthitis. The author considers progressive slowing of the pulse the surest sign of cerebellar abscess.

## 540.

## Dislocation of the Cuboid.

CH. DUJARIER (*Bull. et Mém. Soc. Chir. de Paris*, May 8th, 1923, p. 650) records a case of this very rare type of injury. A mechanic had his foot caught in the spokes of a wheel, and on admission to hospital there was an irregularity on the dorsum of the foot and a marked projection on the outer border of the foot in front of the external malleolus. On the plantar aspect of the foot no deformity was present but a depression corresponding to the projection on the dorsum. Movements at the ankle-joint were complete and painless, but absent at the mid-tarsal joint. Radiograms showed a dislocation of the cuboid bone. Reduction was carried out without difficulty, and the patient started to walk on the tenth day. The mechanism of the injury appears to depend on flexion and adduction of the mid-tarsal joint, a separation of the calcaneo-cuboid joint being produced, with stretching of the ligaments. Diagnosis is easy immediately following the injury, but later, owing to the oedema, is possible only by x-ray examination.

## 541.

## Hydatid Cysts of the Erector Spinae Muscles.

C. LASSEIRE and P. LANEX (*Journ. de Méd. de Bordeaux et de la Région de la Sud-Ouest*, March 25th, 1923, p. 188) have collected records of 26 cases of this disease and have seen 3 other cases in less than two years. Although hydatid cysts may occur in the muscles of any region they show a predilection for the spinal muscles. They are at first spheroidal and may remain unilocular, but more frequently they become multilocular, and following lines of least resistance penetrate between the muscles. Some French authors consider that traumatism may determine the localization of the echinococcus embryo, others regard the subsequent discovery of a cyst as a coincidence. The authors describe the formation of the outer wall of fibrous tissue. As the cyst grows it tends to penetrate more deeply, and Cruveilhier states that in this respect it resembles an aneurysm. "The growth of the cyst is irregular; its prolongations embrace the bony surfaces, laying bare the vertebral laminae and irritating the pleura, when it is situated in the dorsal region." Thus it may produce absorption of large bony surfaces, and in two cases the autopsy revealed hydatids in the spinal canal, pressure on the cord having produced paraplegia. In one of Lasserre's cases a preliminary diagnosis of spinal caries had been made, but aspiration of the swelling yielded debris of hydatid membrane. The cyst was incised and an immense number of daughter cysts, varying in size from that of a pea to that of a pullet's egg, escaped. The cyst wall was sutured to the skin and the cavity washed out with ether and drained. Three months after operation daughter cysts occasionally escaped through a sinus, but seven months after operation cicatrization was complete. The authors find that usually patients have no symptoms prior to the discovery of the tumour; exceptionally they experience vague pain and discomfort. The majority of authors state that the "hydatid thrill" is rare, and as a diagnostic sign is therefore uncertain, but when present it is associated with "a drum-like resonance elicited on auscultatory percussion" (Barnett).

## Ophthalmology.

### 542. Retrobulbar Optic Neuritis due to Latent Posterior Sinusitis.

L. VAN DEN WILDEMBURG (*Le Scalpel*, May 26th, 1923, p. 561) has observed three cases of the above condition recently. He considers that delay in such cases is liable to be followed by loss of vision in one eye or even both, and that exploratory operation by the median nasal route in doubtful cases will do no harm. The optic nerve is in close proximity to the sphenoidal and posterior ethmoidal cells. Frequently (30 per cent.) a single sphenoidal cell is in relation with both optic nerves. A retrobulbar neuritis, in the absence of other assignable cause, should lead one to suspect sinusitis. After ten days of neuritis, optic atrophy may set in. The author approaches the sphenoidal sinus by submucous resection of the nasal septum, thus mobilizing the latter. Both sphenoidal sinuses are explored, by removing the septum between the two. As much of the anterior wall as possible is removed, especially at its lower part, to ensure good drainage. The cases in question were as follows: (1) A male, aged 48, who was subject to colds, had had periorbital and right frontal headache for five months. He complained of sudden diminution of vision, so that he could not read. The nasal septum was deviated to the right; radiograms were negative. Exploratory puncture of the sphenoidal sinus was negative. It was decided to resect the nasal septum in order to cure the nasal obstruction, and in the course of this operation the sphenoidal sinus was opened, by removing the anterior wall. The lining membrane was thick and bluish, appearing almost cystic; this was curetted away. The frontal sinus also was explored; it contained no secretion, but the lining was thickened. After operation the headaches disappeared, and right vision improved from 6/24 to 6/12, after which it remained stationary. (2) A medical student complained of periorbital headaches and of practically total blindness of the left eye. Exploration of the sphenoidal sinus was negative. The maxillary sinus was then explored through the canine fossa, and through that the posterior ethmoidal cells were examined and found to be the seat of chronic inflammation. Left vision improved until the patient could count fingers more than a metre away. The headaches were cured. (3) A male, aged 27, complained of loss of visual acuity in the right eye after severe cold in the head. Right vision, 6/36; papilla swollen. Eventually, other treatments failing, the sphenoidal sinus was opened. No abnormality could be detected. Vision, however, improved to 6/18 within two months, and then remained stationary. The author considers that the free ventilation of the sphenoidal cells may have had something to do with the improvement. All other explorations in this case were negative.

### 543. Fundamental Considerations in the Correction of Squint.

A. WHITMIRE (*Arch. of Ophthalmol.*, May, 1923, p. 242) reviews the various theories with regard to squint and its treatment. He comes to two conclusions: (1) Anomalies of this character should be first corrected by refraction if possible. This will be sufficient in many cases in which the deviation is of the periodic variety. When the subject of the squint is hypermetropic full correction should be given. (2) Operation is the last resort, and the relief it affords is in most instances simply cosmetic. He is, however, very insistent on the advantages accruing from early operation. He holds that the subject derives so much benefit, both physically and mentally, from the correction of the deformity that operation should not be delayed after it is found that correcting glasses are not going to produce a cure. The operation he favours is resection and advancement of one muscle, with tenotomy of the opposing muscle. He considers that it is an unsound procedure to advance a muscle without at the same time tenotomizing its antagonist. Further, he lays great stress upon the importance of inserting an anchor stitch, the ends of which he attaches by means of strapping to the nose or temple in order to support the resected muscle.

### 544. Quinine Amblyopia.

J. N. EVANS (*Amer. Journ. of Ophthalmol.*, April, 1923, p. 271) describes a case of quinine amblyopia which presented certain unusual features. The patient, a man, in a state of intoxication swallowed a dose of approximately 100 grains of quinine sulphate. To ordinary doses of the drug he had no idiosyncrasy, as he was in the habit of taking doses of 6 grains three times a day. On waking his vision was reduced to perception of light, but he had no nausea, vomiting, diarrhoea, ringing in the ears, nor deafness. When seen some four days later the pupils were slightly dilated

and reacted sluggishly to light, the vision of each eye was 6/9, the visual fields did not extend outwards beyond 20 degrees. In general he felt well, with the exception of a feeling of coldness in the hands and feet. Ophthalmoscopically there was slight uniform pallor of both discs and the arteries were somewhat narrowed; on one small artery there was a plaque, distal to which the calibre of the vessel narrowed markedly, and scattered in places throughout the central fundus there were many small roundish spots of a creamy colour, the edges of which were blurred. As the case progressed more plaques formed on the arteries and recurring crops of spots made their appearance, the old spots fading away and their place being taken by new ones. The arteries gradually became more and more narrowed, and this narrowing seemed to be associated with the previous plaque formation. Evans concludes by saying that it is possible that the plaques and peculiar spots may have no relation to the quinine poisoning, though the rapid absorption of such a large quantity of the drug may have made visible pathological changes typical of this intoxication which are not usually visible.

### 545. Tumour of the Optic Nerve.

HUMPHREY NEAME (*Brit. Journ. of Ophthalmol.*, May, 1923, p. 209) describes two cases of this condition, and he concludes from his pathological examination that one case was an example of gliomatosis of the optic nerve and the other of endothelioma having its origin in the endothelium of the arachnoid sheath of the nerve. A very full account of the pathological examination of the two tumours is given and microphotographs are shown in the paper. With regard to the differential diagnosis, he states that in endothelioma (1) the age is greater; (2) exophthalmos more often precedes visual disturbance; (3) limitation of movement is more frequently present; (4) circulatory obstruction in lids and conjunctiva is more frequent; (5) pain is present; (6) intraocular extension is more frequent. In the case of the endothelioma the tumour was removed by dividing the external canthus, and after incising the conjunctiva the external rectus muscle was divided between sutures and the eyeball drawn outwards. In this manner the tumour was able to be removed without the necessity of bone resection.

## Obstetrics and Gynaecology.

### 546. Clinical Features of Tubal Pregnancy.

C. LENORMANT and G. HARTMANN-KEPPEL (*Gynéc. et Obstét.*, 1923, vii, 4, p. 273) record a series of 51 cases of tubal pregnancy, of which 8 came to operation with haemato salpinx in the absence of intraperitoneal haemorrhage, 24 with clinical signs and anatomical evidence of free peritoneal bleeding, 4 with partially and 13 with completely encysted intraperitoneal haemorrhage. These four conditions, in the order named, are regarded as successive stages in the clinical course of haemorrhage due to tubal pregnancy. Haemato-salpinx due to tubal gestation was in the majority of instances diagnosed prior to the occurrence of rupture or abortion, as salpingitis; a history of retardation of the menses was only elicited exceptionally. Among the 26 cases of free intraperitoneal haemorrhage two instances of tubal abortion are recorded, and in the author's former series of cases there were 13 ruptures and only 1 abortion. Seven patients only reported amenorrhoea, and one had suffered, prior to the rupture of the tube, from metrorrhagia. The two patients with tubal abortion were operated on comparatively late—four and six days respectively after the onset of abdominal pain; the effused blood was moderate in amount and not even partially encysted. There were 3 deaths in the series, of 26 cases; the operation preferred was unilateral salpingectomy without drainage. The 13 cases of encysted peritoneal haemorrhage (pelvic haematocoele) included 3 only in which there was a history of amenorrhoea, and 4 had more or less abundant metrorrhagia; a correct preoperative diagnosis was made in 7 cases. In 2 of the 13 cases in this series, and in no fewer than 5 in a former series of 11, the haematocoele was infected and suppurating. All the cases of encysted effusion were treated by abdominal operation without mortality.

547. L. BRADY (*Bull. of Johns Hopkins Hosp.*, May, 1923, p. 152) describes 50 cases of ectopic pregnancy operated on during five years. Six patients were pregnant for the first time; in 7 only could previous pelvic infection be excluded. Fewer than half of the series gave a history of a missed menstrual period, and three-quarters had had irregular menstrual bleeding. Pyrexia was present in 25, and in 6

instances exceeded 100.5°; in none of the cases of unruptured tubal gestation, however, was the temperature greater than normal. Secretion of the breasts was present in 8 cases, and in two primiparous women was of genuine diagnostic assistance. Abdominal examination showed shifting dullness in 4 patients; bluish discoloration of the umbilicus, as described by Cullen, was not noted. Blood crepitus was made out after pelvic examination in 5 patients. In 72 per cent. of cases a correct preoperative diagnosis was attained. There were 9 instances of unruptured tubal pregnancy, as compared with 20 each of tubal rupture and abortion; one case of pregnancy occupying the cornu and right half of the uterus is included in the series, and this patient, whose abdomen was closed without further operative procedure, was delivered normally at term.

#### 518. Pregnancy and Heart Disease.

D. GRANT CAMPBELL (*Canadian Med. Assoc. Journ.*, April, 1923, p. 244) records the experience of the Montreal Maternity Hospital with regard to 159 patients suffering from heart disease admitted between 1905 and 1921. He concludes that in (1) mitral stenosis, (2) auricular fibrillation, and (3) myocarditis in the absence of endocarditis and pericarditis, pregnancy is a grave complication; the two last conditions contraindicate marriage and pregnancy, and, in his opinion, if pregnancy occurs, they call for immediate induction of abortion without awaiting the onset of decompensation. Mitral regurgitation, aortic regurgitation, aortic stenosis, and congenital lesions, on the other hand, are comparatively little affected by pregnancy and do not justify the physician in forbidding marriage. Patients with mitral stenosis, without evidence of myocarditis or history of previous heart failure, may bear one or two children, but they should be carefully watched, and each pregnancy causes considerable and lasting damage to the heart. Signs and symptoms of impending cardiac failure are found in breathlessness, palpitation, precordial pain, and râles at the bases of the lungs; intervention is then called for, and as a rule induction of labour or a vaginal Caesarean operation is preferable to abdominal section. If all goes well up to the time of labour the first stage is borne well, but the second places considerable strain on the heart and it is usually wise to terminate labour under general anaesthesia by application of forceps or otherwise. In patients with purely myocardial lesions it is the pregnancy rather than labour which exercises a prejudicial effect: 14 out of 28 in this group had rapid and easy labours, yet 7 died as a direct result of pregnancy and others succumbed within a short time.

#### 549. Benign Tumours of the Female External Genitalia.

GIRONCOLI (*Arch. Ital. di Chirurg.*, April, 1923, p. 177) has collected from the literature 75 cases of benign tumours of the external genital organs of women. These tumours of the vulva are usually fibromata, or more rarely lipomata, with gradations in between; they very rarely become sarcomatous. In size they vary from a cherry to an adult head. Etiologically, heredity and traumata seem to play a recognizable part; usually they originate in the connective tissue; in some cases they appear to start from the round ligament. It is hardly possible to differentiate the fibromatous from the lipomatous type except by microscopic examination. Prognosis is good unless ulceration and subsequent pyaemia set in, or more rarely in the case of sarcomatous degeneration. Removal is the only treatment. The author gives a bibliography of 100 references.

## Pathology.

#### 550. Histopathology of the Intestine in Cholera.

E. W. GOODPASTURE (*Philippine Journ. of Science*, April, 1923, p. 413) gives the results of a series of twenty-five *post-mortem* examinations of cases of cholera. He points out that the nature of the intoxicating substance is still doubtful, and that it has yet to be determined whether the intestinal lesions are due to direct action by poisonous material or are part of a general toxæmia. It was evident that the vibrios of the disease are capable of invading the intestinal tissue locally and producing an inflammatory reaction with polymorphonuclear leucocyte exudate. The one constant feature was a subepithelial oedema in the small intestine, and the author considers that this may have been due rather to splanchnic congestion accompanying general intoxication than to direct action of toxic material within the lumen. Minute *ante-mortem* necrosis and ulceration occurred in at least two of the cases, and was recognizable as such by the acute inflammatory appearance of the ulcers. Since the

organism can invade tissues and produce inflammatory exudate and ulceration an acute ulcerative enteritis might be expected as the typical lesion, but this is the exception. Desquamation of epithelium is apparently a *post-mortem* effect, due to the action of bacteria or enzymes of intestinal fluid on an epithelial layer displaced by oedema during life. In some cases, however, this does occur before death, as evidenced by the finding of casts in the stools. The author emphasizes that, although in certain instances the organisms may directly produce acute ulceration, they are not always a cause of it, and that such appearances are to be regarded as a complication and not part of the typical pathology of cholera. The evidence he adduced indicated that the vibrios were almost entirely confined to the lumen of the gut, and that such toxic substances as they produced were absorbed early through an intact mucosa.

#### 551. Malignant Tumour and Syphilitic Infection.

W. H. BROWN and LOUISE PEARCE (*Journ. Exper. Med.*, May, 1923, p. 601) describe the development of a malignant tumour in the scar of a scrotal chancre in the rabbit appearing about four years after inoculation with syphilis. The specific infection pursued a mild but chronic course with periods of relapse, and eventually there developed locally in the skin lesions which showed active and atypical epithelial cell proliferation such as is common to chronic inflammatory processes. At about the same time there occurred extensive degenerative changes in the skin accompanied by an atypical growth of hair follicles and producing diffuse and nodular induration and thickening. In course of time a growth appeared in the scrotum which recurred after removal, and spread locally and to internal organs by metastasis. The authors offer no explanation of the origin of the neoplasm, but they point out that the change took place gradually and with periods of relative inactivity before the growth became established and acquired malignant characteristics. They note that this feature is not peculiar to tumours, but is common to conditions which pursue a relapsing course and occurs typically in syphilitic infections. The conditions producing the changes, therefore, were not necessarily confined to the growth itself and were not purely local in character. *Post-mortem* appearances included leucoplakia of the tongue and buccal mucous membrane, chronic inflammatory lesions of the oesophagus with atypical epithelial cell proliferation, and a nodular growth in the testis which differed from that in the scrotum; there was also widespread deterioration of organs and tissues, much of which had occurred previous to the development of the tumour. The growth, therefore, arose in an organism with well marked organic impairment, and the authors consider there was sufficient evidence for assuming that the factor of greatest causal importance was constitutional rather than local. In further experimental work it was found possible to transplant a spontaneous malignant growth in a syphilitic rabbit by the intratesticular route where the subcutaneous and intracuticular method failed. Antispecific treatment was undertaken with a view to eliminating syphilitic infection, and the transplanted tumour was found to be highly malignant in the first and second generations.

#### 552. Types of Organism in Tuberculous Children.

J. K. GORDON and E. W. BROWN (*Amer. Journ. Dis. Children*, March, 1923, p. 234) have carried out a series of investigations at the Children's Hospital, Boston, U.S.A., to determine the types of organism in tuberculous children. Their cases consisted of 30 tuberculous patients ranging in age from 4 months to 11 years, all of whom resided in the Boston district. The bovine organism was identified in 10 instances, or 33 per cent. Twenty-three of the total number of patients were under 5 years of age. In 6 of these, or 25 per cent., the organism was of the bovine type. The remaining 7 patients were between the ages of 5 and 16 years, and among these there were 4 instances of bovine infection, or 57 per cent. There was thus a greater actual incidence of bovine infection in children under 5 years of age, although the number of bovine cases in patients between 5 and 12 was relatively greater. In infants under 1 year the bovine organism was found in only one instance. Twenty-two of the total number of cases were known to be fatal. In 12 a necropsy was obtained. In all the cases in which the origin of infection was in the alimentary tract the organism was bovine in type, whereas the human bacillus was recovered from all the cases in which the point of origin was found *post-mortem* in the respiratory tract. In 7 cases a history of exposure to tuberculous infection in the family or elsewhere was obtained; 6 of these were infected with the human and one with the bovine organism. The only conclusions to be drawn from these figures, according to the authors, who are carrying out further investigations, is that the percentage of bovine tuberculosis in the Boston district is unnecessarily high.
